This volume is dedicated to our colleagues, David R. Boone, Don J. Brenner, Richard W. Castenholz, and Noel R. Krieg, who retired from the Board of Trustees of Bergey's Manual Trust as this edition was in preparation. We deeply appreciate their efforts as editors and authors; they have devoted their time and many years in helping the Trust meet its objectives.

Preface to Volume Two of the Second Edition of *Bergey's Manual® of Systematic Bacteriology*

There is a long-standing tradition for the Editors of *Bergey's Manual* to open their respective editions with the observation that the new edition is a departure from the earlier ones. As this volume goes to press, however, we recognize a need to deviate from this practice, by offering a separate preface to each volume within this edition. In part, this departure is necessary because the size and complexity of this edition far exceeded our expectations, as has the amount of time that has elapsed between publication of the first volume of this edition and this volume.

Earlier, we noted that systematic procaryotic biology is a dynamic field, driven by constant theoretical and methodological advances that will ultimately lead to a more perfect and useful classification scheme. Clearly, the pace has been accelerating as evidenced in the super-linear rate at which new taxa are being described. Much of the increase can be attributed to rapid advances in sequencing technology, which has brought about a major shift in how we view the relationships among *Bacteria* and *Archaea*. While the possibility of a universally applicable natural classification was evident as the First Edition was in preparation, it is only recently that the sequence databases became large enough, and the taxonomic coverage broad enough to make such an arrangement feasible. We have relied heavily upon these data in organizing the contents of this edition of *Bergey's Manual of Systematic Bacteriology,* which will follow a phylogenetic framework based on analysis of the nucleotide sequence of the small ribosomal subunit RNA, rather than a phenotypic structure. This departs from the First Edition, as well as the Eighth and Ninth Editions of the *Determinative Manual*. While the rationale for presenting the content of this edition in such a manner should be evident to most readers, they should bear in mind that this edition, as in all preceding ones represents a progress report, rather than a final classification of procaryotes.

The Editors remind the readers that the *Systematics Manual* is a peer-reviewed collection of chapters, contributed by authors who were invited by the Trust to share their knowledge and expertise of specific taxa. Citation should refer to the author, the chapter title, and inclusive pages rather than to the Editors. The Trust is indebted to all of the contributors and reviewers, without whom this work would not be possible. The Editors are grateful for the time and effort that each expended on behalf of the entire scientific community. We also thank the authors for their good grace in accepting comments, criticisms, and editing of their manuscripts. We would also like to thank Drs. Hans Trüper, Brian Tindall, and Jean Euzéby for their assistance on matters of nomenclature and etymology.

We would like to express our thanks to the Department of Microbiology and Molecular Genetics at Michigan State University for housing our headquarters and editorial office and for providing a congenial and supportive environment for microbial systematics. We would also like to thank Connie Williams not only for her expert secretarial assistance, but also for unflagging dedication to the mission of Bergey's Manual Trust and Drs. Julia Bell and Denise Searles for their expert editorial assistance and diligence in verifying countless pieces of critical information and to Dr. Timothy G. Lilburn for constructing many of the phylogenetic trees used in this volume. We also extend our thanks to Alissa Wesche, Matt Chval and Kristen Johnson for their assistance in compilation of the bibliography.

A project such as the *Systematics Manual* also requires the strong and continued support of a dedicated publisher, and we have been most fortunate in this regard. We would also like to express our gratitude to Springer-Verlag for supporting our efforts and for the development of the Bergey's Document Type Definition (DTD). We would especially like to thank our Executive Editor, Dr. William Curtis for his courage, patience, understanding, and support; Catherine Lyons for her expertise in designing and developing our DTD, and Jeri Lambert and Leslie Grossberg of Impressions Book and Journal Services for their efforts during the pre-production and production phases. We would also like to acknowledge the support of ArborText, Inc., for providing us with state-of-the-art SGML development and editing tools at reduced cost. Lastly, I would like to express my personal thanks to my fellow trustees for providing me with the opportunity to participate in this effort, to Drs. Don Brenner, Noel Krieg, and James Staley for their enormous efforts as volume editors and to my wife, Nancy, and daughter, Jane, for their continued patience, tolerance and support.

Comments on this edition are welcomed and should be directed to Bergey's Manual Trust, Department of Microbiology and Molecular Genetics, 6162 Biomedical and Physical Sciences Building, Michigan State University, East Lansing, MI, USA 48824-4320. Email: garrity@msu.edu

George M. Garrity

Preface to the First Edition of *Bergey's Manual*® of *Systematic Bacteriology*

Many microbiologists advised the Trust that a new edition of the *Manual* was urgently needed. Of great concern to us was the steadily increasing time interval between editions; this interval reached a maximum of 17 years between the seventh and eighth editions. To be useful the *Manual* must reflect relatively recent information; a new edition is soon dated or obsolete in parts because of the nearly exponential rate at which new information accumulates. A new approach to publication was needed, and from this conviction came our plan to publish the *Manual* as a sequence of four subvolumes concerned with systematic bacteriology as it applies to taxonomy. The four subvolumes are divided roughly as follows: (a) the Gram-negatives of general, medical or industrial importance; (b) the Gram-positives other than actinomycetes; (c) the archaeobacteria, cyanobacteria and remaining Gram-negatives; and (d) the actinomycetes. The Trust believed that more attention and care could be given to preparation of the various descriptions within each subvolume, and also that each subvolume could be prepared, published, and revised as the area demanded, more rapidly than could be the case if the *Manual* were to remain as a single, comprehensive volume as in the past. Moreover, microbiologists would have the option of purchasing only that particular subvolume containing the organisms in which they were interested.

The Trust also believed that the scope of the *Manual* needed to be expanded to include more information of importance for systematic bacteriology and bring together information dealing with ecology, enrichment and isolation, descriptions of species and their determinative characters, maintenance and preservation, all focused on the illumination of bacterial taxonomy. To reflect this change in scope, the title of the *Manual* was changed and the primary publication becomes *Bergey's Manual of Systematic Bacteriology*. This contains not only determinative material such as diagnostic keys and tables useful for identification, but also all of the detailed descriptive information and taxonomic comments. Upon completion of each subvolume, the purely determinative information will be assembled for eventual incorporation into a much smaller publication which will continue the original name of the *Manual*, *Bergey's Manual of Determinative Bacteriology*, which will be a similar but improved version of the present *Shorter Bergey's Manual*. So, in the end there will be two publications, one systematic and one determinative in character.

An important task of the Trust was to decide which genera should be covered in the first and subsequent subvolumes. We were assisted in this decision by the recommendations of our Advisory Committees, composed of prominent taxonomic authorities to whom we are most grateful. Authors were chosen on the basis of constant surveillance of the literature of bacterial systematics and by recommendations from our Advisory Committees.

The activation of the 1976 Code had introduced some novel problems. We decided to include not only those genera that had been published in the Approved Lists of Bacterial Names in January 1980 or that had been subsequently validly published, but also certain genera whose names had no current standing in nomenclature. We also decided to include descriptions of certain organisms which had no formal taxonomic nomenclature, such as the endosymbionts of insects. Our goal was to omit no important group of cultivated bacteria and also to stimulate taxonomic research on "neglected" groups and on some groups of undoubted bacteria that have not yet been cultivated and subjected to conventional studies.

The invited authors were provided with instructions and exemplary chapters in June 1980 and, although the intended deadline for receipt of manuscripts was March 1981, all contributions were assembled in January 1982 for the final preparations. The *Manual* was forwarded to the publisher in June 1982.

Some readers will note the consistent use of the stem -var instead of -type in words such as biovar, serovar and pathovar. This is in keeping with the recommendations of the Bacteriological Code and was done against the wishes of some of the authors.

We have deleted much of the synonymy of scientific names which was contained in past editions. The adoption of the new starting date of January 1, 1980 and publication of the Approved Lists of Bacterial Names has made mention of past synonymy obsolete. We have included synonyms of a name only if they have been published since the new starting date, or if they were also on the Approved Lists and, in rare cases with certain pathogens, if the mention of an old name would help readers associate the organism with a clinical problem. If the reader is interested in tracing the history of a name we suggest he or she consult past editions of the *Manual* or the *Index Bergeyana* and its *Supplement*. In citations of names we have used the abbreviation AL to denote the inclusion of the name on the Approved Lists of Bacterial Names and VP to show the name has been validly published.

In the matter of citation of the *Manual* in the scientific literature we again stress the fact that the *Manual* is a collection

of authored chapters and the citation should refer to the author, the chapter title and its inclusive pages, not the Editor.

To all contributors, the sincere thanks of the Trust is due; the Editor is especially grateful for the good grace with which the authors accepted comments, criticisms and editing of their manuscripts. It is only because of the voluntary and dedicated efforts of these authors that the *Manual* can continue to serve the science of bacteriology on an international basis.

A number of institutions and individuals deserve special acknowledgment from the Trust for their help in bringing about the publication of this volume. We are grateful to the Department of Biology of the Virginia Polytechnic Institute and State University for providing space, facilities and, above all, tolerance for the diverted time taken by the Editor during the preparation of the book. The Department of Microbiology at Iowa State University of Science and Technology continues to provide a welcome home for the main editorial offices and archives of the Trust and we acknowledge their continued support. A grant (LM-03707) from the National Library of Medicine, National Institutes of Health to assist in the preparation of this and the next volume of the *Manual* is gratefully acknowledged.

A number of individuals deserve special mention and thanks for their help. Professor Thomas O. McAdoo of the Department of Foreign Languages and Literatures at the Virginia Polytechnic Institute and State University has given invaluable advice on the etymology and correctness of scientific names. Those assisting the Editor in the Blacksburg office were R. Martin Roop II, Don D. Lee, Eileen C. Falk and Michael W. Friedman and their help is sincerely appreciated. In the Ames office we were ably assisted by Gretchen Colletti and Diane Triggs during the early period of preparation and by Cynthia Pease during the major portion of the editing process. Mrs. Pease has been responsible for the construction of the List of References and her willingness to handle the cumbersome details of text editing on a big computer is gratefully acknowledged.

John G. Holt

Preface to the First Edition of *Bergey's Manual® of Determinative Bacteriology*

The elaborate system of classification of the bacteria into families, tribes and genera by a Committee on Characterization and Classification of the Society of American Bacteriologists (1911, 1920) has made it very desirable to be able to place in the hands of students a more detailed key for the identification of species than any that is available at present. The valuable book on "Determinative Bacteriology" by Professor F. D. Chester, published in 1901, is now of very little assistance to the student, and all previous classifications are of still less value, especially as earlier systems of classification were based entirely on morphologic characters.

It is hoped that this manual will serve to stimulate efforts to perfect the classification of bacteria, especially by emphasizing the valuable features as well as the weaker points in the new system which the Committee of the Society of American Bacteriologists has promulgated. The Committee does not regard the classification of species offered here as in any sense final, but merely a progress report leading to more satisfactory classification in the future.

The Committee desires to express its appreciation and thanks to those members of the society who gave valuable aid in the compilation of material and the classification of certain species. . . .

The assistance of all bacteriologists is earnestly solicited in the correction of possible errors in the text; in the collection of descriptions of all bacteria that may have been omitted from the text; in supplying more detailed descriptions of such organisms as are described incompletely; and in furnishing complete descriptions of new organisms that may be discovered, or in directing the attention of the Committee to publications of such newly described bacteria.

David H. Bergey, *Chairman*

Class I. **Alphaproteobacteria** *class. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Al.pha.pro.te.o.bac.te′ ri.a. Gr. n. *alpha* name of first letter of Greek alphabet; Gr. n. *Proteus* ocean god able to change shape; Gr. n. *bakterion* a small rod; M.L. fem. pl. n. *Alphaproteobacteria* class of bacteria having 16S rRNA gene sequences related to those of the members of the order *Caulobacterales*.

The class *Alphaproteobacteria* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the class contains the orders *Caulobacterales*, *"Parvularculales"*, *Rhizobiales*, *Rhodobacterales*, *Rhodospirillales*, *Rickettsiales*, and *Sphingomonadales*.

Type order: **Caulobacterales** Henrici and Johnson 1935a, 4.

Order I. **Rhodospirillales** Pfennig and Truper 1971, 17[AL]

George M. Garrity, Julia A. Bell and Timothy Lilburn

Rho.do.spi.ril.la′ les. M.L. neut. n. *Rhodospirillum* type genus of the order; *-ales* suffix to denote order; M.L. fem. n. *Rhodospirillales* the *Rhodospirillum* order.

The order *Rhodospirillales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the order contains the families *Rhodospirillaceae* and *Acetobacteraceae*.

Order is morphologically, metabolically, and ecologically diverse. Includes chemoorganotrophs, chemolithotrophs, and facultative photoheterotrophs; some of the latter are also able to grow photoautotrophically. Other species can grow methylotrophically.

Type genus: **Rhodospirillum** Molisch 1907, 24 emend. Imhoff, Petri and Süling 1998, 796.

Family I. **Rhodospirillaceae** Pfennig and Trüper 1971, 17[AL]

George M. Garrity, Julia A. Bell and Timothy Lilburn

Rho.do.spi.ril.la′ ce.ae. M.L. neut. n. *Rhodospirillum* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Rhodospirillaceae* the *Rhodospirillum* family.

The family *Rhodospirillaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Rhodospirillum* (type genus), *Azospirillum*, *Inquilinus*, *Levispirillum*, *Magnetospirillum*, *Phaeospirillum*, *Rhodocista*, *Rhodospira*, *Rhodovibrio*, *Roseospira*, *Skermanella*, *Thalassospira*, and *Tistrella* (type genus). *Inquilinus*, *Thalassospira*, and *Tistrella* were proposed after the cut-off date for inclusion in this volume (June 30, 2001) and are not described here (see Coenye et al., 2002; López-López et al., 2002; and Shi et al., 2002, respectively).

Preferred mode of growth for most genera is photoheterotrophic under anoxic conditions in light. Grow chemotrophically in the dark. *Azospirillum*, *Magnetospirillum*, and *Skermanella* are chemoorganotrophic. Motile by means of polar flagella; may have lateral flagella.

Type genus: **Rhodospirillum** Molisch 1907, 24 emend. Imhoff, Petri and Süling 1998, 796.

Genus I. **Rhodospirillum** *Molisch 1907, 24[AL] emend. Imhoff, Petri and Süling 1998, 796*

Johannes F. Imhoff

Rho.do.spi.ril′ lum. Gr. n. *rhodon* the rose; M.L. neut. n. *Spirillum* a bacterial genus; M.L. neut. n. *Rhodospirillum* the rose *Spirillum*.

Cells are vibrioid to spiral shaped, are motile by means of bipolar flagella, and multiply by binary fission. **Gram negative, belonging to the *Alphaproteobacteria*.**. Internal photosynthetic membranes are present as vesicles or as lamellae forming a sharp angle to the cytoplasmic membrane. Photosynthetic pigments are **bacteriochlorophyll *a*** (esterified with phytol or geranylgeraniol) and **carotenoids of the spirilloxanthin series** with spirilloxanthin itself lacking in some species. **Ubiquinones and rhodoquinones with 8 or 10 isoprene units** are present. **Major cellular fatty acids are $C_{18:1}$, $C_{16:1}$, and $C_{16:0}$**, with $C_{18:1}$ as dominant component (51–55% of total fatty acids).

Grow preferentially photoheterotrophically under anoxic conditions in the light. **Photoautotrophic growth with molecular hydrogen and sulfide** as photosynthetic electron donors may occur. **Chemotrophic growth occurs under microoxic to oxic conditions in the dark.** Some species are very sensitive to oxygen; others grow equally well aerobically in the dark. **Fermentation and oxidant-dependent growth may occur.** Polysaccharides, poly-β-hy-

droxybutyric acid and polyphosphates may be present as storage products. Growth factors required. **Mesophilic freshwater bacteria with preference for neutral pH.**

The mol% G + C of the DNA is: 62.1–63.5.

Type species: **Rhodospirillum rubrum** (Esmarch 1887) Molisch 1907, 25 (*Spirillum rubrum* Esmarch 1887, 230.)

Further descriptive information

Two species of *Rhodospirillum* are currently known. *Rhodospirillum rubrum*, the type species, is one of the most intensively studied of the phototrophic bacteria. Numerous investigations on the physiology and enzymology of this species have focused on its metabolic properties, in particular CO_2 fixation and characterization of ribulose-1,5-bisphosphate carboxylase (Tabita, 1995), ATP generation and coupling-factor ATPase (Gromet-Elhanan, 1995), and nitrogenase and nitrogen fixation (Ludden and Roberts, 1995).

R. rubrum grows very well under photoheterotrophic conditions, but it can also grow under photoautotrophic conditions with molecular hydrogen (Klemme, 1968) or sulfide as the electron donor if supplied at low concentrations (Hansen and van Gemerden, 1972). Autotrophic CO_2 fixation is well documented and occurs via ribulose-1,5-bisphosphate carboxylase (Anderson and Fuller, 1967a, b). This enzyme has been highly purified and is well characterized (e.g., Tabita and McFadden, 1974a, b; Tabita, 1995). Ribulose-1,5-bisphosphate carboxylase is derepressed only at low CO_2 tensions (1.5–2.0% of the atmospheric tension) and can make up to 50% of the total soluble protein of the cells under such conditions (Sarles and Tabita, 1983). In the presence of malate or acetate, however, CO_2 is not assimilated via the reductive pentose phosphate cycle, but by other carboxylating reactions.

Under anoxic dark conditions, *R. rubrum* is able to ferment sugars and pyruvate (Kohlmiller and Gest, 1951; Gürgün et al., 1976; Gorrell and Uffen, 1977). Pyruvate is cleaved by pyruvate formate lyase, which is specifically induced under these growth conditions (Uffen, 1973; Jungermann and Schön, 1974). From formate, H_2 and CO_2 are formed by a CO-sensitive formic hydrogen lyase (Gorrell and Uffen, 1977). H_2, CO_2, acetate, and eventually propionate are produced as fermentation products from pyruvate. *R. rubrum* is able to gain energy from the coupling of CO oxidation and H_2 evolution and induces the synthesis of a carbon monoxide dehydrogenase on exposure to CO under anoxic conditions (Bonam et al., 1989; Kerby et al., 1995).

Rhodospirillum rubrum is also able to perform an anaerobic dark metabolism with DMSO and trimethylamine-N-oxide as electron acceptors (Schultz and Weaver, 1982). Under these conditions, growth is possible with succinate, malate, and acetate as substrates, and CO_2 and DMSO or trimethylamine are formed (Schultz and Weaver, 1982).

Rhodospirillum species can grow with ammonia or N_2 as sole nitrogen source (Siefert, 1976; Madigan et al., 1984). The nitrogenase of *R. rubrum* is subject to post-translational inactivation by ADP-ribosylation under energy-limiting conditions and if fixed nitrogen compounds are available (see Ludden and Roberts, 1995). Ammonia assimilation is mediated by the glutamine synthetase/glutamate synthase reactions, which are NADPH-dependent in *R. rubrum* (Brown and Herbert, 1977). Although a nitrate reductase is present in *R. rubrum*, growth with nitrate as sole nitrogen source apparently is not possible (Katoh, 1963; Taniguchi and Kamen, 1963; Ketchum and Sevilla, 1973; Klemme, 1979). Purines can be used as a nitrogen source under anoxic conditions in the light and under oxic conditions in the dark (Aretz et al., 1978).

Comparably few studies have been performed with *Rhodospirillum photometricum* (Pfennig et al., 1965; Lehmann, 1976; Sarkar and Banerjee, 1980), which is very sensitive to oxygen and does not grow under oxic conditions in the dark (as does *R. rubrum*; Pfennig, 1969b), but only under microoxic conditions, provided the oxygen tension is lower than 0.5 kPa (Lehmann, 1976). Like *Phaeospirillum* species, *R. photometricum* is presumably unable to induce a second electron transport chain in the presence of oxygen and therefore depends on microoxic conditions in which the internal membrane system and the light-driven electron transport chain are fully expressed. Accordingly, the cells are fully pigmented under these growth conditions (Lehmann, 1976).

Two different types of alcohols are esterified with the bacteriochlorophyll *a* of *Rhodospirillum* species. Besides phytol, which is present as an alcohol in the majority of the Purple Nonsulfur Bacteria (PNSB), geranylgeraniol is the major component of *R. rubrum* and of some strains of *R. photometricum* (Brockmann and Knobloch, 1972; Künzler and Pfennig, 1973). Carotenoids of the spirilloxanthin series are present in *Rhodospirillum* species, but *R. photometricum* is unable to synthesize the end product, spirilloxanthin, and accumulates intermediates of this pathway, such as lycopene, rhodopin, anhydrorhodovibrin, and rhodovibrin (Schmidt, 1978).

Growth of *R. photometricum* is completely inhibited at penicillin concentrations of only 10 U/ml, whereas in *R. rubrum*, complete inhibition occurs at penicillin concentrations of more than 1000 U/ml (Weaver et al., 1975a).

Enrichment and Isolation Procedures

Media and growth conditions used for isolation and cultivation of freshwater PNSB in general can also be applied for *Rhodospirillum* species. Various recipes for appropriate media have been developed in different laboratories (see Biebl and Pfennig, 1981; Imhoff, 1988; Imhoff and Trüper, 1992). One of these, a mineral salts medium that has been used for cultivation of the great majority of PNSB over many years is given in the footnote below.[1] Standard techniques for the isolation of anaerobic bacteria in agar dilution series and on agar plates can be applied for *Rhodospirillum* species (Biebl and Pfennig, 1981; Imhoff and Trüper, 1992), if care is taken to establish and maintain oxygen-free conditions, especially for oxygen-sensitive species. This can be achieved by addition of 0.05% sodium ascorbate or 0.025% thioglycolate to the growth media in completely filled screw-capped bottles.

---

1. AT medium contains (g/l): KH_2PO_4, 1.0; $MgCl_2 \cdot 6H_2O$, 0.5; $CaCl_2 \cdot 2H_2O$, 0.1; NH_4Cl, 1.0; $NaHCO_3$, 3.0; Na_2SO_4, 0.7; NaCl, 1.0; sulfate-free trace element solution SLA (Imhoff and Trüper, 1977; Imhoff, 1992), 1 ml; and vitamin solution VA (Imhoff and Trüper, 1977; 1992), 1 ml. Organic carbon sources (routinely 10 mM sodium malate, sodium succinate, sodium pyruvate, or sodium acetate) and, for oxygen-sensitive strains, 0.5 g sodium ascorbate or 0.25 g thioglycolate are added separately. The initial pH is adjusted to 6.9. Vitamin solution VA contains in 100 ml of double distilled water: biotin, 10 mg; niacin amide, 35 mg; thiamine dichloride, 30 mg; *p*-aminobenzoic acid, 20 mg; pyridoxal hydrochloride, 10 mg; calcium pantothenate, 10 mg; and vitamin B_{12}, 5 mg.

The trace element solution SLA has the following composition: $FeCl_2 \cdot 4H_2O$, 1.8 g; $CoCl_2 \cdot 6H_2O$, 250 mg; $NiCl_2 \cdot 6H_2O$, 10 mg; $CuCl_2 \cdot 5H_2O$, 10 mg; $MnCl_2 \cdot 4H_2O$, 70 mg; $ZnCl_2$, 100 mg; H_3BO_3, 500 mg; $Na_2MoO_4 \cdot 2H_2O$, 30 mg; and $Na_2SeO_3 \cdot 5H_2O$, 10 mg. These components are dissolved in 1 liter of double distilled water. The pH of the solution is adjusted with HCl to 2–3.

Maintenance Procedures

Cultures can be preserved by standard techniques in liquid nitrogen or at −80°C in a mechanical freezer.

Differentiation of the genus *Rhodospirillum* from other genera

A number of chemotaxonomic properties distinguish *Rhodospirillum* species from other spiral-shaped Purple Nonsulfur Bacteria (PNSB). They differ from *Phaeospirillum* species, their closest relatives, in major quinone components and cytochrome c structure. Large-type cytochromes c_2 are present in *R. rubrum* and *R. photometricum*, whereas small-type cytochromes c_2 were found in *Phaeospirillum* species (Ambler et al., 1979). Major differentiating properties for phototrophic bacteria in the *Rhodospirillaceae* are shown in Table BXII.α.1. The phylogenetic relationships of these bacteria based on 16S rDNA sequences are shown in Fig. 1 (p. 124) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A.

Taxonomic Comments

Traditionally all spiral-shaped phototrophic PNSB have been assigned to the genus *Rhodospirillum* (Pfennig and Trüper, 1974). Recognition of the large amount of chemotaxonomic and phylogenetic diversity in the PNSB, and their presence in different groups of the *Proteobacteria*, initially led to the taxonomic reclassification of those species belonging to the *Betaproteobacteria*. *"Rhodospirillum tenue"* was assigned to *Rhodocyclus tenuis* (Imhoff et al., 1984) and this reclassification was later supported by 16S rDNA sequence analyses (Hiraishi et al., 1991a). After this reclassification, all species of the genus *Rhodospirillum* were *Alphaproteobacteria*, though the group remained very heterogeneous in phenotypic properties and genetic relationships.

The description of new species, assigned to the genus *Rhodospirillum*, based merely on their spiral shape, continued until recently, although most of them were quite distinct from *Rhodospirillum rubrum*, the type species of this genus. Four halophilic species were classified together with several freshwater species of the genus *Rhodospirillum*. In addition, *Rhodospirillum centenum* (Favinger et al., 1989) was assigned to this genus, though significant differences from *Rhodospirillum rubrum* had been stated in the species description. More recently, the great genetic distance among the spiral-shaped PNSB has been recognized in several proposals. *Rhodospirillum centenum* was transferred to a new genus as *Rhodocista centenaria* (Kawasaki et al., 1992). Another new spiral-shaped species, *Rhodospira trueperi*, was assigned to a new genus based on significant phenotypic and genotypic differences from *Rhodospirillum rubrum* and other known PNSB (Pfennig et al., 1997).

The anticipated heterogeneity of the genus *Rhodospirillum* became clearly apparent with the 16S rDNA sequence information of most of the known species (Kawasaki et al., 1993b; Imhoff et al., 1998), and these data implied that the spiral-shaped *Alphaproteobacteria* are phylogenetically quite distantly related to each other and do not warrant classification in one and the same genus. Therefore, a reclassification of the spiral-shaped phototrophic *Alphaproteobacteria*, based on distinct phenotypic properties and 16S rDNA sequence similarities, has been proposed (Imhoff et al., 1998; see Table BXII.α.1 and Fig. 1 [p. 124] of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A).

Major quinone components and fatty acid composition, salt requirements, and phylogenetic relationships based on 16S rDNA sequences were considered of primary importance in defining and differentiating these genera. Several phylogenetic lines of salt dependent species were recognized and the salt-dependence was regarded as a genus-specific property (Imhoff et al., 1998). Four of the genera of spiral-shaped phototrophic *Alphaproteobacteria* were defined as salt-dependent and three are freshwater bacteria. Only *R. rubrum* and *R. photometricum* were maintained as species of the genus *Rhodospirillum*. All other species were transferred to the new genera *Phaeospirillum*, *Rhodovibrio*, *Rhodothalassium*, and *Roseospira* (Imhoff et al., 1998) and are considered in the respective chapters of this volume.

List of species of the genus Rhodospirillum

1. **Rhodospirillum rubrum** (Esmarch 1887) Molisch 1907, 25[AL] (*Spirillum rubrum* Esmarch 1887, 230.)
rub′rum. M.L. neut. adj. *rubrum* red.

Cells are vibrioid shaped to spiral, 0.8–1.0 μm wide; one complete turn of a spiral is 1.5–2.5 μm wide and 7–10 μm long (Fig. BXII.α.1). Internal photosynthetic membranes are of the vesicular type (Fig. BXII.α2). Anaerobic liquid cultures are pink to deep red, without a brownish tinge, under all conditions. Under oxic conditions, cells are colorless to light pink. Living cells show absorption maxima at 375–377, 510–517, 546–550, 590–595, 807–808, and 881–885 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with geranylgeraniol as major and phytol as minor component) and carotenoids of the spirilloxanthin series with spirilloxanthin as the predominant component.

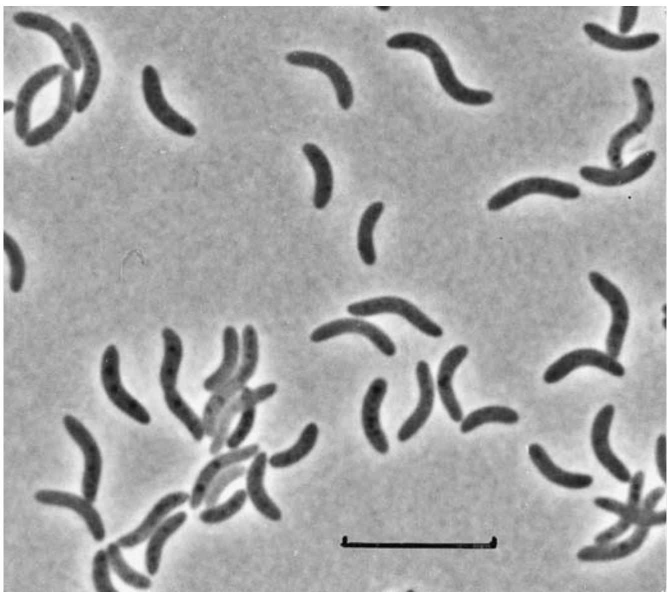

FIGURE BXII.α.1. *Rhodospirillum rubrum* ATCC 11170. Phase-contrast micrograph. Bar = 10 μm. (Courtesy of N. Pfennig).

Cells preferentially grow photoheterotrophically under anoxic conditions in the light with various organic compounds as carbon and electron sources. Photoautotrophic growth occurs with H_2 and sulfide as electron donors. Chemotrophic growth occurs under microoxic to oxic conditions in the dark. Fermentative metabolism with pyruvate under anoxic dark conditions and "oxidant-dependent" anaerobic dark metabolism are also possible. The carbon sources utilized are shown in Table BXII.α.2. In addition, alanine and asparagine are used and some strains use propanol. Ammonia, N_2, several amino acids, and in some strains, nitrate, adenine, guanine, xanthin, and uric acid may be used as nitrogen source. Sulfate can serve as sole sulfur source. Small amounts of yeast extract may be favorable. Biotin is required as a growth factor.

Mesophilic freshwater bacterium with optimum growth at 30–35°C and pH 6.8–7.0 (pH range: 6.0–8.5). Habitat: stagnant and anoxic freshwater habitats that are exposed to the light. Major quinone components are Q-10 and RQ-10.

The mol% G + C of the DNA is: 63.8–65.8 (Bd).
Type strain: ATCC 11170, DSM 467, NCIB 8255.
GenBank accession number (16S rRNA): D30778, M32020.

2. **Rhodospirillum photometricum** Molisch 1907, 24[AL]
pho.to.me′tri.cum. Gr. n. *phos* light; Gr. adj. *metricus* measuring; M.L. neut. adj. *photometricum* light measuring.

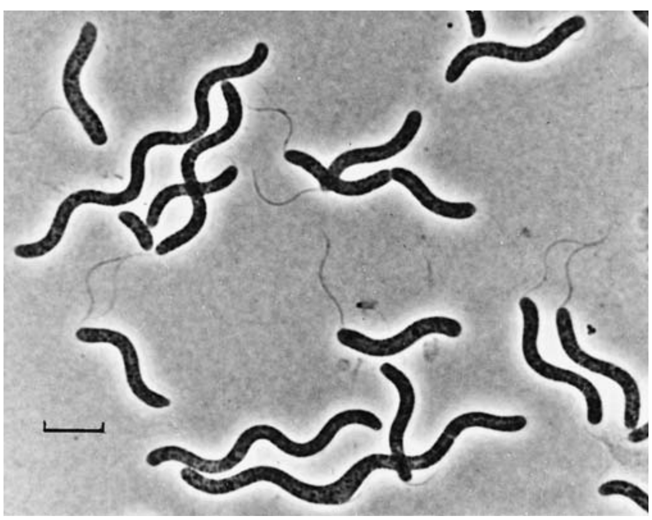

FIGURE BXII.α.3. *Rhodospirillum photometricum* NTHC 132, cultured on malate-yeast extract medium. Phase-contrast micrograph. Bar = 10 μm. (Courtesy or N. Pfennig).

Cells are spirals, 1.1–1.5 μm wide; one complete turn of a spiral is 2.5–4 μm wide and 4–7 μm long; cells 14–30 μm long are common (Fig. BXII.α.3). Internal photosynthetic membranes consist of several lamellar stacks forming a sharp angle with the cytoplasmic membrane. Anaerobic liquid cultures are brown-orange to brown-red or dark brown.

Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol and in some strains also with geranylgeraniol) and carotenoids of the spirilloxanthin series. Spirilloxanthin is lacking, but the biosynthetic precursors lycopene and rhodopin are present as major components.

Cells preferentially grow photoheterotrophically under anoxic conditions in the light with various organic compounds as carbon and electron sources. Chemotrophic growth at very low oxygen tensions, but not under oxic growth conditions, is possible. Under microoxic conditions cells are fully pigmented. Carbon sources utilized are shown in Table BXII.α.2. In addition, asparagine, maltose, sucrose, raffinose, adonitol, and dulcitol are used. Not used are cyclohexane carboxylate, mannose, galactose, xylose, and inositol. Nitrogen sources utilized are ammonia, N_2, alanine, glutamate, and asparagine; not utilized are nitrate, urea, and arginine. Sulfate, thiosulfate, cysteine, thioglycolate, and, at low concentrations, sulfide can be used as sulfur sources. Ascorbic acid may be required as a reductant. Nicotinic acid is required as a growth factor.

Mesophilic freshwater bacterium with optimum growth at 25–30°C and pH 6.5–7.5. Habitat: stagnant and anoxic freshwater habitats that are exposed to the light. Major quinone components are Q-8 and RQ-8.

The mol% G + C of the DNA is: 64.8–65.8 (Bd) and 63 (T_m).

Type strain: ATCC 49918, DSM 122, NTHC 132.

GenBank accession number (16S rRNA): AJ222662.

Genus II. **Azospirillum** *Tarrand, Krieg and Döbereiner 1979, 79*[AL] *(Effective publication: Tarrand, Krieg and Döbereiner 1978, 978) emend. Falk, Döbereiner, Johnson and Krieg 1985, 117*

José Ivo Baldani, Noel R. Krieg, Vera Lúcia Divan Baldani, Anton Hartmann and Johanna Döbereiner

A.zo.spi.ril′ lum. Fr. n. *azote* nitrogen; Gr. n. *spira* a spiral; M.L. dim. neut. n. *spirillum* a small spiral; *Azospirillum* a small nitrogen spiral.

Plump, slightly-curved and straight rods, 0.6–1.7 × 2.1–3.8 μm, often with pointed ends. Intracellular granules of poly-β-hydroxybutyrate are present. Enlarged, pleomorphic forms may occur in old, alkaline cultures, under conditions of excess oxygen or other stress. Gram negative to Gram variable. **Motile in liquid media by a single polar flagellum**; on solid media at 30°C, numerous lateral flagella of shorter wavelength may also be formed. **Nitrogen fixers, exhibiting N_2-dependent growth under microaerobic conditions.** Grow well under an air atmosphere in the presence of a source of fixed nitrogen such as an ammonium or glutamate salts. Cells previously grown in presence of an inorganic nitrogen source may fix nitrogen in air provided that all added nitrogen is exhausted and nitrogenase is derepressed. Possess mainly a respiratory type of metabolism with oxygen and, with some strains, nitrate or nitrite as the terminal electron acceptor. Fermentative metabolism may also occur. **Under severe oxygen limitation, some strains may dissimilate nitrate to nitrite or to nitrous oxide and nitrogen gas.** Optimal temperature for growth varies from 33 to 41°C and pH from 5.5 to 7.5. Some strains may grow and form light or dark pink colonies, often wrinkled and nonslimy, on potato agar. Oxidase positive. Chemoorganotrophic; some strains are facultative hydrogen autotrophs. **Grow well on salts of organic acids such as malate, succinate, lactate or pyruvate. D-fructose and certain carbohydrates may also serve as carbon sources.** Some species require biotin. Growth in presence of 3% NaCl has been observed for some species. **Occur free-living in the soil or associated with the roots, stems, leaves, and seeds** mainly of cereals and forage grasses, although they have also been isolated from coconut plants, vegetables, fruits, legume, and tuber plants. May also be found in freshwater lakes. Root nodules are not induced.

The mol% G + C of the DNA is: 64–71.

Type species: **Azospirillum lipoferum** (Beijerinck 1925) Tarrand, Krieg and Döbereiner 1979, 79 (Effective publication: Tarrand, Krieg and Döbereiner 1978, 978) (*Spirillum lipoferum* Beijerinck 1925, 353.)

Further descriptive information

Morphology In complex media such as MPSS broth[1], *A. lipoferum* and *A. brasilense* grow as plump, slightly curved rods and straight cells having a diameter of ~1.0 μm. Many of the cells have pointed ends. In semisolid nitrogen-free malate (NFb) medium[2], *A. lipoferum* develops predominantly into pleomorphic cells within 48 h (Fig. BXII.α.4), in contrast to *A. brasilense*, which retains mainly the vibrioid form. *A. lipoferum* grows as elongated cells (1.4–1.7 μm × 5 to over 30 μm long), which are nonmotile and have an S shape or helical shape (Fig. BXII.α.4). These forms eventually seem to fragment into shorter ovoid forms, many of which become very large and rounded and may contain several cells filled with phase-refractile granules (probably poly-β-hydroxybutyrate). Alkalinization of the malate medium, due to oxidation of the malate, may be related to development of pleomorphism in *A. lipoferum.* Pleomorphism fails to occur when the organisms are cultured in semi-solid nitrogen-free D-glucose medium, which does not become alkaline (Fig. BXII.α.5).

In semi-solid nitrogen-free malate medium, *A. brasilense* grows mainly as motile, vibrioid cells. Nonmotile, enlarged, pleomorphic forms (C forms) may also occur, especially in older cultures (Eskew et al., 1977; Tarrand et al., 1978), on the surface of nitrogen-free agar media (Berg et al., 1980), in association with plant callus cultures (Berg et al., 1979), or in association with the roots of grass seedlings (Umali-Garcia et al., 1980). A capsule is formed external to the outer wall membrane of C forms (Fig. BXII.α.6) and may be a protective mechanism against unfavorable levels of oxygen under nitrogen-fixing conditions (Berg et al., 1980). Very large, rounded forms containing several cells may be produced (Fig. BXII.α.6). The ultrastructure of the C forms indicates little similarity to the cysts of *Azotobacter.* Lamm and Neyra (1981) have reported that strains of *A. brasilense* and *A. lipoferum* enriched in C forms exhibit a resistance to desiccation and temperature not found in cultures lacking these forms. Cyst forms of *A. brasilense* could be physiologically active in the wheat rhizosphere, as shown by a high level of 16S rRNA-directed oligonucleotide binding (Assmus et al., 1995). Cysts are capable of fixing nitrogen in the absence of an exogenous carbon source (Okon and Itzigsohn, 1992). *A. amazonense* does not develop pleomorphic cells when grown in the semi-solid LGI medium because the pH is maintained around 6. Even when a very poor subsurface pellicle is formed in semi-solid NFb medium (this species is sensitive to alkaline pH), no such cells are observed. In LGI medium, cells remain motile and vibrioid. However, cultures maintained two to three weeks on the bench develop agglomerated cells like cysts due to the dryness of the medium.

Pleomorphic cells have been observed for the species *A. halopraeferens*, *A. irakense*, and *A. largimobile*, depending on the growth conditions. In the case of *A. halopraeferens* this phenomenon is observed in older and very alkaline conditions whereas very long cells (30 μm) are observed when *A. irakense* is grown in nutrient broth (Fig. BXII.α.7). On the other hand, *A. largimobile* forms multicellular conglomerates of nonmotile cells mainly under unfavorable conditions. The most recently described species, *A. doebereinerae*, also develops pleomorphic cells in semi-solid NFb medium.

Encapsulation may be related to resistance to Gram-decolorization exhibited by a small proportion of cells when cultured on MPSS agar at 37°C for 48–72 h. Gram-variability appears to be more pronounced with *A. brasilense* than with *A. lipoferum.*

1. MPSS broth (g/l): peptone (Difco), 5.0; succinic acid (free acid), 1.0; $(NH_4)_2SO_4$, 1.0; $MgSO_4 \cdot 7H_2O$, 1.0; $FeCl_3 \cdot 6H_2O$, 0.002; $MnSO_4 \cdot H_2O$, 0.002; pH adjusted to 7.0 with KOH. For solid media add 15.0 g/l agar.

2. NFb medium (g/l): L-malic acid, 5.0; K_2HPO_4, 0.5; $MgSO_4 \cdot 7H_2O$, 0.2; NaCl, 0.02; trace element solution ($Na_2MoO_4 \cdot 2H_2O$, 0.2 g; $MnSO_4 \cdot H_2O$, 0.235 g; H_3BO_3, 0.28 g; $CuSO_4 \cdot 5H_2O$, 0.008 g; $ZnSO_4 \cdot 7H_2O$, 0.024 g; distilled water, 1000 ml), 2.0 ml; bromthymol blue (0.5% aqueous solution [dissolve in 0.2 N KOH]), 2.0 ml; Fe EDTA (1.64% solution), 4.0 ml, vitamin solution (biotin, 0.01 g; pyridoxin, 0.02 g; distilled water, 1000 ml), 1.0 ml; KOH, 4.0; pH adjusted to 6.8 with KOH. For a semi-solid medium add 1.75 g/l agar; for a solid medium add 15.0 g/l agar.

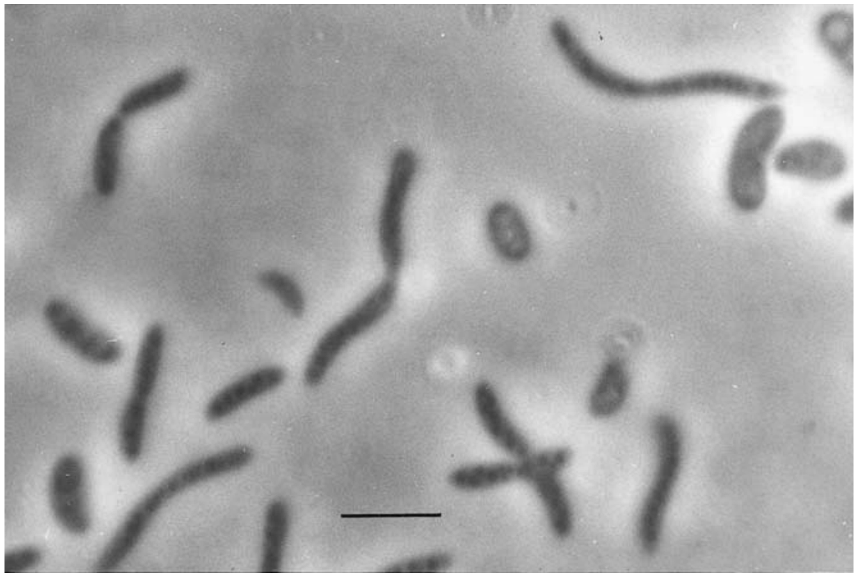

FIGURE BXII.α.4. *Azospirillum lipoferum* ATCC 29707 cultured in semi-solid, nitrogen-free, malate medium at 37°C for 48 h, showing characteristic elongated S-shaped forms and enlarged ovoid forms. Phase contrast microscopy. Bar = 5 μm.

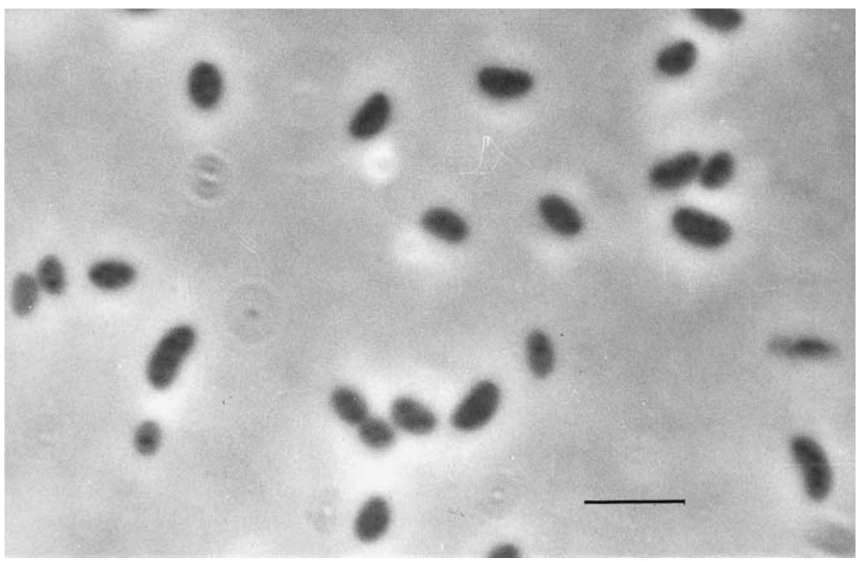

FIGURE BXII.α.5. *Azospirillum lipoferum* ATCC 29707 cultured in semi-solid, nitrogen-free, malate medium at 37°C for 48 h, showing characteristic vibrioid forms. Phase contrast microscopy. Bar = 5 μm.

Cultures grown in MPSS broth appear not to contain encapsulated forms, at least in young cultures, and the cells stain uniformly Gram negative. So far, no Gram variability has been observed for the other *Azospirillum* species.

Poly-β-hydroxybutyrate (PHB) may constitute from 25 to 50% of the dry weight of cells cultured in nitrogen-free media. In cells cultured with an ammonium salt as the nitrogen source, the polymer constitutes only 0.5–1.0% of the cell weight (Okon et al., 1976). However, high amounts of poly-β-hydroxybutyrate are accumulated in cells of *A. brasilense* strain Cd grown in a high C:N medium using D-fructose and ammonium chloride as C and N source (Burdman et al., 1998). The amount of PHB also increases under various stress conditions such as toxic metals and water stress, and this accumulation is correlated with cyst and floc formation where it accounts for up to 65% of the total dry weight (Olubayi et al., 1998). Cells rich in PHB survive better and promote positive effect on cereals (Assmus et al., 1995; Fallik and Okon, 1996). It has been suggested that inoculants generated from flocculated cells are more advantageous because they seem to be more efficient than those originating from nonflocculated cells, and in addition they can be produced on a large scale and easily separated from the growth medium (Neyra et al., 1995; Burdman et al., 1998). A high amount of PHB has been observed in *A. amazonense* species grown under nitrogen-fixing conditions (Fig. BXII.α.8) but not with an inorganic nitrogen source. Intracellular granules (probably PHB) were also observed in old cells of *A. doebereinerae.*

Azospirilla possess a single polar flagellum when grown in

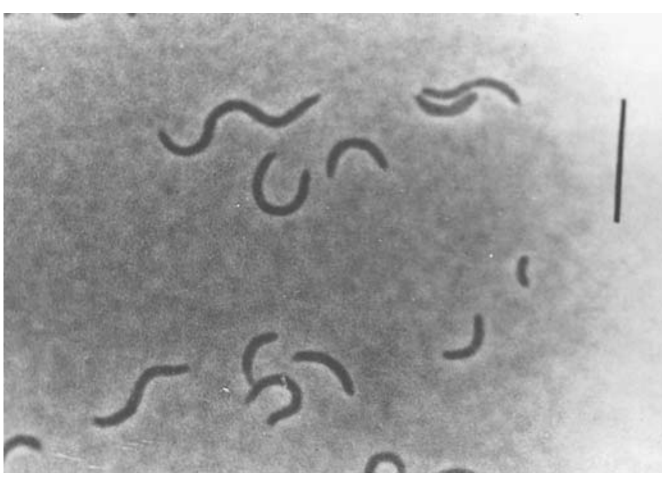

FIGURE BXII.α.7. Phase contrast microscopic examination of *Azospirillum irakense* strain KBC1 grown at 30°C for 20 h in complete nutrient broth showing the curved rods or S-shaped forms. Bar = 10 μm. (Reproduced with permission from K.M. Khammas et al., Research in Microbiology *140:* 679–693, 1989, Editions Scientifiques et Medicales, ©Elsevier, Paris.)

FIGURE BXII.α.8. Transmission electron micrograph of *Azospirillum amazonense* strain ATCC 35119 grown in semi-solid LGI medium for 24 h at 30°C. Note the presence of poly-β-hydroxybutyrate granules inside the cell. (∼× 13,000). (Reproduced with permission from F.M. Magalhães et al., Anais da Academia Brasileira de Ciencias *55:* 417–430, 1983, ©Academia Brasileira de Ciencias, Rio de Janeiro.)

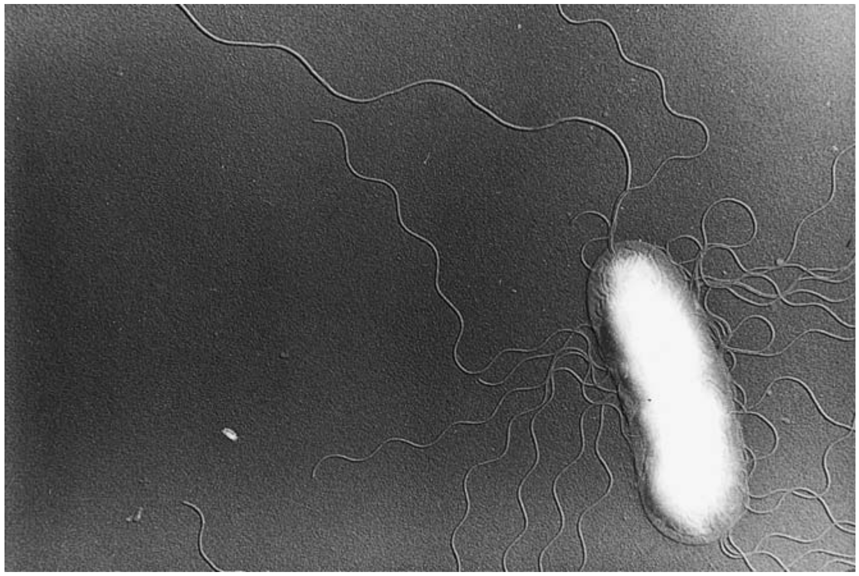

FIGURE BXII.α.9. Electron micrograph of *Azospirillum brasilense* ATCC 29145 cultured on MPSS agar at 30°C for 24 h. Both the single polar flagellum and the numerous lateral flagella can be seen. Shadowed with tungsten oxide. (~× 15,000).

liquid media. However, when cultured on MPSS agar at 30°C numerous lateral flagella in addition to the polar flagellum are formed in the species *A. lipoferum* and *A. brasilense* (see Fig. BXII.α.9). Lateral flagella are also observed in strains of *A. irakense* grown in nutrient broth but not in *A. amazonense*. The polar flagellum appears to be thicker than the lateral flagella and has a longer wavelength. *A. largimobile* cells have a mixed flagellation with a single polar flagellum and 1–10 distinct lateral flagella of different thickness and wavelength when grown in LWA medium. The polar flagellum is not only involved in aero- and chemotaxis (Grishanin et al., 1991), but also in the first adsorption step in the attachment process of *A. brasilense* to wheat roots (Michiels et al., 1991). The function of the lateral flagella is unknown, although a mutant of *A. brasilense* strain Cd lacking both polar and lateral flagella developed a stronger flocculation of cells when grown in a high C:N medium containing D-fructose and ammonium chloride as C and N source (Burdman et al., 1998).

Cultural characteristics On BMS agar[3] after 1–2 weeks of incubation at 33–35°C, colonies of *A. brasilense* and *A. lipoferum* are pink, opaque, irregular or round, often wrinkled, and typically have umbonate elevations (Döbereiner and Baldani, 1979). Pigmentation is best on BMS agar incubated under light. Certain strains and variants of *A. brasilense* form colonies that have a very deep pink color (Eskew et al., 1977; Tarrand et al., 1978). In one such strain (ATCC 29729), this intense color is attributable to the formation of several carotenoid pigments that occur only under aerobic conditions and may be related to protection of the nitrogenase from oxidative damage (Nur et al., 1981). This hypothesis was supported by the study of Hartmann and Hurek (1988) who compared carotenoid-overproducing mutants of *A. brasilense* strain Sp7 and carotenoid-negative mutants of strain Cd. Carotenoid overproducing mutants exhibited slightly higher oxygen tolerance. On the other hand, no pigment has been observed for strains of the other *Azospirillum* species.

In nitrogen-free media, nitrogen fixation occurs only under microaerobic conditions ($pO_2 \cong 0.003$ atm), due to lack of oxygen protection mechanisms for the nitrogenase. In liquid nitrogen-free media, there is no growth or nitrogen fixation under an air atmosphere except when cells are previously grown in the presence of an exogenous nitrogen source such as glutamate or ammonium chloride (Pedrosa and Yates, 1984; Baldani et al., 1986a). In this case, strains are grown in conical flasks (250 ml) with 100 ml liquid NFbHP[4] medium containing a nitrogen source at 32°C and 120 rpm. Derepressed cells are obtained when the culture reaches an OD_{550} of approximately 1.0. This is the easiest way to obtain nitrogenase-derepressed cells for physiological and biochemical studies, especially when a large number of strains are to be assayed. The fastest growth rates are obtained in continuous or batch cultures when the oxygen input is in equilibrium with bacterial respiration. Depending on the cell density, a gas mixture containing from 1 to 25% oxygen can be bubbled through the culture to achieve this. A simpler way to obtain N_2-dependent growth is by culturing the organisms in semi-solid nitrogen-free media incubated under an air atmosphere. Here, growth is initiated as a thin veil or disc-like pellicle several mil-

3. BMS agar: washed, peeled, sliced potatoes, 200 g; L-malic acid, 2.5 g; KOH, 2.0 g; raw cane sugar, 2.6 g; vitamin solution (biotin, 0.01 g; pyridoxin, 0.02 g; distilled water, 1000 ml), 1.0 ml; bromthymol blue (0.5% alcoholic solution), 2 drops; agar, 15.0 g. The potatoes are placed in a gauze bag, boiled in 1 liter of water for 30 min, then filtered through cotton, saving the filtrate. The malic acid is dissolved in 50 ml of water and the bromthymol blue added. KOH is added until the malic solution is green (pH 7.0). This solution, together with the cane sugar, vitamins and agar, is added to the potato filtrate. The final volume is made up to 1 liter with distilled water. The medium is boiled to dissolve the agar, then sterilized by autoclaving.

4. NFbHP medium (g/l): KH_2PO_4, 4.0; K_2HPO_4, 6.0; $MgSO_4 \cdot 7H_2O$, 0.2; NaCl, 0.1; $CaCl_2$, 0.02; Nitrilotriacetic acid 0.056; $FeSO_4 \cdot 7H_2O$, 0.02; sodium lactate, 5.0; biotin, 0.0001; $Na_2MoO_4 \cdot 2H_2O$, 0.002; $MnSO_4 \cdot H_2O$, 0.00235; H_3BO_3, 0.0028; $CuSO_4 \cdot 5H_2O$, 0.00008; $ZnSO_4 \cdot 7H_2O$, 0.00024. Phosphate solutions were autoclaved separately and left to cool before adding to the medium. The volume is completed to 1000 ml and the final pH is 6.8. NH_4Cl is added to a concentration of 20 mM when liquid medium is used. For solid medium add 12 g/l of agar before autoclaving.

limeters or 1 cm below the surface of the medium at a point where the rate of diffusion of oxygen into the medium corresponds to the respiration rate of the organisms so that no excess oxygen remains in solution. As the bacteria multiply, the disc of growth migrates closer to the surface until finally it is just below the surface. The time taken for the veil to move to the surface depends on the *Azospirillum* species. In the case of *A. lipoferum*, *A. brasilense*, and *A. irakense*, the pellicle reaches the surface 30–42 h after incubation, whereas with *A. amazonense*, *A. halopraeferens*, and *A. doebereinerae* it takes around 3–4 days. Okon et al. (1980) have found a similar veil or disc formation even in media containing a source of fixed nitrogen, suggesting that the organisms may prefer microaerobic conditions even when not fixing nitrogen. Under these conditions, the growth is much faster. It has been shown that cells grown in semi-solid NFb or LGI medium containing nitrate can fix nitrogen provided that all accumulated nitrite is reassimilated by the cells and the nitrogenase is derepressed (Magalhães et al., 1983; Baldani et al., 1986a). The optimum level of dissolved oxygen for nitrogenase activity was 0.2 kPa oxygen in *A. brasilense*, *A. lipoferum*, and *A. amazonense* (Hartmann et al., 1985). At transiently increased oxygen levels, a reversible inhibition (switch off) of nitrogenase activity occurred, which was accompanied by a reversible covalent modification of the dinitrogenase reductase of *A. brasilense* and *A. lipoferum* (Hartmann and Burris, 1987). Recently, Vande Broek et al. (1996) demonstrated that *A. brasilense* is slightly more oxygen-sensitive than *A. irakense*, based on the maximum oxygen concentration at which activation of an *A. brasilense nifH–gusA* fusion and acetylene reduction was still observed under the experimental conditions. Comparison of *A. amazonense* and *A. brasilense* grown in nitrogen-free media in batch cultures seemed to show that the first species is much more oxygen sensitive than the latter (Magalhães et al., 1983). However, measurements in a well-mixed chamber where respiration rates, ARA, and dissolved O_2 were controlled showed that nitrogen fixation and derepression of the nitrogenase of *A. amazonense* is tolerant of a somewhat higher pO_2 than those of *A. lipoferum* and *A. brasilense* (Hartmann et al., 1985). This factor seems to be due to the presence of an oxygen-tolerant hydrogenase in *A. amazonense* (Fu and Knowles, 1989).

When supplied with a source of fixed nitrogen, such as an ammonium salt or nitrate, azospirilla can grow under aerobic conditions. Nitrate is assimilated by an assimilatory nitrate reductase (Neyra and van Berkum, 1977). Azospirilla reduce nitrate to nitrite either by an aerobic assimilatory pathway or an anaerobic dissimilatory or respiratory pathway. A group of *A. amazonense* strains (called nir^{++}) assimilates nitrite much faster than most strains of the species (called nir^{+}). Approximately half of the strains of *A. lipoferum* and *A. brasilense* so far isolated can dissimilate nitrite further to nitrous oxide and nitrogen gas (Neyra et al., 1977). Maximum dissimilatory nitrite reductase activity of *A. brasilense* has been observed to occur at high pH values between 7.6 and 8.5 and only under anaerobic conditions (Zimmer et al., 1984). Denitrification has not been observed among strains of *A. amazonense*, *A. irakense*, and *A. largimobile* but it was detected in all strains of *A. halopraeferens*. Nitrite reductase (*nir*) is the key enzyme for denitrification in *Azospirillum* (Magalhães et al., 1978). Plant roots were shown to be mostly infected by non-denitrifying strains (nir^{-}) of *A. lipoferum* and *A. brasilense*. Most of the roots infected by *A. amazonense* strains belong to the nir^{++} group. Chlorate-resistant spontaneous mutants lacking the dissimilatory nitrate reductase (nir^{-} mutants) and/or the nitrite reductase (nir^{-} mutants) have been isolated from *A. lipoferum* and *A. brasilense* species. Nitrogenase activity is retained by such mutants and proceeds even in the presence of 10 mM nitrate. A comparison of several nitrate reductase negative (nir^{-}) mutants of *A. brasilense* strain Sp245 with the wild type carried out in a monoxenic wheat test tube experiment demonstrated the role of nitrate reductase in nitrate assimilation by wheat plants (Ferreira et al., 1987).

Steady-state cultures of denitrifying strains of *A. brasilense* have been obtained under anaerobic conditions in malate containing 100 mM nitrate. When the level of nitrate is lowered to 20 mM, nitrogenase activity occurs but growth is severely decreased (Nelson and Knowles, 1978). Anaerobic suspensions of nitrogenase-containing cells in NFb medium containing 10 mM nitrate exhibit nitrate-dependent nitrogenase activity after 30–60 min, but no growth occurs (Neyra and van Berkum, 1977; Scott et al., 1979); during this period nitrite is accumulated in the medium. A transitory, nitrate-dependent acetylene reduction has been observed in *A. lipoferum* and *A. brasilense* in nitrogen-fixing but not in NO_3^--grown cultures (Bothe et al., 1981).

In peptone-based media, *A. lipoferum* and *A. brasilense* grow abundantly under anaerobic conditions due to the denitrification process, with the nitrate being reduced to nitrite or to nitrous oxide and nitrogen gas. NO_3-dependent anaerobic growth has not yet been shown for *A. amazonense*, *A. halopraeferens*, *A. irakense*, and *A. largimobile*. Other compounds such as nitrite, nitrous oxide, and dimethylsulfoxide (DMSO) can also be used as alternative electron acceptors by *A. lipoferum* and *A. brasilense* strains when NH_4^+ is supplied as a nitrogen source (Döbereiner, 1992a; Hartmann and Zimmer, 1994).

Low concentrations of ammonium completely inhibit nitrogenase activity in *A. lipoferum* and *A. brasilense* (Pedrosa and Yates, 1984; Hartmann et al., 1986). This mechanism, known as "NH_4^+ switch on/off", which involves reversible ADP-ribosylation of the nifH-protein (Fu et al., 1989), has not been observed in *A. amazonense*. In *A. amazonense*, a less effective, noncovalent, reversible inhibition of nitrogenase activity by ammonium chloride occurs. Assimilation of ammonium in azospirilla is mediated by the GS-GOGAT pathway. Glutamate dehydrogenase (GDH), glutamate–oxaloacetate–aminotransferase (GOT), and glutamate–pyruvate–aminotransferase (GTP) also play a role when a high level of ammonium or glutamate is present. *A. lipoferum* and *A. amazonense* exhibit high activities of these enzymes and are able to fix nitrogen using glutamate as carbon and nitrogen source when supplied at low concentrations (1–2 mM), whereas *A. brasilense* and *A. halopraeferens* fix nitrogen in the presence of higher levels of glutamate (20 mM) due to the low rate of glutamate assimilation (Hartmann and Zimmer, 1994). While the amino acids aspartate and histidine showed the same differential effect as glutamate on the nitrogenase activity of azospirilla, the amino acids glutamine, asparagine, arginine, and alanine inhibited nitrogenase effectively (Hartmann et al., 1988).

Azospirillum mutants able to fix nitrogen in the presence of external ammonium sources have been developed. Prototrophic mutants of *A. brasilense* resistant to ethylenediamine (EDA) and able to excrete NH_4^+ were selected. Studies carried out under gnotobiotic conditions showed that these mutants support the growth of wheat plants better than the wild type strains (Christiansen-Weniger and Van Veen, 1991).

Nitrogenase complex The nitrogenase system of *Azospirillum* consists of two components: the Mo–Fe protein and the Fe protein (Ludden et al., 1978). An activating factor for the Fe protein

(Mn^{2+}-dependent activation process) is required for *A. lipoferum* and *A. brasilense* (Ludden et al., 1978; Pedrosa and Yates, 1984) but not for *A. amazonense* (Song et al., 1985). So far, no studies have been carried out for the other *Azospirillum* species. The activating factor is interchangeable with that from *Rhodospirillum rubrum*. An alternative nitrogenase system 3 (Fe-nitrogenase) in addition to the Mo-nitrogenase has been suggested in *A. brasilense* strain Cd (Chakraborty and Samaddar, 1995) but it lacks confirmation. A highly purified dinitrogenase (MoFe-protein) in an active form was obtained from *A. amazonense* (Song et al., 1985) and shown to be a tetramer of 210 kDa with subunits (α2β2) having molecular weights of 50 and 55 kDa, respectively. The dinitrogenase reductase (Fe-protein) is a dimer with subunits of 31 and 35 kDa. Similar results were observed with *A. doebereinerae* strains grown under dinitrogen-dependent conditions, as detected by immunoassay of blotted cell extracts against the Fe-protein of *R. rubrum* and *A. vinelandii* antisera (Eckert et al., 2001). The molecular weights of the nitrogenase component peptides from *A. brasilense* strain Sp7 were determined by immunoprecipitation against antisera from *K. pneumoniae* and were estimated to be 60 kDa and 64 kDa for MoFe protein subunits and 33 kDa and 36 kDa for Fe protein subunits (Nair et al., 1983). The nitrogenase system *in vivo* in *A. lipoferum*, *A. brasilense*, and *A. amazonense* does not liberate H_2 because the latter is recycled by a hydrogenase (Berlier and Lespinat, 1980; Chan et al., 1980; Volpon et al., 1981; Pedrosa and Yates, 1984; Fu and Knowles, 1988). No data are yet available for the other species.

Hydrogenase and autotrophy *A. lipoferum* has the potential for H_2-dependent autotrophic growth under nitrogen-fixing or non-nitrogen-fixing conditions. Strain 208 was able to grow autotrophically under an atmosphere of $H_2/CO_2/O_2/N_2$ (20:5:2:73) in liquid NFb medium (Sampaio et al., 1981). Both ribulose-1,5-bisphosphate carboxylase (RubPcase) and hydrogenase activities were present and were much higher in autotrophically grown cells than in lactate-grown cells. In contrast to *A. lipoferum*, *A. brasilense* ATCC 29145 showed only marginal growth with H_2 under autotrophic conditions. Málek and Schlegel (1981) found that all of the strains of *A. lipoferum* they tested (including the type strain) were capable of hydrogenase activity and autotrophic growth when the O_2 concentration in the gas atmosphere was less than 2% (v/v). RubPcase and hydrogenase activities were present. In the absence of a source of combined nitrogen, the growth rate was very slow under autotrophic conditions and ceased at a cell concentration of 0.2 g/l. With an ammonium salt present, the growth rate was much faster. None of the strains of *A. brasilense* tested was capable of autotrophic growth. In addition, no reports are yet available on autotrophic growth for the other described species of *Azospirillum*.

Methylotrophy Both *A. brasilense* ATCC 29145 and *A. lipoferum* Sp 208 grow well on methane, methanol, or formate as sole energy sources (Sampaio et al., 1981). *A. lipoferum* cells derepressed under CH_4 were devoid of RubPcase and hydrogenase activities; however, RubPcase, but not hydrogenase, could be induced by CO_2 in the presence of methane. These results strongly suggest that *A. brasilense* and *A. lipoferum* have potential for methylotrophic growth and according to Sampaio et al. (1982), these two species could be classified as facultative methylotrophs. However, these authors were not able to demonstrate ^{14}C-incorporation into *A. brasilense* and *A. lipoferum* biomass. These results have not yet been confirmed by other studies, and there are no reports of methylotrophy in other azospirilla species.

Nutritional characteristics Compounds that can serve as sole carbon and energy sources for N_2-dependent growth of *A. brasilense*, *A. lipoferum*, *A. halopraeferens*, *A. irakense*, *A. largimobile*, and *A. doebereinerae* include malate, succinate, pyruvate, and lactate. *A. amazonense* strains can also use these carbon sources, but their sensitivity to alkaline pH values inhibits growth and misleading results can be obtained. A highly buffered medium can circumvent the problem, provided that the initial pH is around 6.0. D-Fructose can also be used as a carbon source by all species except *A. irakense*, in which variable results have been observed. D-Glucose is not used by *A. brasilense* and *A. halopraeferens*. α-Ketoglutarate is used by *A. lipoferum* and by some strains of *A. irakense*. Sucrose has been used as the main carbon source for N_2-dependent growth of *A. amazonense* and *A. irakense*. Studies using ^{14}C as a tracer have been carried out to evaluate the uptake of D-fructose, D-glucose, sucrose, mannitol, and α-ketoglutarate by *A. brasilense*, *A. lipoferum*, and *A. amazonense* (see Döbereiner and Pedrosa, 1987, for more details). The results confirmed the carbon metabolism already known for these species through use of other methodologies. No similar type of study has yet been carried out for the other azospirilla species.

Metabolic characteristics All enzyme activities of the catabolic Embden–Meyerhof–Parnas pathway, the Entner–Doudoroff pathway, and the tricarboxylic acid cycle have been detected in *A. brasilense*, *A. lipoferum*, and *A. amazonense*. However, there are differences among these species, as pointed out by Döbereiner and Pedrosa (1987) and Hartmann and Zimmer (1994) and reviewed here. Unfortunately, no similar studies have been carried out for the other species of *Azospirillum*. The type strains of *A. brasilense* and *A. lipoferum* have been found to phosphorylate fructose to fructose-l-phosphate by means of a phosphoenolpyruvate phosphotransferase system (Goebel and Krieg, 1984). Although both *A. brasilense* and *A. lipoferum* possess glucokinase, only *A. lipoferum* is permeable to D-glucose. Hexokinase activity occurs only in *A. lipoferum*. Sucrose-grown *A. amazonense* cells catabolize D-glucose and D-fructose (produced by the action of β-fructofuranosidase on sucrose) exclusively by the Entner–Doudoroff pathway (Martinez-Drets et al., 1985). *A. amazonense* strains possess fructokinase and glucokinase but not hexokinase. Enzymes of the Embden–Meyerhof–Parnas pathway and the Entner–Doudoroff pathway occur in D-fructose-grown cells of *A. brasilense* and *A. lipoferum*. High levels of NAD(P)-glucose 6-P-dehydrogenase, required for 6-phosphogluconate synthesis, have been detected in strains of *A. lipoferum* and *A. amazonense* but not in *A. brasilense* (Martinez-Drets et al., 1985). On the other hand, the enzyme 1-phosphofructokinase, involved in the phosphorylation of D-fructose, is present in large amounts in *A. lipoferum* and *A. brasilense* but absent in sucrose-grown *A. amazonense*. All three species above lack the key enzyme of the oxidative branch of the hexose monophosphate pathway (HMP). D-Gluconate is metabolized via the Entner–Doudoroff pathway in *A. lipoferum* and *A. brasilense*. Although *A. amazonense* possesses all three enzymes involved in the metabolism of D-gluconate it is unable to grow on this carbon source, probably because it lacks a gluconate transport system (Martinez-Drets et al., 1985). No information is yet available for the other species.

A. lipoferum exhibits weak fermentative ability in media containing D-glucose or D-fructose as a carbon source and with a source of fixed nitrogen. *A. largimobile* possesses fermentative ability in media containing carbohydrate, as determined by the Hugh–Leifson test (Ben Dekhil et al., 1997a). Although strains from all *Azospirillum* species grow far better aerobically than an-

aerobically, strains of *A. largimobile* have been considered facultative anaerobes. *A. lipoferum* is capable of acidifying D-glucose or D-fructose media anaerobically, of forming very small amounts of gas in Durham vials, of exhibiting slight growth in D-glucose or D-fructose broth under anaerobic conditions, and of forming minute colonies on D-glucose or D-fructose agar anaerobically. Variable results for these tests occur within some strains, and variants with decreased fermentative ability can be selected. Such variants continue to require biotin, use D-glucose as a sole carbon source for N_2-dependent growth, and exhibit the characteristic pleomorphic changes associated with this species. *A. largimobile* also produces acid (but no gas) from D-fructose, D-glucose, D-galactose, D-ribose, and sucrose, whereas *A. halopraeferens* produces acid from D-fructose but only aerobically. No acid is produced from D-glucose or D-fructose in *A. brasilense*, *A. amazonense*, and *A. irakense* either aerobically or anaerobically in a peptone-based medium. Acid is also produced from D-fructose and D-glucose in *A. doebereinerae* strains grown anaerobically (API50 test) (Eckert et al., 2001).

By an auxanographic method using media containing ammonium sulfate as the nitrogen source (Tarrand et al., 1978), the following compounds serve universally as sole carbon sources for all *A. lipoferum*, *A. brasilense*, and *A. halopraeferens* strains: malate, succinate, lactate, pyruvate, fumarate, β-hydroxybutyrate, D-gluconate, glycerol, and D-fructose. *A. irakense* and *A. amazonense* are also able to use these organic acids as carbon source; however, *A. amazonense* strains require a pH of approximately 6.0 in order to use the organic acids for N_2-dependent growth. No data are available for the use of organic acids as carbon source in *A. largimobile*. D-Gluconate and glycerol are not used by *A. amazonense* and *A. irakense*, whereas *A. largimobile* uses glycerol but not D-gluconate. D-Fructose is also catabolized by the other azospirilla species although variable results have been observed for *A. irakense*. Citrate and D-mannitol are not used by strains of *A. amazonense*, *A. irakense*, and *A. brasilense*. A few strains of *A. halopraeferens* do not catabolize citrate. D-Glucose is used by all azospirilla species except *A. halopraeferens* and most strains of *A. brasilense*. However, *A. brasilense* cannot use D-glucose as a sole carbon source for N_2-dependent growth, and it also produces a lower degree of acidification of glucose than does *A. lipoferum* (Tarrand et al., 1978). The use of D-galactose as carbon source is variable among strains of *A. brasilense* and negative for all strains of *A. halopraeferens*, whereas sucrose is catabolized only by strains of *A. amazonense* and *A. irakense*. *N*-acetylglucosamine is used by *A. largimobile*, *A. lipoferum*, *A. irakense*, variable for *A. amazonense* strains but not used by *A. brasilense* and *A. doebereinerae*. No information is available for *A. halopraeferens*.

The following tests are universally positive for the genus *Azospirillum*: oxidase, phosphatase (weak in *A. largimobile*), urease, and esculin hydrolysis. The following tests are universally negative: starch and gelatin hydrolysis, production of water-soluble pigments, and indole production. Acidification of media containing lactose, sucrose, L-rhamnose, cellobiose, erythritol, dulcitol, or melibiose differs among strains and species of *Azospirillum*. Catalase activity ranges from strong to undetectable. The ability to grow anaerobically with nitrate in peptone-based media is positive for *A. lipoferum*, *A. brasilense*, and *A. halopraeferens* but negative for *A. amazonense*, *A. irakense*, and *A. largimobile*. In addition, the ability to dissimilate nitrate to either nitrite or to nitrous oxide and nitrogen gas differs among strains and species of *Azospirillum*. Most strains of *A. lipoferum*, *A. brasilense*, *A. halopraeferens*, and *A. doebereinerae* are able to denitrify. No denitrification has been observed in strains of *A. amazonense*, *A. irakense*, and *A. largimobile*, although a report has been published showing a very low rate of denitrification for strain Y1 of *A. amazonense* (Neuer et al., 1985). Hybridization of DNA from five azospirilla species against the *nozZ*-segments containing the nitrous oxide reductase gene from *P. stutzeri* as a probe produced a positive signal with strains of *A. lipoferum*, *A. brasilense*, and *A. halopraeferens* but not for *A. amazonense* and *A. irakense*, confirming the presence of a N_2O reductase in the former three species and its absence in the last two species (Zimmer et al., 1995).

Pectinolytic activity (pectate lyase and pectin methylesterase) has been detected in strains of *A. irakense* (Khammas and Kaiser, 1991). Strains from this species are able to grow and fix nitrogen when pectin is used as the sole carbon source. Pectolytic activity—pectic lyase and endogalacturonase (Umali-Garcia et al., 1980) and polygalacturonic acid transeliminase (Tien et al. 1981)—has also been reported for some strains of *A. lipoferum* and *A. brasilense*. However, the enzymatic activity appears to be weaker than that of *Erwinia* (Tien et al., 1981). In addition, Khammas and Kaiser (1991) failed to demonstrate pectinolytic activity in these two species of *Azospirillum* as well as in strains of *A. amazonense*. Quite recently it was observed that *A. irakense* strain KBC1 also possesses cellulolytic activity—endoglucanase, cellobiohydrolase, and β-glucosidase activities (Vande Broek et al., 1998). No similar activities (pectinolytic and cellulolytic) have been tested for strains of *A. halopraeferens*, *A. largimobile*, and *A. doebereinerae*.

Production of the plant growth substance indoleacetic acid, and also indolelactic acid, gibberellin, and cytokinin-like substances, has been reported in strains of *A. brasilense* (Reynders and Vlassak, 1979; Tien et al., 1979). The production of indole-3-acetic acid by *A. brasilense* and *A. lipoferum* strains has been confirmed by many authors (Hartmann et al., 1983; Fallik et al., 1989; Bar and Okon, 1995) and the pathway for synthesis of IAA as well as the regulatory mechanism involved have been suggested (see Hartmann and Zimmer, 1994; Vande Broek et al., 1998). However, the production of cytokinins and gibberellins is still not clear because these products were detected only via bioassays in very old cultures (see Hartmann and Zimmer, 1994). More recently, the production of abscisic acid in *A. brasilense* (Iosipenko and Ignatov, 1995) and gibberellic acid in strains of *Azospirillum lipoferum* (Bottini et al., 1989) and other azospirilla (Rasul et al., 1998) was demonstrated using the HPLC technique. However, the production was detected with 10-d-old cells. The production of IAA in *Azospirillum irakense* is very low and the gene *trpD*, encoding phosphoribosyl anthranilate transferase, was proposed to be involved in the repression of IAA production (Zimmer et al., 1991). No information about the production of phytohormones by the other *Azospirillum* species is available. Plant response to inoculation with *Azospirillum*, mainly increase in root area, has been reported and attributed to phytohormones such as IAA produced by these bacteria (Bashan and Holguin, 1997).

Other substances such as the vitamins thiamin, niacin, pantothenic acid (Rodelas et al., 1993) and riboflavin (Dahm et al., 1993) have also been detected in *A. brasilense* strains. It has also been reported that *Azospirillum lipoferum* is able to degrade 4-chloronitrobenzene (Russel and Muszynki, 1995) and more recently it was demonstrated that many strains (73 out of 110) of *A. lipoferum* and *A. brasilense* are able to produce cyanide (Gonçalves and Oliveira, 1998). The ability to oxidize phenolic derivatives like syringic aldehyde, acid, or acetosyringone has been detected in *A. lipoferum* strain 4T and is carried out by laccase—an oxidase widespread in fungi and higher plants (Faure et al., 1996).

Azospirillum spp. isolated from saline soils exhibited different

degree of osmotolerance. *A. halopraeferens*, isolated from sodic alkaline soils of Pakistan, exhibited the highest osmotolerance, followed by *A. brasilense*, *A. lipoferum*, and *A. amazonense* (Hartmann, 1988); the osmotolerance of *A. irakense* lies between *A. halopraeferens* and *A. brasilense* (Khammas et al., 1989). As compatible solutes in *Azospirillum*, trehalose, glycine betaine, glutamate, and proline were characterized (Hartmann et al., 1991). *A. halopraeferens* is able to take up choline efficiently and to convert it into the most potent osmoprotectant, glycine betaine (Hartmann, 1988; Hartmann et al., 1991). In *A. brasilense* Sp7, a binding protein-dependent, high-affinity uptake of glycine betaine was demonstrated and glycine betaine stimulated growth and nitrogen fixation in *A. brasilense* (Hartmann, 1988; Riou and Rudulier, 1990). In osmotolerant *Azospirillum* spp., choline and glycine betaine, as well as glutamate, proline, and other amino acids, are not or only slightly used as nitrogen or nitrogen and carbon sources (Hartmann et al. 1988; Khammas et al., 1989). Dehydroproline (DHP)-resistant bacteria with improved osmoregulatory properties are available for *A. brasilense* Sp7 (Hartmann et al., 1992). The fact that these mutants appear spontaneously at relatively high rates suggests the ecophysiological importance of this trait.

Under iron-limiting conditions, *A. lipoferum* and *A. brasilense* release the phenolate siderophores 2,3- and 3,5-dihydroxybenzoic acid conjugated with lysine and leucine or ornithine and serine, respectively, which has been called spirillobactin (Saxena et al., 1986; Bachhawat and Ghosh, 1987b). The Fe(III)-spirillobactin complex is taken up via a high-affinity uptake receptor, which involves a specific outer membrane receptor (Bachhawat and Ghosh, 1987a). It has been shown for *A. brasilense* Sp245 that the siderophores ferrichrome, ferrichrysin, and coprogen, as well as the main siderophore of *Streptomyces*, ferrioxamine B, can be used as iron sources too (Hartmann, 1988). However, the iron-scavenging properties vary much among different *Azospirillum* species and strains; e.g., *A. brasilense* strain Sp7 was only a weak siderophore scavenger (Hartmann, 1988). Under severe iron-limiting conditions, which drastically inhibit the growth of *A. brasilense* Sp7 wild type, spontaneous mutants that could readily use coprogen- and ferrichrysin-bound iron, appeared (Hartmann et al., 1992). The high-affinity iron uptake systems of *A. halopraeferens*, *A. irakense*, and *A. doebereinerae* have not yet been studied. Among azospirilla, only *A. irakense* isolates can efficiently hydrolyze desferrioxamine (Winkelmann et al., 1999). The ecological relevance of this unique physiological property has not yet been elucidated. High-affinity-mediated siderophore acquisition could be an important trait for competitiveness in a highly populated habitat such as the rhizosphere.

Genetic characteristics Genetic transformation to generate antibiotic-resistant derivatives has been reported for *A. brasilense* ATCC 29145 (Mishra et al., 1979). Genetic transformation has been also demonstrated for other strains of *A. brasilense* and *A. lipoferum* (Wood et al., 1982; Fani et al., 1986) More recently, DNA transformation of *Azospirillum* using a high-voltage electroporation mechanism was developed (Vande Broek et al., 1989); however, the methodology worked only for *A. brasilense* strains and not for *A. lipoferum* strains. There are no reports of DNA transformation for the other *Azospirillum* species. In contrast to transformation, conjugation appears to be the most efficient method of gene transfer for *Azospirillum* species (see Döbereiner and Pedrosa, 1987). More recently, a *nifH–gusA* fusion plasmid pFAJ21 was transferred by a biparental mating to *A. irakense* (Vande Broek et al., 1996). However, there are no reports of conjugation for the other described *Azospirillum* species.

Genetic recombination has been demonstrated in *A. brasilense* ATCC 29145, using plasmid R68-45 (derived from *Pseudomonas aeruginosa*) to mobilize the chromosome (Franche et al., 1981). The mode of gene transfer promoted by the plasmid appeared to be unpolarized, suggesting the existence of multiple origins of transfer. Similar results were obtained by Bazzicalupo and Gallori (1983) using strains Sp7 and Sp6 of *A. brasilense.* Although much progress has been made, the data obtained so far do not allow a genetic map to be drawn for the chromosome of *A. brasilense.* Several difficulties in constructing the genetic map using this technique have been pointed out by Döbereiner and Pedrosa (1987). Nevertheless, most of the genes involved in the nitrogen fixation process have already been identified in *A. brasilense* and *A. lipoferum* and located on the chromosome (Vande Broek and Vanderleyden, 1995). In addition, the organization and regulation of the *nif* genes as well as the genes involved in nitrogen metabolism are well established in *A. brasilense* (Elmerich et al., 1997). Little information is available so far for the other *Azospirillum* species.

Plasmids and bacteriophages The occurrence of multiple large plasmids in *A. brasilense* and *A. lipoferum* strains was reported by Wood et al. (1982). The authors called these megaplasmids "minichromosomes" that varied in size from 42 to 1850 MDa. Two plasmids of very high molecular weight (1700 and >1800 Kb) have also been observed in several strains (24 out of 28) of *A. brasilense* isolated from sugarcane plants (Caballero-Mellado et al., 1999). These authors also observed that the megaplasmid of 1700 Kb and the plasmid of approximately 600 Kb carry genes homologous to the 16S rDNA, thus reinforcing the hypothesis of the presence of minichromosomes in *Azospirillum brasilense.* More recently, the genome structure of five *Azospirillum* species was analyzed by pulsed-field gel electrophoresis (Martin-Didonet et al., 2000). The authors detected the presence of 8–10 replicons in the species *A. lipoferum* and *A. brasilense* (0.15–2.5 Mbp) and 4–5 in the species *A. amazonense*, *A. irakense*, and *A. halopraeferens* (0.22–2.7 Mbp). They also observed the hybridization of a 16S rDNA probe to some replicons, confirming the existence of multiple chromosomes in the genus. In addition, the authors observed that the *nifHDK* operon is present in the largest replicon. Strains of *A. brasilense* and *A. lipoferum* harboring 1–7 plasmids ranging from 4 to 310 MDa have been described by other authors (Franche and Elmerich, 1981; Plazinski et al., 1983). Plasmids have also been detected in strains of *A. amazonense* and *A. halopraeferens*; however they are present in low numbers and are small in size (Elmerich et al., 1991). No information is yet available for *A. doebereinerae.* Many reports have shown that *Azospirillum* plasmids harbor genes involved in the plant–bacterium interaction and other physiological functions. A plasmid called p90, present in many *A. lipoferum* and *A. brasilense* strains, carries genes involved in chemotaxis, motility, and plant root adsorption (Michiels et al., 1994; Vande Broek and Vanderleyden, 1995). In addition, it also carries *nod* and *exo* genes that are homologous to those frequently found in legume-nodulating rhizobia (Onyeocha et al., 1990). Other functions such as production of melanin in *A. lipoferum* (Givaudan et al., 1991) and IAA biosynthesis in *A. brasilense* (Katzy et al., 1995) have also been detected. The p90 plasmid tagged with Tn5 was mobilized to *Agrobacterium tumefaciens* at a frequency of 10^{-4}, but self-transfer of p90 was not demonstrated (Onyeocha et al., 1990).

Lysogenicity is common in *Azospirillum* (Döbereiner and Pedrosa, 1987). It has been detected in many strains of *A. lipoferum* and *A. brasilense* and the lysis is inducible by mitomycin C (Fran-

che and Elmerich, 1981; Elmerich et al., 1982). However, not all strains of these two species are lysogenic. Temperate bacteriophage Al-1—isolated from soil samples from Brazil—was purified and showed a size and morphology similar to that of coliphage λ (Elmerich, 1983). This phage is lysogenic to some strains of both species (see Döbereiner and Pedrosa, 1987). Phage Ab-1 particles from *A. brasilense* Sp7 were characterized and shown to be infective to strains Sp7 and Cd of *A. brasilense* but not to strains Sp35, Sp59a, RG20a, and Br17 of *A. lipoferum* (Germida, 1984). The presence of bacteriophages in strains of the other species of *Azospirillum* has not been determined.

Bacteriocins Production of bacteriocins has been observed in many strains of *A. lipoferum* and *A. brasilense* in pure culture, but this seems not to be the case for strains living in soil or associated with roots (Oliveira and Drozdowicz, 1981; 1988). Catechol-type siderophores with antimicrobial activity against various bacterial and fungal isolates have been detected in 27 strains of *Azospirillum* (Shah et al., 1992).

Antigenic characteristics Antisera prepared against whole cells have been used in the indirect fluorescent antibody technique to distinguish between *A. lipoferum* and *A. brasilense* and also between groups of strains (Schank et al., 1979; De Polli et al., 1980). Several other reports applying polyclonal antisera to evaluate the colonization of grass plants by *A. lipoferum* and *A. brasilense* have been published (see Kirchhof et al., 1997b, for more details). More recently, with the help of hybridoma technology, several strain-specific monoclonal antibodies were developed for *A. brasilense* (Kirchhof et al., 1997b). Three classes of monoclonal antibodies with high specificity for *Azospirillum brasilense* Sp7 have been characterized by Schloter et al. (1994). One class recognizes a 100 kDa protein subunit of the polar flagellum, and the other two bind to an 85 kDa outer membrane protein and to polysaccharide, respectively. Monoclonal antibodies specific for *A. brasilense* strain Sp245 and *A. brasilense* strain Wa5 were recently characterized (Schloter and Hartmann, 1996; Schloter et al., 1997). As antibody-binding cell surface components, lipopolysaccharides and outer membrane proteins were identified. Studies of wheat root colonization by the above strains using the strain-specific monoclonal antibodies showed that strain Sp245 colonizes the inner root tissue endophytically whereas strain Sp7 colonizes only the root surface (Schloter and Hartmann, 1998). No monoclonal antibodies for other *Azospirillum* species have been produced; therefore, strain-specific root colonization studies involving other species are lacking.

Ecology Azospirilla have a worldwide distribution and occur in large numbers (up to 10^7/g) in rhizosphere soils and in association with the roots, stems and leaves of a large variety of different plants. Most isolates have been obtained from tropical forage grasses and from cereal plants grown in tropical regions. However, azospirilla have also been frequently isolated from plants grown in temperate regions, including graminoids grown in the Canadian High Arctic sites (Nosko et al., 1994). The idea that *Azospirillum* species were limited to grass plants is no longer tenable. *A. lipoferum* and *A. brasilense* have a widespread occurrence and colonize various plants including legumes, vegetables, and fruits (Bashan and Holguin, 1997; Kirchhof et al., 1997a; Weber et al., 1999). *A. amazonense* has been isolated from roots of maize, sorghum, rice, wheat, forage grasses, and palm trees grown around Brazil. It has also been isolated from roots and stems of sugarcane plants grown in Brazil, from sugarcane roots grown in Hawaii and Thailand, and more recently, from pineapple and banana fruits grown in Brazil (Weber et al., 1999). The other *Azospirillum* species appeared to be more restricted: *A. halopraeferens* has so far only been found associated with Kallar grass plants grown in Pakistan. *A. irakense* has so far been isolated from rice plants grown in Iraq (Khammas et al., 1989) and from a freshwater pond in the botanical garden in Tübingen, Germany (Winkelmann et al., 1996). *A. largimobile* has only been isolated from a freshwater lake located in Australia (Ben Dekhil et al., 1997a) while *A. doebereinerae* was so far isolated from roots of the C_4-graminaceous plant *Miscanthus* grown in Germany (Eckert et al., 2001).

In field-grown maize, azospirilla occur on the surface of roots, in the outer cortex, inner cortex, and in the stele (Patriquin and Döbereiner, 1978). Infection of the inner cortex and stele occurs in the absence of significant bacterial colonization or collapse of outlying tissues. Paraxylem vessels can be completely plugged with the bacteria. Infection occurs initially in root branches and spreads longitudinally into main roots. In monoaxenic cultures of pearl millet and guinea grass, azospirilla are found within the mucigel layer of roots and become firmly attached to root hairs. The bacteria enter the roots through lysed root hairs and void spaces created by epithelial desquamation and lateral root emergence (Umali-Garcia et al., 1980). Azospirilla have been observed in intercellular locations within the middle lamella of root tissues; they have also been observed intracellularly, sometimes in very large numbers.

The above observations of root colonization were recently confirmed for *A. brasilense* strains Sp245 and Sp7 inoculated into wheat plants and evaluated using sophisticated techniques such as confocal laser scanning microscopy (SCLM) coupled with fluorescent probes (Assmus et al., 1995), as well as the use of strain-specific monoclonal antibodies (Schloter and Hartmann, 1998) and *nifH–gus* fusion (Vande Broek et al., 1993). There was a marked predominance of *A. brasilense* in the root hair zone as compared with the root tips of wheat plants. *A. brasilense* strain Sp245 was repeatedly detected in the interior of root hairs whereas *A. brasilense* strains Sp7 and Wa3—both isolated from a rhizosphere—colonized only the rhizoplane (Assmus et al., 1995). Strain Sp245, already known to be a colonizer of the root interior (Baldani et al., 1986b), could be found in the intercellular space of the root parenchyma and inside cortex and parenchyma cells, with the point of emergence of lateral roots being the most probable infection site (Assmus et al., 1997). More recently, it was observed that microcolonies are formed in the intercellular space of wheat roots inoculated with strain Sp245, but not with strains Sp7 and Wa3, and that the plant genotype influenced root colonization (Schloter and Hartmann, 1998). Use of strain Sp245 expressing the *gusA* gene showed that the bacteria initially concentrate in the root-hair zones and at sites of lateral root emergence. Proliferation to the other parts of the root was dependent on the status of the nitrogen and carbon sources present in solution (Vande Broek et al., 1993). Although the complete process of association between *Azospirillum* and the host grass plant is still unclear and a model has already been suggested (Del Gallo and Fendrik, 1994), it is known that the colonization requires the attachment of the cell to the root surface. This attachment occurs in two steps: one that is fast, weak, and probably mediated by bacterial proteins, and the second phase (also called anchoring) which is longer and irreversible and probably involves extracellular surface polysaccharides and the polar flagellum (see Vande Broek and Vanderleyden, 1995, for more details). It has been suggested that the *rpoN* gene, involved in nitrate reduction, nitrogen fixation, and cell motility,

also controls the colonization of wheat plants by *A. brasilense* Sp7 (Pereg-Gerk et al., 1998). Because the ability of most strains of *Azospirillum* to colonize both the surface and root interior, including the stems and leaves of grass, these bacteria were included in the group called facultative endophytic diazotrophs (Baldani et al., 1997). This term was suggested to distinguish them from the obligate endophytic bacteria that include *Gluconacetobacter diazotrophicus*, a bacterium found colonizing sugarcane plants endophytically (Döbereiner, 1992b).

Several field inoculation experiments applying mainly strains of *A. brasilense* and *A. lipoferum*, and in a few cases *A. amazonense*, have been carried out in the last 20 years at various locations around the world. About 60–70% of all field experiments showed positive effects of the inoculation, with significant yield increases ranging from 5 to 30% (Okon and Labandera-Gonzalez, 1994; Baldani et al., 1997). Few commercial inoculants are available, probably because of the inconsistency and low percentage of response to inoculation. There is still a debate about the main mode of action by which these bacteria contribute to the nitrogen accumulated by the plants. Effects of plant-growth promoting substances, nitrogen fixation *per se*, and the ability of the bacterial nitrate reductase to help in the incorporation of nitrogen assimilated from the soil by the plant (Baldani et al., 1997) have also been mentioned as the major factors involved in the response of the plant to *Azospirillum* inoculation.

Enrichment and Isolation Procedures

Tenfold serial dilutions of roots, stems, or leaf samples are inoculated into 10-ml cotton-plugged serum vials containing 5 ml of semisolid medium and incubated for up to one week at the optimal temperature. Soil samples or smashed pieces (5–8 mm long) of plant tissues can also be used but the incubation time should be only 40–48 h. Nitrogenase activity can be tested by acetylene reduction assay for those vials containing pellicles on the surface.

For vials exhibiting acetylene reduction, a second serial transfer is made. In the case of *A. brasilense*, *A. lipoferum*, and *A. doebereinerae*, the pellicle is transferred to semisolid NFb medium. After 24 h, the growth is streaked out on plates of solid NFb medium containing 0.02 g/l yeast extract. After 1 week, typical small, white, dense, single colonies are sub-cultured to semisolid NFb medium, where subsurface growth in the form of a veil is a presumptive indication of successful enrichment. For final purification, cultures are streaked onto BMS agar and the typical pink, often wrinkled, colonies are transferred for storage and identification (Döbereiner et al., 1995).

For *A. amazonense*, the pellicle is transferred to semi-solid LGI medium[5] and after 3–4 d streaked out on plates of LGI medium containing 0.02% yeast extract. After 5 d, small (2 mm diameter) whitish colonies with firm, dense, but not tenacious consistency and which are partially imbedded into the agar are selected and transferred to new LGI vials and, if growing well, streaked on BMS agar for final purification. On this medium, large, white, flat colonies with raised margin are formed.

For *A. halopraeferens*, roots of *Leptocholoa fusca* plants are collected and the rhizoplane soil separated, diluted, and inoculated into semi-solid modified NFb medium, named SM[6] (containing vitamins, 0.25% NaCl; pH adjusted to 8.5), and incubated at 41°C. Culture from vials showing nitrogenase activity, as determined by the acetylene reduction method, are then transferred to fresh semi-solid SM medium and after 48–72 h of incubation the pellicle is suspended in the same medium containing yeast extract (0.02%). Aliquots are then used to seed molten, cooled (45°C), soft SM (0.8% agar), which is then poured into Petri dishes and incubated for 1 week. Small, white colonies are visible within the agar and are further purified by embedding in the same way. For final purification, colonies are again transferred to semi-solid SM medium and streaked on Tryptic soy agar; cream-colored, circular, flat colonies with an entire margin are formed. No growth occurs on BMS or Congo red agar medium.

For *A. irakense* species, rhizosphere and roots of rice plants are crushed, suspended in sterile distilled water, diluted, and inoculated into semisolid NFb medium. The intermediate purification steps basically follow those for *A. lipoferum*. The final purification is performed on modified semisolid AAM medium[7] (containing 4 ml/l of a 1.64% solution of FeEDTA; pH of medium adjusted to 6.5). Subsurface pellicles are streaked out on the modified AAM agar plates. Colonies formed after 4 d are translucent, glistening, and convex with a regular margin, 1 mm diameter.

In the case of *A. largimobile*, one drop of fresh lake water is spread onto the surface of lake water agar (LWA) plates, dried and incubated for up to 8 d at 28°C. Colonies grown on LWA for 72 h at 28°C are 1–2 mm in diameter, colorless, translucent, low convex, and round, with an entire edge and smooth surface and they readily coalesce. These colonies, containing unicellular or multicellular forms, are further purified on LWA agar where very active motile cells containing refractile granules appear 4–8 h after incubation. These motile cells have a striking resemblance to cells of *Beijerinckia* species. To ensure that the phenomenon of multicellular form occurs, the cells are again inoculated in LWA or lake water salt agar (LWSA). Although *A. largimobile* has shown these peculiar characteristics, strains from this species are able to grow and fix nitrogen in semisolid NFb medium, with many aspects of their growth resembling *A. lipoferum*.

The following method has been used for the specific enrichment of *A. lipoferum*. A nitrogen-free mineral medium is inoculated with soil samples or washed root pieces and incubated under a gas atmosphere of $O_2/CO_2/H_2/N_2$ (5:10:30:55). After one

5. LGI medium (g/l): Sucrose, 5.0; K_2HPO_4, 0.2; KH_2PO_4, 0.6; $MgSO_4{\cdot}7H_2O$, 0.2; $CaCl_2{\cdot}2H_2O$, 0.02; $Na_2MoO_4{\cdot}2H_2O$, 0.002; bromothymol blue 0.5% in 0.2 N KOH, 5ml; FeEDTA (1.64% solution), 4 ml; vitamin solution (biotin, 0.01g; pyridoxal-HCl, 0.02g; distilled water, 100ml), 1 ml; pH adjusted to 6.0–6.2 with H_2SO_4 and the final volume completed to 1000 ml with distilled water. For semi-solid medium, 1.8 g/l agar was added. For solid medium, add 15 g/l agar and 20–50 mg/l yeast extract.

6. SM medium (g/l): DL-malic acid, 5.0; KOH, 4.8; NaCl, 1.2; $NaSO_4$, 2.4; $NaHCO_3$, 0.5; $CaCl_2$, 0.22; $MgSO_4{\cdot}7H_2O$, 0.25; K_2SO_4, 0.17; Na_2CO_3, 0.09; Fe-EDTA, 0.077; K_2HPO_4, 0.13; biotin, 0.0001; $MnCl_2{\cdot}4H_2O$, 0.0002; H_3BO_3, 0.0002; $ZnCl_2$, 0.00015; $CuCl_2{\cdot}2H_2O$, 0.000002; $Na_2MoO_4{\cdot}2H_2O$, 0.002; distilled water, completed to 1000 ml. The final pH of the medium is 8.5 and it does not require further adjustment. For semisolid medium, 2.0 g/l agar were added. Malic acid, KOH, and agar are dissolved in one-half of the total volume and autoclaved. The remaining salts are sterilized by filtration after dissolving them in one-half of the total volume and discarding the precipitate after centrifugation. For solid medium, 8 g/l agar and 20 mg/l yeast extract were added.

7. AAM defined medium (g/l): K_2HPO_4, 2.0; KH_2PO_4, 6.0; $MgSO_4{\cdot}7H_2O$, 0.2; NaCl, 0.1; $CaCl_2{\cdot}2H_2O$, 0.026; $Na_2MoO_4{\cdot}2H_2O$, 0.002; $FeCl_3$, 0.01; NH_4Cl, 1.0; distilled water, 1000 ml. The pH is adjusted to 6.0. For semisolid medium, 1.9 g/l agar were added and the NH_4Cl was omitted. For solid medium, 15 g/l agar were added. The carbon sources are sterilized separately (i.e., DL-sodium malate) or filter sterilized (i.e., sucrose) and added aseptically to the minimal medium to give a final concentration of 0.03M.

week, 0.5 ml of the suspension is transferred to fresh medium and incubated as before. The procedure is repeated 2 or 3 times before serial dilutions are plated onto nitrogen-free mineral media containing 1.5% (w/v) agar. Colonies are selected and propagated under autotrophic conditions.

A method has been developed and used to isolate *A. lipoferum* from the rhizosphere of rice plants (Tran Van et al., 1997). Serial dilutions of crushed roots and rhizosphere soil suspensions are inoculated into 18 × 180-mm tubes, each tube containing 8 ml of one of four different liquid N-free media: distilled water, KCl solution (8.5 g/l), NFb liquid medium, and soil extract (obtained by autoclaving a soil suspension in water (50% w/v) at 130°C for 1h and filtering through cellulose filters followed by autoclave treatment). The tubes are incubated at 30–32°C for 15 d in the dark to prevent growth of algae or cyanobacteria. A pellicle is formed 2 mm below the surface of the liquid, and when examined under the microscope normally shows the presence of spiral motile cells. Samples (10 µl) of the pellicle, from the highest dilution, are plated on nutrient agar medium and incubated for 48–72 h. All colony types are then purified. The authors claim that these methods are much simpler than the use of semisolid media; however, many more colonies have to be checked for the presence of nitrogen-fixing ability.

Maintenance Procedures

Stock cultures of *A. brasilense*, *A. lipoferum*, and *A. doebereinerae* may be maintained in semisolid NFb medium at 8–30°C with monthly transfers for *A. brasilense* and biweekly transfers for *A. lipoferum* (Döbereiner, 1992a). Stocks may also be maintained on trypticase soy agar with monthly transfer (Tyler et al., 1979). *A. brasilense* remains viable for several years and *A. lipoferum* for 3–6 months in sterile vermiculite moistened with potato broth; drying should be avoided by tightly sealing the vials with screw caps. A combination of soil and farmyard manure (1:1) can maintain a population of *A. brasilense* at high levels for up to 6 months (Tilak et al., 1979).

Strains can also be kept lyophilized for many years. Cells grown on slanted NFb medium (malic acid is replaced by glucose for *Azospirillum lipoferum* strains) for 48–72 h at 30°C are suspended in 2 ml of a lyophilization solution consisting of 10% sucrose and 5% peptone in 100 ml water. Aliquots (0.2 ml) are then distributed into lyophilization ampules and lyophilization performed as recommended for rhizobia.

For preservation in liquid N_2, heavy suspensions of cells harvested from MPSS broth or MPSS agar plates are prepared in nutrient broth containing 10% (v/v) dimethyl sulfoxide (Tarrand et al., 1978) or in TSS broth (1% trypticase, 0.5% succinate with salts as in NFb medium) in which 15% of the water is replaced by glycerol (Tyler et al., 1979). The suspensions are placed in vials and preserved in liquid nitrogen.

A. amazonense strains may also be maintained in semisolid LGI medium at 30°C with biweekly transfers. Strains from this species have been maintained for more than 15 years in test tubes containing LGI agar medium supplemented with yeast extract and covered with mineral oil. The cultures should never be stored in BMS agar medium even under oil because of the pH sensitivity of the bacteria. Cultures can also be maintained lyophilized after growth for 48–72 h at 30°C in a medium with sucrose as the sole carbon source and following the procedure described above.

A. halopraeferens cells may be maintained at 41°C by biweekly transfer in semi-solid SM medium supplemented with 0.25% NaCl and adjusted to pH 7.2 (Reinhold et al., 1987). They can also be maintained in liquid nitrogen as described for the other species of *Azospirillum*. *A. irakense* cells are maintained at room temperature on slants of modified AAM agar medium (Khammas et al., 1989) and *A. largimobile* can be maintained on LWA or LWSA agar medium according to the description by Skerman et al. (1983).

Azospirilla can also be maintained for long periods in water. Two colonies grown on the specific agar medium are transferred to micro tubes containing 0.5 ml of distilled sterile water and stored at room temperature. To revive, the cells are homogenized and 20–100 µl are transferred to semi-solid medium and incubated at the appropriate temperature.

Procedures for Testing Special Characters

D-Glucose and sucrose used as sole carbon source for growth in semi-solid nitrogen-free medium For D-glucose, a loopful of culture from each species grown in the appropriate semi-solid or liquid medium is inoculated into a tube of semi-solid, nitrogen-free, D-glucose medium (the specific carbon source is replaced by 1.0% D-glucose which has been sterilized by filtration). *A. lipoferum*, *A. amazonense*, and most strains of *A. doebereinerae* form a veil or disc of growth in the depths of the medium; within 3 d at 35–37°C this disc migrates close to the surface of the medium and becomes very dense. *A. brasilense* and *A. halopraeferens* either give no response or form a slight pellicle in the depths of the medium that later disperses. The difference in response between these four species is very pronounced. The other two species, *A. irakense* and *A. largimobile*, also use D-glucose but this characteristic has not been checked under nitrogen-fixing conditions.

For sucrose, a loopful of culture from *A. amazonense* or *A. irakense* grown in liquid medium is inoculated into a vial of semi-solid LGI medium containing sucrose as sole carbon source, and the pH is adjusted to 6.0–6.2 for *A. amazonense* and 6.5 for *A. irakense*. *A. amazonense* forms a fine pellicle below the surface very similar to that of the other species in NFb medium except that growth is initially slower; however, a thick surface pellicle is formed after 3–4 d. *A. irakense* forms a white pellicle 2 mm below the surface after 1 d of incubation but reaches the surface within 2–3 d. The other species do not use sucrose as sole carbon source, although some variants of *Azospirillum lipoferum* have been found to use sucrose for growth.

Biotin requirement Glassware should be rinsed copiously with distilled water and subsequently baked in an oven to destroy traces of biotin. A medium of the following composition is used (g/l): K_2HPO_4, 0.5; succinic acid (free acid), 5.0; $FeSO_4 \cdot 7H_2O$, 0.01; $Na_2MoO_4 \cdot 2H_2O$, 0.002; $MgSO_4 \cdot 7H_2O$, 0.2; NaCl, 0.1; $CaCl_2 \cdot 2H_2O$, 0.026; $(NH_4)_2SO_4$, 1.0. The pH is adjusted to 7.0 with KOH solution. Biotin (0.0001 g/l) is added to one portion. The biotin-free and biotin-containing media are sterilized in 5.0-ml amounts in screw-capped tubes by autoclaving. Cultures grown in MPSS broth are inoculated by a loop into 25 ml of one-quarter-strength nutrient broth (Difco) and incubated at 37°C for 24 h. The cells are harvested by centrifugation, washed twice with 10-ml portions of sterile distilled water, and suspended in water to a turbidity of 20 Klett units (blue filter, 16-mm tubes). An aliquot (0.1 ml) of this suspension is used to inoculate each 5.0 ml of medium (with and without biotin). The cultures are incubated for 48 h at the optimal temperature for the species. In cases where growth occurs in the absence of biotin, a second serial transfer is made to media with and without biotin, using 0.1 ml

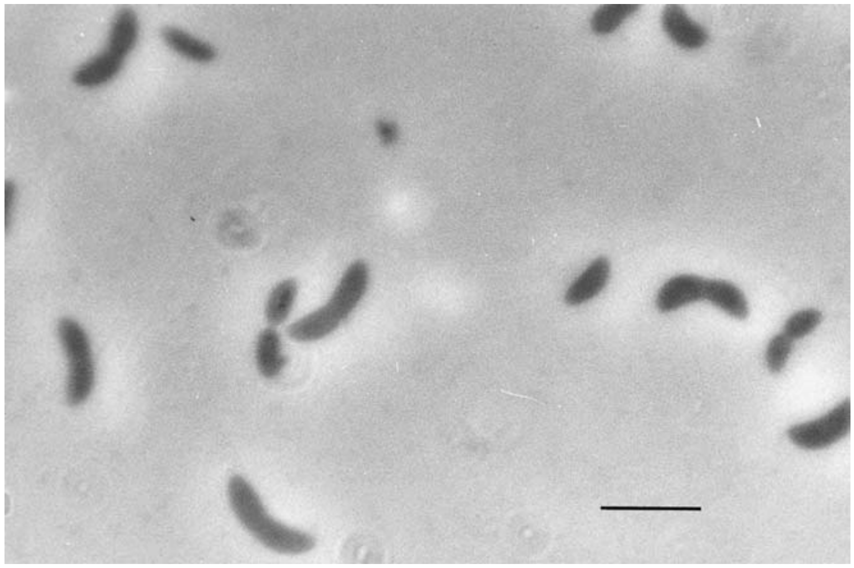

FIGURE BXII.α.10. *Azospirillum brasilense* ATCC 29145 cultured in MPSS broth at 37°C for 24 h. Phase-contrast microscopy. Bar = 5 μm.

from the first culture. This procedure may be repeated at least ten times to make sure that strains are not dependent on biotin.

Development of pleomorphic cells A loopful of growth from a 24 h-old MPSS broth culture is inoculated into a tube of semi-solid, nitrogen-free, malate medium (containing 0.05 g/l yeast extract or 0.0001 g/l biotin). The cultures are examined by phase-contrast microscopy after incubation at 37°C for 24–48 h (Fig. BXII.α.10). *A. brasilense* and *A. amazonense* remain mainly vibrioid and motile, whereas *A. lipoferum* becomes wider, longer, nonmotile, and S-shaped or helical. These forms of *A. lipoferum* eventually undergo fragmentation into shorter, ovoid cells, many of which become very large and pleomorphic and are filled with refractile granules. *A. halopraeferens* strains also develop wider, longer and S-shaped cells, which seldom exceed a length of 5 μm. In some cases, very long cells are also observed. Cells of *A. irakense* grown in complete nutrient broth medium are much longer and reach a size of up to 30 μm. *A. largimobile* cells lose motility and form multicellular conglomerates that become optically refractile and reproduce by multi-planar septation. *A. doebereinerae* strains remain motile after growth overnight in liquid medium, but the cells become long and pleomorphic after prolonged growth in semisolid N-free NFb medium.

Auxanographic method for sole carbon sources The following ingredients are dissolved in 50 ml of distilled water passed through a Bantam multibed resin cartridge (Barnstead Co., Boston, MA): $(NH_4)_2SO_4$, 1.0 g; $MgSO_4 \cdot 7H_2O$, 1.0 g; K_2HPO_4, 2.0 g; $FeCl_3 \cdot 6H_2O$, 0.0047 g; $MnSO_4 \cdot H_2O$, 0.0025 g; $ZnSO_4 \cdot 7H_2O$, 0.00072 g; $CuSO_4 \cdot 5H_2O$, 0.000125 g; $CoSO_4 \cdot 7H_2O$, 0.00014 g; H_3BO_3, 0.000031 g; and $Na_2MoO_4 \cdot 2H_2O$, 0.000245 g. The pH is adjusted to 2.5 with HCl to dissolve precipitates and then adjusted to 7.0 with KOH. Biotin (0.0001 g) and $CaCO_3$ (0.001 g) are added and the medium is sterilized by autoclaving. The sterile medium is added aseptically to an equal volume of sterile agar solution (15.0 g purified agar (Difco) in 500 ml of distilled water, sterilized by autoclaving) at 45–50°C. Cells are prepared as for the determination of biotin requirement (previous paragraph) except that the final suspension is adjusted to 30 Klett units instead of 20. Two ml of the cell suspensions are used to spread 20 ml of molten medium at 45–50°C in a Petri dish. After solidification of the medium, sterile 7-mm diameter paper discs (punched from Beckman electrophoresis filter paper, Cat. No. 319328) are dipped into 5% (w/v) aqueous solutions of carbon sources sterilized by filtration. (Solutions of organic acids are adjusted to pH 7.0 with KOH before sterilization.) The saturated discs are then placed near the periphery of the seeded agar plates (3 discs/plate). The plates are incubated at 37°C for 72 h. Any visible zone of turbidity around the discs, as judged by holding the plates against a black background and illuminating them with oblique lighting from the rear, constitutes a positive growth response. New kits for testing these properties are now available on the market (i.e., Biolog, API galleries) and the instructions from the manufacturers should be followed.

Acidification of peptone-based D-glucose medium The following medium is used (g/l): peptone (Difco), 2.0; $MgSO_4 \cdot 7H_2O$, 1.0; $(NH_4)_2SO_4$, 1.0; $FeCl_3 \cdot 6H_2O$, 0.002; $MnSO_4 \cdot H_2O$, 0.002; bromothymol blue (dissolved in dilute KOH), 0.025. The medium is made up to a volume of 950 ml, adjusted to pH 7.0 and sterilized by autoclaving. After it has cooled, 50 ml of a 20% (w/v) solution of D-glucose (sterilized by filtration) is added aseptically. The development of a yellow color during incubation for 96 h at 37°C indicates acidification.

Fermentative ability Tubes of peptone–D-glucose or D-fructose media, or defined D-glucose or D-fructose broth (Tarrand et al., 1978), are inoculated and placed in GasPak jars (BBL) containing a fresh catalyst. The jars are evacuated, filled once with N_2 and three times with H_2, sealed and incubated at 37°C for up to 2 weeks. Development of a yellow color indicates acidification. Slight growth in the form of a sediment can be detected by agitating the tubes.

Test for autotrophic growth (Málek and Schlegel, 1981) A mineral medium having the following composition (per liter) is used: KH_2PO_4, 2.3 g; $Na_2HPO_4 \cdot 2H_2O$, 2.9 g; NH_4Cl, 1.0 g; $MgSO_4 \cdot 7H_2O$, 0.5 g; $CaCl_2 \cdot 2H_2O$, 0.01 g; ferric ammonium cit-

rate, 0.05 g; and trace element solution[8], 6.0 ml. When necessary, the medium is supplemented with the appropriate growth factors. For testing in liquid culture, 20-ml portions of the medium are distributed into 100- or 250-ml Erlenmeyer flasks. After inoculation, the flasks are placed in desiccator jars or anaerobic jars. The jars are then evacuated and filled with the following gas mixture: $O_2/CO_2/H_2/N_2$ (2:10:60:28). The jars are incubated at 30–37°C with shaking and are periodically evacuated and refilled with fresh gas mixture. For testing growth on agar plates, the mineral medium is solidified with 1.5% agar.

Oligonucleotide probes Probes complementary to a highly variable stretch of helix 55–59 of the 23S rRNA were designed and are available for five species of *Azospirillum* (Kirchhof et al., 1997b). Oligonucleotide probes based on partial 16S rRNA gene sequences have also been designed by Kabir et al. (1995) and were species specific for *A. lipoferum* and *A. amazonense*; another probe recognized both *A. brasilense* and *A. amazonense*. The sequences and dissociation temperatures (°C) of probes used for phylogenetic studies of azospirilla are shown in Table BXII.α.3. Bulk nucleic acids are isolated from strains that were cultivated overnight in nutrient broth or DYGS liquid medium (g/l: dextrose, 2.0; peptone, 1.5; yeast extract, 2.0; K_2HPO_4, 0.5; $MgSO_4$, 0.5; L-glutamic acid 1.5; pH adjusted to 6–6.5), and transferred to a positively charged nylon membrane via spot blotting. Hybridization with radioactive or nonradioactive DIG-labeled probes is performed for 2–12 h (radioactive) or 16 h (nonradioactive) according to the method of Kirchhof et al. (1997a). Signals are detected by autoradiography. Most recently, a comprehensive set of whole-cell-binding 16S rRNA-targeted oligonucleotide probes was developed at genus and species level for all species of the *Azospirillum* cluster (Stoffels et al., 2001). Using fluorescently labeled diagnostic oligonucleotide probes, direct species identification of single cells, as well as *in situ* localization studies, is possible.

Differentiation of the genus *Azospirillum* from other genera

Table BXII.α.4 indicates the characteristics of *Azospirillum* that distinguish it from other diazotrophic bacteria belonging to the *Alphaproteobacteria*.

8. Trace element solution SL-6 (Pfennig, 1974) contains (g/l of distilled water): $ZnSO_4 \cdot 7H_2O$, 0.1; $MnCl_2 \cdot 4H_2O$, 0.03; H_3BO_3, 0.3; $CoCl_2 \cdot 5H_2O$, 0.2; $CuCl_2 \cdot 2H_2O$, 0.01; $NiCl_2 \cdot 6H_2O$, 0.02; and $Na_2MoO_4 \cdot 2H_2O$, 0.03.

Taxonomic Comments

In 1921–1922, Beijerinck observed extensive development of a spirillum-like bacterium in nitrogen-deficient D-glucose and mannitol solutions that had been inoculated heavily with garden soil or soil from a sand bed. Although the organism grew well at first, it was later displaced by competitive growth of *Azotobacter* and *Clostridium*. However, when calcium malate or lactate was employed as the carbon source instead of the carbohydrates, the organism grew well and was not overgrown by other nitrogen fixers. Beijerinck found that partially purified cultures of the spirillum exhibited increases in nitrogen at the expense of malate, whereas cultures lacking the spirillum failed to show such increases. Pure cultures of the spirillum failed to grow in the absence of a source of fixed nitrogen, and Beijerinck suggested that good growth in partially purified cultures might be attributable to the microaerophilic nature of the spirillum, as suggested by microaerotactic band formation in wet mounts. In general, cells cultured in sugar media were plump, curved rods containing many lipoidal droplets, which sometimes distorted the shape of the cells. On malate or lactate agar, the cells tended to be thinner and straighter, while in dilute bouillon they exhibited a distinct spirillum shape with one or more helical turns. Because of the ease of cultivation on salts of organic acids, as well as the spirillum shape exhibited under certain conditions, Beijerinck considered the organism to be a member of the genus *Spirillum* and to be a bridging organism linking the genus *Spirillum* with the genus *Azotobacter*. He initially named the organism *A. largimobile*, but later renamed it *Spirillum lipoferum* (Beijerinck, 1925). Later studies of *Spirillum lipoferum* by Schröder (1932) also failed to demonstrate N_2 fixation by pure cultures, and the organism was forgotten for many years except for a few scattered reports. However, in 1963 Becking isolated an organism resembling *Spirillum lipoferum* that showed uncontestable nitrogenase activity. Finally, the discovery of the association of such organisms with plant roots (Döbereiner and Day, 1976) caused much interest in *Spirillum lipoferum* and led to detailed taxonomic studies. Tarrand et al. (1978) reserved Beijerinck's specific epithet *lipoferum* for their DNA homology group II (i.e., *A. lipoferum*), because this group seemed to correspond in more ways to Beijerinck's description of *Spirillum lipoferum*, particularly with regard to growth with glucose or mannitol and to formation of spirillum-shaped cells under certain conditions. Since Beijerinck's strains no longer exist, however, their correspondence with homology group II cannot be estimated with certainty.

Analysis of rRNA cistrons indicates that the genus *Azospirillum*

TABLE BXII.α.3. Oligonucleotide sequence probes used for phylogenetic studies of *Azospirillum* species [a]

[a]Symbols: +, typically positive; −, typically negative; ±, differ among strains; D, differs among species; MP, monopolar single flagellum; BT, bipolar tuft; BS, bipolar single flagellum; PT, peritrichous; L, lateral flagella.

[b]*Beijerinckia* may be straight, slightly curved, or pear shaped.

[c]A few helical cells can be observed in *A. halopraeferens*.

[d]Motility depends on the growth conditions (substrate and age).

belongs to the α-subclass of *Proteobacteria* (De Ley, 1992). This subclass, proposed by Woese et al. (1984b), corresponds to the rRNA superfamily IV described by De Ley (1978) and De Smedt et al. (1980). The majority of the nitrogen-fixing bacteria occur as six major groups within the α subclass, with three of them containing most of the known diazotrophic bacteria. The first cluster exhibits 75°C $T_{m(e)}$ and includes the endophytic diazotroph *Gluconacetobacter diazotrophicus* (Yamada et al., 1998a) (formerly *Acetobacter diazotrophicus*) and the first nitrogen-fixing bacterium from the genus *Gluconacetobacter* described (Gillis et al., 1989). The second cluster is formed by *Zymomonas*, *Rhizomonas*, and *Sphingomonas*. A nitrogen-fixing bacterium isolated from rice plants has been identified as *Pseudomonas paucimobilis* (Bally et al., 1983) and is linked to the *Sphingomonas paucimobilis* rRNA branch at $T_{m(e)}$ of 76°C (Gillis and Reinhold-Hurek, 1994). The third cluster comprises the nitrogen-fixing bacteria of the genus *Rhizobium*, *Sinorhizobium*, and *Mesorhizobium*, which are linked at $T_{m(e)}$ of 74.4°C to other non-nitrogen-fixing bacteria of the class. A small cluster is formed by the genera *Rhodobacter* and *Paracoccus* and is linked to the rRNA branch at $T_{m(e)}$ of 67°C. In this cluster the diazotrophic species *Rhodobacter capsulatus* is found. The last two clusters are formed by diazotrophic bacteria that are linked to the main rRNA branch of this class at very similar $T_{m(e)}$ values. The first cluster is formed by *Bradyrhizobium*, *Azorhizobium*, *Beijerinckia*, and *Xanthobacter* in addition to *Rhodopseudomonas*, and is linked to the rRNA branch at 70.4°C $T_{m(e)}$, while the last one—formed by *Azospirillum*, *Rhodospirillum*, *Aquaspirillum peregrinum*, and *Magnetospirillum magnetotacticum*—links at 71°C $T_{m(e)}$. Because the last cluster contains the taxa most closely related to *Azospirillum*, their phenotypic and genetic characteristics should be compared with those of the genus *Azospirillum*.

Aquaspirillum peregrinum exhibits phenotypic characters in common with *Azospirillum*: shows nitrogenase activity under microaerophilic conditions; has cell diameter quite similar to that of some *Azospirillum* species but differs from the latter by having helical cells with flagella in bipolar tufts; a mol% G + C of 60–64; an aquatic habitat rather than an association with plants. A relationship between *Azospirillum* and *Rhodospirillum* is indicated by the 16S rRNA cistron analysis where both genera are linked at 71°C $T_{m(e)}$ within the *Alphaproteobacteria*. Certain phenotypic similarities are also shared specially by the species *A. lipoferum* and *R. rubrum*. The most striking similarity concerns the activation factor for the Fe protein of nitrogenase. This factor has so far been found only in *Azospirillum* and *Rhodospirillum* (Ludden et al., 1978). It is also required for activation of the Fe protein of *A. brasilense* but not for that of *A. amazonense* (Döbereiner and Pedrosa, 1987). *A. lipoferum* and *R. rubrum* share a growth requirement for biotin. Both *Azospirillum* and *R. rubrum* form a pink or red pigment when grown in the dark under aerobic conditions and form intracellular poly-β-hydroxybutyrate. Despite these similarities, there are some significant differences between the two species. *Azospirillum* is not phototrophic, moreover, *R. rubrum* possesses bipolar tufts of flagella and has cells that are thinner and more helical than those of *Azospirillum*. The mol% G + C of the DNA of *R. rubrum* is 64–66, in contrast to the value of 69–70 for *Azospirillum lipoferum*. The complete 16S rRNA gene sequence of all six *Azospirillum* species has shown that *A. amazonense* and *A. irakense* form a subcluster with *Rhodocista centenaria* (basonym *Rhodospirillum centenum*) (Ben Dekhil et al., 1997a). This *Rhodospirillum* species is also a nitrogen-fixing, nonsulfur, purple phototrophic bacterium, accumulates poly-β-hydroxybutyrate, and has a mol% G + C of the DNA of 68.3, very close to that of *A. amazonense* (67–68); however, it has the ability to form cytoplasmic "R" bodies (Favinger et al., 1989), a characteristic not present in *Azospirillum*.

The species *Magnetospirillum magnetotacticum* (formerly *Aquaspirillum magnetotacticum*), and members of the phototrophic genus *Rhodospirillum* are the nearest relatives of the genus *Azospirillum*, based on 16S rRNA gene sequence analysis (Xia et al., 1994; Ben Dekhil et al., 1997a). Cells from *M. magnetotacticum* are obligately microaerophilic, accumulate poly-β-hydroxybutyrate, fix nitrogen only under microaerophilic conditions, and have a mol% G + C of the DNA of 65 that is in the same range as that of *Azospirillum* (64–71). However, the smaller cell size, type of flagellation, and formation of coccoid bodies 3–4 weeks after growth, as well as the occurrence of magnetite-containing "magnetosomes", excludes it from the genus *Azospirillum*.

The nitrogen fixer *Azorhizobium caulinodans* resembles *Azospirillum* in being a free-living, obligately aerobic, small rod that fixes N_2 microaerobically, as well as being a plant-associated dia-

zotroph. However, the host–bacterium interaction (stem nodule formation) is far more highly specialized than that of *Azospirillum* for symbiotic nitrogen fixation. In addition, *Azorhizobium caulinodans* forms a main cluster with *Xanthobacter autotrophicus*, *Beijerinckia*, and *Bradyrhizobium* which links at 70.4°C $T_{m(e)}$ to the root of the *Alphaproteobacteria*; *Azospirillum* links at 71°C $T_{m(e)}$.

Xanthobacter autotrophicus resembles some species of *Azospirillum* in being a microaerophilic nitrogen fixer, having an association with rice plants, and having a mol% G + C of the DNA (65–70) that is similar to that of *Azospirillum*. However, the cells differ by being smaller (and under certain conditions exhibiting branching), nonmotile, and forming a yellow pigment.

The genus *Beijerinckia* lies within the same *Alphaproteobacteria* group and forms a subcluster together with *Bradyrhizobium*, *Azorhizobium*, and *Xanthobacter* which links to the main RNA branch at 71°C $T_{m(e)}$, according to the rRNA cistron dendrogram for this class (De Ley, 1992). Although *Beijerinckia* cells are straight or slightly curved rods with a diameter similar to that of *Azospirillum*, other characteristics such as the ability to fix nitrogen aerobically, occurrence as a free-living bacterium in soil, and low mol% G + C values (55–61) prevent the inclusion of this genus in *Azospirillum*. Nevertheless, the *Azospirillum largimobile* conglomerate cells show a striking resemblance to cells of *Beijerinckia* species.

By DNA–DNA hybridization, *A. brasilense* strains exhibit a continuum of similarity values with the type strain, ranging from ~70 to 100%. Within the species *A. lipoferum*, strains exhibit similarity values of 70–76% with the type strain. In the case of *A. amazonense*, similarity values range from 56 to 100% with the type strain. A DNA–DNA homology value of 100% was observed for hybridization of one strain of *A. halopraeferens* with the type strain. Within the species *A. irakense*, strains exhibited similarity values of 71–97% with the type strain. For *A. largimobile*, the similarity value was 65% (one isolate) with the type strain.

From DNA–DNA hybridization studies using a membrane-filter competition method, *A. lipoferum* and *A. brasilense* initially were reported to exhibit similarity values of 31–34% (Tarrand et al., 1978). Use of the S1 nuclease method, however, indicated that *A. lipoferum* ATCC 29707 and *A. brasilense* ATCC 29145 exhibited lower similarity values (14–17%) to each other (Falk et al., 1985). A much lower degree of similarity (2–6%) was observed when both species were hybridized against *Azospirillum amazonense* ATCC 35119 (Falk et al., 1985). In the case of *Azospirillum halopraeferens* (LMG 7108), a similarity value of <25% was observed between the three species (Reinhold et al., 1987). A low degree of similarity (4–11%) was also exhibited by the type strain of *Azospirillum irakense* (CIP 103311) to the four above-mentioned species (Khammas et al., 1989). The recently described *Azospirillum largimobile*—formerly *Conglomeromonas largomobilis*—exhibited a very low degree of similarity to *A. amazonense* (5–7%) and *A. brasilense* (13–14%) (Falk et al., 1986); however, it showed a high level of similarity (40–47%) to *Azospirillum lipoferum*. Because of this similarity and other morphological characteristics, Falk et al. (1986) considered strains from this group as belonging to *Azospirillum lipoferum*. Based on the binary sequence similarity values of 16S rRNA genes, Ben Dekhil et al. (1997a) demonstrated that this new species shared 97.1% similarity with *A. lipoferum* but much less with *A. brasilense* (95.2%) and *A. amazonense* (91.7%). Although this difference is small, the authors proposed *A. largimobile* as a new species based on the DNA hybridization data.

An analysis based on the similarity values of the 16S rRNA genes of *Azospirillum* species versus the type species *A. lipoferum* indicates the occurrence of two subgroups within the genus. One includes *A. lipoferum*, *A. brasilense*, *A. halopraeferens*, *A. doebereinerae*, and *A. largimobile*; the other includes *A. amazonense* and *A. irakense* (Ben Dekhil et al., 1997a). In addition, this study showed that *A. brasilense* is most closely related to *A. lipoferum*, followed by *A. halopraeferens* and *A. largimobile*. Fani et al. (1995b) also have observed that *A. lipoferum* and *A. brasilense* are very closely related species, whereas *A. amazonense* was the most divergent. Xia et al. (1994) showed that all type strains of *Azospirillum* formed a deep-branching clade within the *Alphaproteobacteria* when the 16S rDNA sequences were compared. The most recent comprehensive 16S rDNA sequence study of Stoffels et al. (2001) also confirmed a high degree of relatedness among *Azospirillum* species and that they form a cohesive phylogenetic cluster within the *Alphaproteobacteria*. A strain-specific molecular identification of *Azospirillum* strains is possible using RFLP analysis of the whole genome using rarely cutting restriction nucleases and pulsed-field gel electrophoresis (Gündisch et al., 1993).

Acknowledgments

This chapter is dedicated to the memory of the late Dr. Johanna Döbereiner, the Brazilian soil microbiologist, who, during a long and distinguished career, identified and characterized many novel nitrogen-fixing bacteria.

List of species of the genus Azospirillum

1. **Azospirillum lipoferum** (Beijerinck 1925) Tarrand, Krieg and Döbereiner 1979, 79[AL] (Effective publication: Tarrand, Krieg and Döbereiner 1978, 978 (*Spirillum lipoferum* Beijerinck 1925, 353.)
li.po′ fe.rum. Gr. n. *lipus* fat; L. v. *fero* to carry; M.L. adj. *lipoferus* fat bearing.

The characteristics are as described in Tables BXII.α.4, BXII.α.5, and BXII.α.6. The morphological characteristics are depicted in Figs. BXII.α.4 and BXII.α.5. The characteristic pleomorphism seen in malate medium does not occur in D-glucose medium. Cells of certain strains become much thinner and very long in malate medium. Use of D-glucose as the sole carbon source for nitrogen-fixation-dependent growth is more efficient at pH 5.5–6.5 than at pH 7.0–7.5.

All strains stain uniformly Gram negative when cultured in MPSS broth. Most strains stain uniformly Gram negative when cultured for 48–72 h on MPSS agar but a few strains exhibit a small proportion of cells that are resistant to Gram decolorization.

Colonies are not slimy on BMS agar. When 0.5% D-glucose is added to the medium, some strains form large, slimy, white colonies. Star-shaped colonies have also been observed for some strains grown on BMS agar plates (Fig. BXII.α.11).

Aerobic growth in liquid media containing a source of fixed nitrogen often shows extensive clumping, particularly in defined media. No growth occurs anaerobically in the absence of a source of fixed nitrogen. However, nitrogen fixation can be observed in liquid medium containing glutamate when the cells reach an optical density of approximately 1.0 and all available nitrogen is consumed.

Strains of *A. lipoferum* that are able to grow lithoautotrophically with H_2 contain an uptake hydrogenase as well as RubPcase. They can be categorized as aerobic hydrogen-oxidizing bacteria.

Physiological and nutritional characteristics of the species are presented in Tables BXII.α.5 and BXII.α.6. Variants with decreased fermentative ability may arise but continue to require biotin, use D-glucose as a sole carbon source for N_2-dependent growth, and exhibit the characteristic pleomorphism associated with this species in malate medium.

Strains of this species have been found colonizing several plants including cereals, forage grasses, vegetables, legumes, and the fruits of banana and pineapple plants.

The mol% G + C of the DNA is: 69–70 (T_m).

Type strain: BR11080, Sp 59b, ATCC 29707, DSM 1691.

GenBank accession number (16S rRNA): M59061.

Additional Remarks: Reference strains: ATCC 29708 (BR11115; Sp Rg 20a), ATCC 29709 (BR11084; Sp Br 17), ATCC 29731 (BR11087; Sp Rg 6xx). The accession numbers of the 16S rDNA sequences from reference strains ATCC 29708 and ATCC 29731 deposited at the EMBL are X79729 and X79730, respectively (Fani et al., 1995a). Other 16S sequences from WO3 and NCIMB 11861 have received the accession numbers X79741 (Fani et al., 1995a) and Z29619 (Xia et al., 1994), respectively.

2. **Azospirillum amazonense** Magalhães, Baldani, Souto, Kuykendall and Döbereiner 1984, 355[VP] (Effective publication: Magalhães, Baldani, Souto, Kuykendall and Döbereiner 1983, 417.)

am.a.zo.nen′se. M.L. adj. *amazonense* pertaining to the Amazon region of Brazil, South America.

The characteristics are as described in Tables BXII.α.4, BXII.α.5, and BXII.α.6, with the following additional features. Colonies on potato agar medium (BMS) containing malate plus sucrose as sole carbon source are 0.5 cm in diameter and are flat with elevated borders. The colonies become bigger and flat with well-delineated borders when both carbon sources are replaced by D-glucose (Fig. BXII.α.12) and become smaller, wet, and smooth when sucrose is omitted from the BMS medium (Fig. BXII.α.12), indicating the sensitivity of this species to alkaline conditions. This is also the reason why only a scant pellicle formation is observed in semi-solid NFb medium containing malate but not with sucrose as carbon source. The structure of the colonies on BMS plates tends to disappear after a long period of incubation. Very dry, white colonies with well-delineated borders are also observed on BMS plates containing sucrose as sole carbon source. Cells remain vibrioid in semi-solid LGI medium with spinning movement. However, long periods of incubation in semi-solid LGI medium allow formation of conglomerate cells similar to cysts observed for *A. lipoferum*. This may be due to the dryness of the medium.

Significant amounts of PHB granules are observed under N_2 growth conditions but much less in the presence of NH_4^+. Nitrogenase activity is more sensitive than in *A. lipoferum* and *A. brasilense*, and *A. amazonense* has a doubling time of 10 hours, in contrast to 5–6 h for *A. lipoferum* and *A. brasilense* at low pO_2.

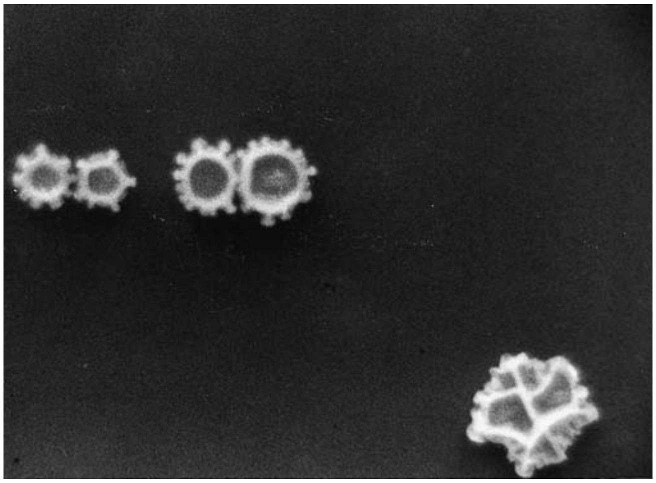

FIGURE BXII.α.11. Colonies of *Azospirillum lipoferum* grown on BMS agar plate for 48 h at 30°C showing starlike forms.

Good aerobic growth occurs in liquid LGI medium containing KNO_3 as nitrogen source but not with NH_4Cl. There is no clumping and the pH remains around 6.0. No growth occurs aerobically in the absence of a source of fixed nitrogen, as observed for the other species. However, nitrogen fixation can be observed in liquid medium containing glutamate when the cells reach optical density around 1.0 and all available nitrogen is consumed.

Fatty acid analysis showed higher amounts of $C_{16:0}$ as compared to the $C_{18:1}$ nonhydroxy fatty acids. This species has been isolated from roots of maize, sorghum, rice and wheat plants, as well as forage grasses grown around Brazil. It was also isolated from roots and stems of sugarcane plants grown in Brazil and from sugarcane roots grown in Hawaii and Thailand. It was also found associated with roots of palm trees from the Amazon region and more recently from pineapple and banana fruits. The root interior of rice, sorghum, and maize was predominantly colonized by *A. amazonense* strains that do not accumulate nitrite rather than those that produce considerable amounts of nitrite, which afterwards is reassimilated.

The mol% G + C of the DNA is: 67–68 (T_m).

Type strain: BR 11142, Am14, Y1, ATCC 35 119, DSM 2787.

GenBank accession number (16S rRNA): Z29616, X79735.

Additional Remarks: Reference strains: ATCC 35120 (BR 11140; Am18; Y2); ATCC 35121 (BR 11141; Am30; Y6). The accession number for the reference strain ATCC 35120 is X79742 (Fani et al., 1995a).

3. **Azospirillum brasilense** Tarrand, Krieg and Döbereiner 1979, 79[AL] (Effective publication: Tarrand, Krieg and Döbereiner 1978, 979.)
bra.si.len′.se. M.L. adj. *brasilense* pertaining to the country of Brazil, South America.

The characteristics are as described for the genus and as given in Tables BXII.α.4, BXII.α.5, and BXII.α.6, with the following additional features. In semisolid, nitrogen-free, malate medium cells remain mainly vibrioid even when the cultures become alkaline, in contrast to the cells of *A. lipoferum*, *A. irakense*, *A. halopraeferens*, and *A. largimobile*. Some encapsulated (C) forms (Fig. BXII.α.6) may occur, especially in older cultures. C forms occur in abundance in colonies grown on the surface of nitrogen-free media, in association with plant callus cultures, in grass seedlings inoculated with this species, or under stress conditions. Flocculated cells of *A. brasilense* strain Cd grown under conditions of stress accumulate up to 60–65% of total dry weight as PHB.

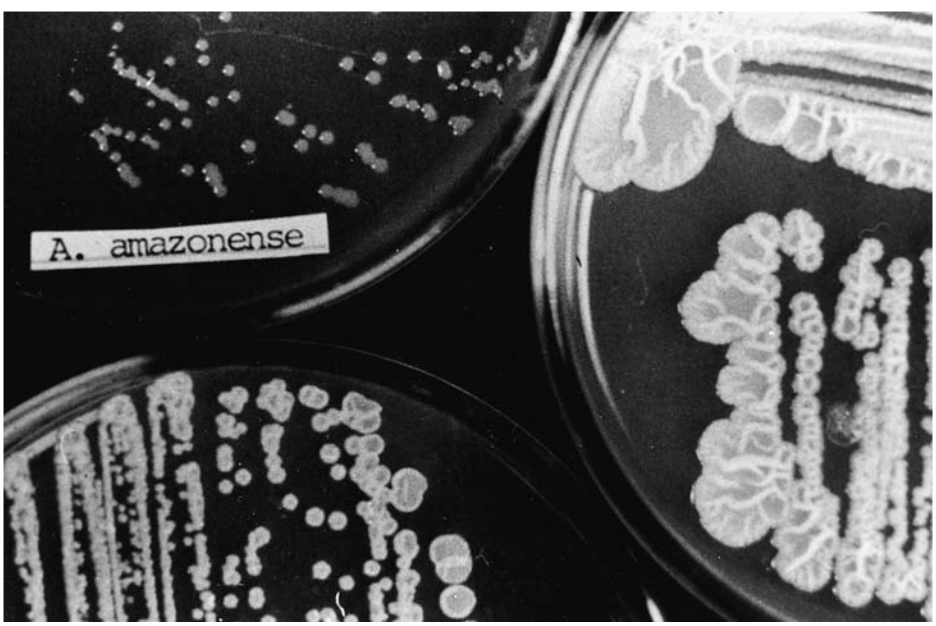

FIGURE BXII.α.12. Colonies of *Azospirillum amazonense* strain ATCC 35119 grown on BMS agar plates containing only malate (*upper left*), malate plus sucrose (*lower left*), or only glucose (*right*) as carbon source for 48 h at 30°C. (Reproduced with permission from J. Döbereiner et al., Brasilia: Embrapa-SPI: Itaguai, RJ: Embrapa-CNPAB, 1995.)

All strains stain uniformly Gram negative when cultured in MPSS broth. Most strains exhibit a small proportion of cells showing resistance to Gram decolorization when cultured on MPSS agar for 48–72 h; this Gram variability may be related to the occurrence of encapsulated forms.

Certain strains and variants of *A. brasilense* form colonies that have a much deeper shade of pink than is usually the case. Carotenoid content has been identified as responsible for the observed characteristic in strain Cd.

Aerobic growth in liquid media containing a source of fixed nitrogen is usually homogeneous and turbid, without clumping. No growth occurs aerobically in the absence of a source of fixed nitrogen. Cells are able to fix nitrogen in liquid aerated medium when pre-grown in the presence of glutamate, up to an optical density around 1.0, and no inorganic nitrogen is available. Strains of this species have been found colonizing several plants including cereals, forage grasses, vegetables, legumes, and banana plants.

The mol% G + C of the DNA is: 70–71 (T_m).

Type strain: BR11001, Sp 7, ATCC 29145, DSM 1690.

GenBank accession number (16S rRNA): X79739.

Additional Remarks: Reference strains: ATCC 29710 (BR11002; Cd); ATCC 29711 (Sp 35). The accession number is Z29617 (Xia et al., 1994) for strain NCIMB 11860.

4. **Azospirillum doebereinerae** Eckert, Weber, Kirchhof, Halbritter, Stoffels and Hartmann 2001, 24[VP]
doeb′er.ein.er.ae. N.L. gen. fem. n. *doebereinerae* of Döbereiner, in honor of Johanna Döbereiner, who isolated and characterized many *Azospirillum* spp., and other diazotrophic plant-associated bacteria.

The characteristics are as described for the genus and as given in Tables BXII.α.4, BXII.α.5, and BXII.α.6, with the following additional features. Cells are Gram negative, oxidase, catalase, and urease positive, curved rods or S shaped. Long cells are observed, especially in alkaline, semi-solid, NFb medium and motile with a winding or snake-like movement. Optimal growth and nitrogen fixation occur in semi-solid NFb medium at 30°C and pH adjusted to 6.5. Production of poly-β-hydroxybutyrate is also observed. No growth or nitrogen fixation occurs in liquid NFb medium. So far, it has been isolated only from the root of *Miscanthus sinensis* cv. "Giganteus" and *Miscanthus sacchariflorus* and also in the rhizosphere soil of these plants grown in Freising, Germany.

The mol% G + C of the DNA is: 70.7 (T_m).

Type strain: GSF71, DSM 13131.

GenBank accession number (16S rRNA): AJ238567.

5. **Azospirillum halopraeferens** Reinhold, Hurek, Fendrik, Pot, Gillis, Kersters, Thielmans and De Ley 1987, 48[VP]
ha.lo.prae′fe.rens. Gr. n. *hals* salt, the sea L. v. *praeferre* to prefer; M.L. part. adj. *halopraeferens* salt preferring.

The characteristics are as described for the genus and as given in Tables BXII.α.4, BXII.α.5, and BXII.α.6, with the following additional features. Cells are Gram negative, oxidase, and urease positive, vibrioid to S shaped. A few long, helical cells are observed in older, more alkaline medium. Cells are motile in liquid media with rapid corkscrew-like motion. Optimal growth and nitrogen fixation occur in semi-solid SM medium containing 0.25% NaCl at 41°C and pH adjusted to 7.2. Strains are able to grow with 3% NaCl but no nitrogenase activity is observed. No colonies are formed in BMS or Congo Red medium. Good growth is observed in tryptic soy agar where the colonies are cream-colored, circular and flat with an entire margin.

Production of poly-β-hydroxybutyrate is also observed. No growth or nitrogen fixation occurs in liquid SM medium.

Strains of this species show higher osmotolerance than *A. lipoferum*, *A. brasilense*, *A. amazonense*, *A. doebereinerae*, and *A. largimobile*. Growth and nitrogen fixation is stimulated by glycine betaine, as found in *A. brasilense* but not in *A. amazonense* or *A. lipoferum*.

This species seems to have a very restricted habitat. So far, it has been isolated only from the root surface of Kallar grass (*Leptochloa fusca*) grown in saline-sodic soils in Punjab, Pakistan. Attempts to isolate this species from various plants grown in saline-affected soils around Brazil have been unsuccessful.

The mol% G + C of the DNA is: 69–70 (T_m).

Type strain: Au 4, DSM 3675, LMG 7108.

GenBank accession number (16S rRNA): Z29618, X79731.

6. **Azospirillum irakense** Khammas, Ageron, Grimont and Kaiser 1991, 580[VP] (Effective publication: Khammas, Ageron, Grimont and Kaiser 1989, 688.)
i.ra.ken′se. L. neut. adj. *irakense* pertaining to the country of Iraq.

The characteristics are as described for the genus and as given in Tables BXII.α.4, BXII.α.5, and BXII.α.6, with the following additional features. The morphological characteristics of the cells in nutrient broth are shown in Fig. BXII.α.7. The cells are Gram-negative, oxidase and catalase positive, curved, vibrioid to S-shaped rods and can reach a length of 30 μm when grown in nutrient broth. Cells are motile with winding or snake-like movements by a single polar flagellum. Colonies are translucent, glistening, convex with regular margin, 1 mm in diameter after 4 d on NFb medium containing yeast extract (20 mg/l) or on AAM agar medium. On tryptic soy agar, colonies are translucent with an opaque center, convex with regular margin, and 3 mm in diameter after 4 d.

Nitrogen fixation occurs only under microaerobic conditions and cells grow well under air atmosphere in the presence of a nitrogen source such as an ammonium salt. Intracellular granules (PHB) are observed.

The physiological and nutritional characteristics are presented in Tables BXII.α.5 and BXII.α.6. Growth occurs in the presence of up to 3% NaCl, but acetylene reduction is optimal when the NaCl concentration is less than 0.01%. All strains hydrolyze esculin and pectin but not hydroxyquinoline-β-glucuronide. Pectin can support growth and nitrogen fixation could be detected in modified, semisolid, AAM medium after 5–11 days of incubation provided that a small amount of fixed nitrogen as starter is present (Khammas and Kaiser, 1991). The species so far has only been isolated from rhizosphere soil and roots of rice plants grown in the region of Diwaniyah in Iraq.

The mol% G + C of the DNA is: 64–67 (T_m).

Type strain: KBC1, CIP 103311, DSM 11586.

GenBank accession number (16S rRNA): Z29583, X 79737.

7. **Azospirillum largimobile** (Skerman, Sly and Williamson 1983) Ben Dekhil, Cahill, Stackebrandt and Sly 1997b, 915[VP] (Effective publication: Ben Dekhil, Cahill, Stacke-

brandt and Sly 1997a, 74) (*Conglomeromonas largomobilis* subsp. *largomobilis* Skerman, Sly and Williamson 1983, 300.) *lar.gi.mo' bi.le.* L. adj. *largus* a very slow manner (musical); L. v. *mobile* to move; M.L. adj. *largimobile* moving in a very slow manner.

The characteristics are as described for the genus and as given in Tables BXII.α.4, BXII.α.5, and BXII.α.6, with the following additional features. Strains of this species are Gram negative, oxidase, urease, and aminopeptidase positive, and are weakly positive for catalase and phosphatase. Strains exhibit two phases of growth—unicellular and multicellular. Cells are rod shaped with round or tapered ends and a straight or slightly curved axis in the unicellular phase. Motile cells have mixed flagellation. Multicellular conglomerates are formed, with the cells losing motility under unfavorable conditions. The conglomerate dissociates into single motile cells under suitable conditions, forming clear colonies on agar medium. Colonies on lake water agar become buff colored, opaque, low convex, and round with an entire edge and smooth surface after 72 h at 28°C. No encapsulated cells are observed.

N_2 fixation and acetylene reduction were observed only under microaerophilic conditions in semi-solid, nitrogen-free, malate medium with biotin. No nitrogen fixation was detected under aerobic conditions in the presence or absence of a nitrogen source such as ammonium salt.

Other physiological and nutritional characteristics are shown in Tables BXII.α.5 and BXII.α.6. Most of these characteristics of *A. largimobile* are similar to those of *A. lipoferum*, except for acid production from salicin and D-xylose, which is only present in the latter. In addition, *A. largimobile* is DNase positive and shows clearing of egg yolk agar. Strains are able to grow (slowly) in the presence of 2% NaCl. This species is composed of only two strains isolated from fresh lake water in Australia.

The mol% G + C of the DNA is: 69.6–70.8 (T_m).

Type strain: ACM 2041, DSM 9441, UQM 2041.

GenBank accession number (16S rRNA): X90759.

Other Organisms

A noncellulolytic bacterium (strain Mc-2s) having the characteristics of the genus *Azospirillum* was isolated from cellulolytic, nitrogen-fixing, mixed cultures by Wong et al. (1980a). The strain exhibited a biotin requirement, was pleomorphic in nitrogen-deficient malate medium, and could utilize mannitol and α-ketoglutarate. Although these are characteristics of *A. lipoferum*, the strain failed to use D-glucose as a sole carbon source for N_2-dependent growth and did not acidify D-glucose or ribose media. The strain may be a variant of *A. lipoferum*. In another study, Franche and Elmerich (1981) found *Azospirillum* strains K67 and KR77 to be capable of glucose utilization, yet they had no biotin requirement; they were provisionally classified as *A. brasilense*. A third strain, SpN, appeared to be an *A. lipoferum* strain but seemed to require other growth factors in addition to biotin.

Nur et al. (1980) isolated microaerophilic, nitrogen-fixing, vibrioid bacteria having certain characteristics in common with *Azospirillum*. The organisms were associated with grass roots, were vibrioid cells with a single polar flagellum, and could use malate, lactate, arabinose, and galactose, but not mannitol, as sole carbon sources; one isolate could use glucose. Biotin was not required. These strains differed from *Azospirillum* by having a smaller cell diameter (0.5–0.6 μm), by having no lateral flagella, and by forming yellow-pigmented colonies. Their taxonomic placement is uncertain.

Two strains of *Azospirillum* (Am-53 and A1-3) were isolated from soil and plant litter in Göttingen, Germany, as nitrogen-fixing, hydrogen-oxidizing bacteria. These were Gram negative but showed Gram-positive granules and contained lipid droplets. Both had polar flagella and exhibited an active spirillum-like motility. Strain Am-53 (DSM 1727) required biotin, was pleomorphic in nitrogen-deficient malate medium, and in several other characters resembled *A. lipoferum*. Like *A. lipoferum*, it could grow chemolithotrophically on H_2 (Málek and Schlegel, 1981). However, unlike *A. lipoferum*, it could not utilize glucose, malonate, mannitol, or α-ketoglutarate as a sole source of carbon. Strain Al-3 (DSM 1726) was shorter than *A. lipoferum*. The cells were pleomorphic, but in the presence of 2–3% (w/v) NaCl the cells developed an active spinning motility (around the axis). Morphologically and in several other respects, the strain resembled *A. brasilense*; however, it could grow chemolithotrophically on H_2, could utilize glucose and α-ketoglutarate as a sole carbon source, and could produce acid from glucose aerobically, like *A. lipoferum*. A recent 16S rRNA gene sequence analysis showed that both of these *Azospirillum*-like strains were misclassified. The strain DSM 1726 is closely related to *Agrobacterium tumefaciens*, while DSM 1727 is related to bacteria within the *Gammaproteobacteria* (Xia et al., 1994).

A variant of *Azospirillum halopraeferens* was isolated from roots of rice plants grown in soil with pH 8.0 in India (Balasubramanian and Prabhu, 1989). This isolate grows and fixes nitrogen in semi-solid NFb medium, is highly motile and vibrioid. However, it could grow and fix nitrogen in the presence of 5% NaCl, utilize glucose and sucrose, and acidify peptone-based glucose broth. The ability to use D-glucose and sucrose as carbon sources are characteristics of *Azospirillum irakense*, a diazotroph isolated from rice plants grown in Iraq. Therefore, it seems that the Indian isolate may be more closely related to *A. irakense* than to *A. halopraeferens*.

Two groups of strains showing many morphological and physiological characteristics similar to *A. lipoferum* species were isolated from soil and rice plants grown in North Vietnam (Ngoc Dung et al., 1995). One group (Arm 2-2, GL 1-1) could use D-glucose, sucrose, and α-ketoglutarate, but not mannitol. The other group (strain DA 10-1) also utilized glucose and sucrose, but not mannitol or α-ketoglutarate. Neither group required biotin but formed acid from glucose and scarlet colonies on BMS medium. Additionally, neither group showed positive signals when hybridized with *Azospirillum* probes, and they may represent a new species.

Genus III. **Levispirillum** *gen. nov.*

BRUNO POT AND MONIQUE GILLIS

Le.vi.spi.ril' lum. L. adj. *laevus* left; M.L. dim. neut. n. *spirillum* small spiral; *Levispirillum* small spiral-shaped bacteria with left-turning helix.

Gram-negative, **rigid, helical cells 0.4–0.7 μm in diameter and 2–22 μm in length**. Helix is left-handed, determined by focusing on the bottom of the cells: the pattern \\\\ indicates a counterclockwise (left-handed) helix. **A polar membrane is present under the cytoplasmic membrane.** Intracellular polyhydroxybutyric acid and coccoid bodies are usually formed. **Bipolar tufts of flagella.** Chemoorganotrophic with an oxidative type of metabolism, using oxygen as a terminal electron acceptor. One species grows anaerobically with nitrate as electron acceptor. Acid is formed from fructose aerobically and anaerobically. Oxidase, catalase, and phosphatase positive; sulfatase negative. Indole negative and esculin positive. Gelatin is not liquefied in 4 d at 30°C or in 7 d at 20°C. One species can liquefy gelatin at 20°C after 28 d. Growth factors not required. Nonphototrophic. No growth on casein, starch, and hippurate. Nitrogenase activity can occur in anaerobic conditions in the presence of ammonium sulfate. No growth at 3% NaCl. Growth on 1% bile and on EMB agar. L-Glutamate, L-asparagine, L-glutamine, and L-proline used as sole C-source; caproate, isocitrate, D-glucose, D-xylose, L-arabinose, and L-tyrosine, L-methionine, L-serine, L-tryptophan, L-isoleucine, and glycine cannot be used as sole C-source. Isolated from pond water and from putrid infusions of freshwater mussels.

The mol% G + C of the DNA is: 60–64.

Type species: **Levispirillum itersonii** *comb. nov.* (*Aquaspirillum itersonii* (Giesberger 1936) Hylemon, Wells, Krieg and Jannasch 1973b, 370.)

ACKNOWLEDGMENTS

We sincerely acknowledge Dr. N.R. Krieg for kindly providing the template text upon which this chapter was based.

List of species of the genus Levispirillum

1. **Levispirillum itersonii** *comb. nov.* (*Aquaspirillum itersonii* (Giesberger 1936) Hylemon, Wells, Krieg and Jannasch 1973b, 370.)
i.ter.so' ni.i. M.L. gen. n. *itersonii* of Iterson; named for G. Van Iterson, a Dutch bacteriologist.

The morphological characters are shown in Fig. BXII.β.67 and described in Table BXII.β.83. Optimal growth temperature 32–35°C. Chemotaxonomic and physiological characters are as described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Sole carbon sources are listed in Table BXII.β.79. Ammonium salts can serve as sole nitrogen sources. Nitrate supports either no growth or very scanty growth. In 1957, Williams and Rittenberg established a subspecies, subsp. *vulgatum*, to include those strains that use nitrate; however, this could not be confirmed by Terasaki (1979) for the type strain of the subspecies (ATCC 11331), using the methods of Williams and Rittenberg.

Isolated from pond water and from putrid infusions of freshwater mussels.

The two subspecies, subsp. *itersonii* and subsp. *nipponicum*, as represented by the type strains IFO 15648 and IFO 13615, respectively, have been shown to be genotypically related at the species level (Kawasaki et al., 1997). The type strain of *L. itersonii* subsp. *nipponicum*, as represented by the subculture ATCC 33333^{T}, however, could not be located in the *Alphaproteobacteria*, but was found to belong to the *Betaproteobacteria*, where it is a member of the family *Comamonadaceae* (Willems, unpublished results).

The mol% G + C of the DNA is: 60–66 (T_m).

Type strain: Giesberger, ATCC 12639, NCIMB 9070, NRRL B-2053.

GenBank accession number (16S rRNA): Z29620.

a. **Levispirillum itersonii** *subsp.* **itersonii** *subsp. nov.* (*Aquaspirillum itersonii* Hylemon, Wells, Krieg and Jannasch 1973b, 370.)

Morphology and characteristics as for the species. Differs from the subsp. *nipponicum* by having a cell diameter of 0.4–0.6 μm and rapid formation of coccoid bodies (within 7 d).

The mol% G + C of the DNA is: 60–64 (T_m).

Type strain: Giesberger, ATCC 12639, NCIMB 9070, NRRL B-2053.

GenBank accession number (16S rRNA): Z29620.

b. **Levispirillum itersonii** *subsp.* **nipponicum** *subsp. nov.* (*Spirillum itersonii* subsp. *nipponicum* Terasaki 1973, 58.)
nip.po' ni.cum. M.L. neut. adj. *nipponicum* pertaining to the country of Japan.

Morphology and characteristics as for the species. Differs from the subsp. *itersonii* by having a cell diameter of 0.5–0.8 μm and a delayed formation of coccoid bodies (~2 weeks before they become predominant).

The mol% G + C of the DNA is: 66 (T_m).

Type strain: KF 8, ATCC 33333, DSM 11590, IFO 13615.

2. **Levispirillum peregrinum** *comb. nov.* (*Aquaspirillum peregrinum* (Pretorius 1963) Hylemon, Wells, Krieg and Jannasch 1973b, 370.)
pe.re.gri' num. L. neut. adj. *peregrinum* strange, foreign.

The morphological characters are shown in Fig. BXII.β.67 and described in Table BXII.β.83. Optimal growth temperature 32°C. Chemotaxonomic and physiological characters are described in Tables BXII.β.80, BXII.β.81, BXII.β.82, and BXII.β.83. Sole carbon sources are listed in Table BXII.β.79. Ammonium salts can be used as sole nitrogen sources. There are conflicting reports concerning the ability to use nitrate as a sole nitrogen source (Terasaki, 1972, 1979; Hylemon et al., 1973b).

Isolated from a primary oxidation pond and from the putrid infusion of a freshwater mussel.

The two subspecies, subsp. *peregrinum* and subsp. *integrum*, have been shown to be genotypically related at the species level (Pot, 1996; Kawasaki et al., 1997).

The mol% G + C of the DNA is: 60–64 (T_m).

Type strain: ATCC 15387, DSM 1839, NCIB 9435.

a. **Levispirillum peregrinum** *subsp.* **peregrinum** *subsp. nov.* (*Aquaspirillum peregrinum* (Pretorius 1963) Hylemon, Wells, Krieg and Jannasch 1973b, 370.)

Morphology and characteristics as for the species. Differs from the subsp. *integrum* by forming coccoid bodies.

The mol% G + C of the DNA is: 60–62 (T_m).

Type strain: ATCC 15387, DSM 1839, NCIB 9435.

b. **Levispirillum peregrinum** *subsp.* **integrum** *subsp. nov.* (*Spirillum peregrinum* subsp. *integrum* Terasaki 1973, 60.) *in' te.grum.* L. neut. adj. *integrum* unchanged (referring here to failure to form coccoid bodies).

Morphology and characteristics as for the species. Differs from the subsp. *peregrinum* by failing to form coccoid bodies as a predominant form even after 28 d of incubation.

The mol% G + C of the DNA is: 64 (T_m).

Type strain: MF 19, ATCC 33334, DSM 11589, IFO 13617.

Genus IV. Magnetospirillum *Schleifer, Schüler and Ludwig 1992, 291^{VP} (Effective publication: Schleifer, Schüler and Ludwig* in *Schleifer, Schüler, Spring, Weizenegger, Amann, Ludwig and Köhler 1991, 384)*

DIRK SCHÜLER AND KARL-HEINZ SCHLEIFER

Mag.ne' to.spi.ril' lum. Gr. n. *magnes* magnet, comb. form magneto-; Gr. n. *spira* a spiral; M.L. dim. neut. n. *spirillum* a small spiral; *Magnetospirillum* a small magnetic spiral.

Helical (clockwise) **spirilla**, 0.2–0.7 × 3–4 µm. Occur in freshwater sediments. Gram negative. Motile by means of a single flagellum at each pole. Cells **contain variable numbers of magnetosomes**. Intracytoplasmic membranes (magnetosome membrane) are present. Intracellular poly-hydroxy-alkanoate formation. **Magnetotactic. Microaerophilic**, having a respiratory type of metabolism with oxygen as terminal electron acceptor. **Chemoorganotrophic.** Optimum growth temperature is 30°C. No growth in the presence of 1% NaCl. Catalase and oxidase can be absent or present. Denitrify under microaerobic conditions. Growth occurs on various organic acids; carbohydrates are not used. Members form a **monophyletic group within the *Alphaproteobacteria*.**

The mol% G + C of the DNA is: 63–64.

Type species: **Magnetospirillum gryphiswaldense** Schleifer, Schüler and Ludwig 1992, 291 (Effective publication: Schleifer, Schüler and Ludwig *in* Schleifer, Schüler, Spring, Weizenegger, Amann, Ludwig and Köhler 1991, 384.)

FURTHER DESCRIPTIVE INFORMATION

Cells of *Magnetospirillum* are helical and 0.2–0.7 × 3–4 µm. Enlarged pleomorphic forms and coccoid bodies are formed in older cultures and under conditions of excess oxygen. Each magnetotactic cell contains a number of electron-dense intracytoplasmic inclusion bodies (magnetosomes), which are aligned in a linear chain (for details of morphology and ultrastructure of the type strain *M. gryphiswaldense* see Fig. BXII.α.13). The magnetosomes consist of membrane-enveloped cubo-octahedral particles of magnetite (Fe_3O_4) (Balkwill et al., 1980). The size of mature magnetite crystals is 42 nm in diameter. The number of magnetosome particles per cell varies between 0 and 60 depending on growth conditions, oxygen, and iron supply. Magnetite formation requires low oxygen concentrations (<5 kPa) (Blakemore et al., 1985; Schüler and Baeuerlein, 1998). Concentrated suspensions of magnetic cells are dark gray-brown in color, those of nonmagnetic cells are light cream colored. Magnetite formation is coupled to the uptake of bulk amounts of ferric iron at high rates and cells intracellularly accumulate more then 2% iron (dry wt) during magnetite synthesis (Schüler and Baeuerlein, 1998). Production of a hydroxamate-type siderophore has been reported for *M. magnetotacticum* (Paoletti and Blakemore, 1986), but siderophore production could be not detected in *M. gryphiswaldense* (Schüler and Baeuerlein, 1996). Magnetite crystals are enveloped by the magnetosome membrane, which represents an intracytoplasmic membrane compartment with a distinctive protein and lipid composition (Schüler and Baeuerlein, 1997; Gorby et al., 1988). Cells grown under low-iron conditions contain empty magnetosome vesicles. The magnetosome chain is responsible for the tactic response of the cells to magnetic fields that is assumed to have a navigational function by interaction with the Earth's magnetic field (Blakemore and Frankel, 1981). Magnetospirilla exhibit an axial type of magnetotaxis, that is, cells are capable of swimming parallel or antiparallel to the magnetic field by alternately reversing their swimming direction without turning (Frankel et al., 1997).

Magnetospirillum strains are obligately microaerophilic. The level of oxygen tolerance differs between species, and is apparently correlated to the presence or absence of the oxygen-protective enzyme catalase. In semi-solid medium incubated under air atmospheres, initial growth occurs as a thin band some distance from the surface. Colony formation on agar plates is difficult to achieve; surface colonies are formed in *M. magnetotacticum* if catalase is added to the medium (Blakemore et al., 1979) and in *M. gryphiswaldense* on ACA medium (Schultheiss and Schüler, 2003). Best growth occurs in simple media containing short organic acids and minerals (see Tables BXII.α.7 and BXII.α.8). A cytochrome a_1-like hemoprotein (Tamegai et al., 1993), and a cytochrome c_{550} (Yoshimatsu et al., 1995) are present in *M. magnetotacticum.* A ccb-type cytochrome *c* oxidase functions as terminal oxidase in the microaerobic respiration of *M. magnetotacticum* (Tamegai and Fukumori, 1994). A cytochrome cd_1-type nitrite reductase with Fe(II):nitrite oxidoreductase activity and a speculated function in magnetite synthesis is present in *M. magnetotacticum* (Yamazaki et al., 1995). The purification of a ferric iron reductase that is loosely bound to the cytoplasmic membrane was described for *M. magnetotacticum* (Noguchi et al., 1999).

No growth factors are required. Growth occurs with fumarate, tartrate, malate, succinate, lactate, pyruvate, oxalacetate, malonate, β-hydroxybutyrate, and maleate as sole carbon sources. Carbohydrates are not used. N_2, nitrate, and ammonium can serve as sole nitrogen sources (Bazylinski and Blakemore, 1983b; Bazylinski et al., 2000). No growth under strictly anaerobic conditions. However, at low oxygen levels nitrate is dissimilated to nitrous oxide and nitrogen gas in *M. magnetotacticum* (Escalante-Semerena et al., 1980; Bazylinski and Blakemore, 1983a). *Magnetospirillum* species contain $C_{18:1}$, $C_{16:1}$, and $C_{16:0}$ as the major non-polar fatty acids, and $C_{14:0}$, $C_{16:0}$, and $C_{18:0}$ as 3-hydroxy acids; Q-10 is the major ubiquinone (Sakane and Yokota, 1994). *M. gryphiswaldense* and *M. magnetotacticum* contain putrescine and

(*B*) Transmission electron micrograph of a negatively stained cell of *Magnetospirillum gryphiswaldense* showing the bipolar-monotrichous flagellation and the chain of magnetosomes (*arrow*) (Bar = 0.5 μm). (*C*) Transmission electron micrograph of the magnetosome chain of *M. gryphiswaldense*. Cells contain intracellularly up to 60 cubo-octahedral crystals of magnetite (Fe_3O_4) that are 42 nm in size (Bar = 0.1 μm). (*D*) Transmission electron microscopy of a thin-section of a magnetic cell of *M. gryphiswaldense*. Individual magnetite crystals are enveloped by the magnetosome membrane (*arrow*). Cells contain poly-hydroxy-alkanoate granules (PHA) (Bar = 0.1 μm).

spermidine, or putrescine, cadaverine, and spermidine, respectively, as the major polyamines (Hamana et al., 1994).

Enrichment and Isolation Procedures

Magnetospirillum species can be isolated from the oxic–anoxic transition zone of many freshwater sediments. Enrichments of magnetic spirilla can be obtained by the undisturbed incubation of loosely covered jars, filled with 1/3 mud and 2/3 water from the sample origin, during several months at room temperature. As no selective media for the cultivation of magnetic spirilla are known, the effective physical separation of magnetotactic cells from contaminants is crucial in their isolation. Advantage can be taken of the directed, active migration of magnetospirilla in magnetic fields. Large numbers of magnetotactic bacteria can be collected from the sediment-water interface of the enrichments using a bar magnet. Magnetotactic bacteria can then be further separated by a "racetrack" method using semisolid agar or sterile capillaries (Wolfe et al., 1987; Schüler and Köhler, 1992). By application of a magnetic field, magnetotactic bacteria will outswim contaminating organisms and a highly purified inoculum can be collected at the end of the capillary close to the south pole of a bar magnet. The purified inoculum is then transferred to prereduced semisolid, low-nutrient isolation medium, which is incubated under microaerobic atmospheres containing 0.6–1% oxygen (Blakemore et al., 1979). Alternatively, a two-layer sulfide-oxygen gradient medium has proven useful in the isolation of microaerophilic magnetospirilla by creation of a vertical redox gradient (Schüler et al., 1999).

TABLE BXII.α.7. Characteristics differentiating *Magnetospirillum gryphiswaldense* and *M. magnetotacticum*[a]

Characteristics	*M. gryphiswaldense*	*M. magnetotacticum*
Catalase	+	−
Oxidase	+	−[b]
Growth and magnetosome formation in liquid culture exposed to air	+	−

[a]For symbols see standard definitions.

[b]Oxidase test is faintly positive with toluene-treated cells (Maratea and Blakemore, 1981).

Maintenance Procedures

Magnetospirilla may be maintained in semisolid growth medium at 30°C with weekly transfer or at room temperature with monthly transfer. Long-term preservation is accomplished by suspending a dense suspension of cells in liquid growth medium containing

TABLE BXII.α.8. Other characteristics of *M. gryphiswaldense* and *M. magnetotacticum*[a]

Characteristics	*M. gryphiswaldense*	*M. magnetotacticum*
Cell size, μm	0.2–0.7 × 3–4	0.2–0.7 × 3–4
Magnetosomes: 0–60 intracellular cubo-octahedral magnetite (Fe_3O_4) crystals, 42 nm	+	+
Magnetic reaction, sensitivity	+	+
Single bipolar flagella	+	+
Intracellular PHA-formation	+	+
Optimal growth temperature, °C	30	30
Growth in the presence of 1% NaCl	−	−
Growth on carbohydrates	−	−
Growth on fumarate, tartrate, malate, succinate, lactate, pyruvate, oxalacetate, malonate, β-hydroxybutyrate, maleate	+	+
Microaerobic reduction of nitrate	+	+
Growth with N_2 as sole nitrogen source, nitrogenase activity	+	+
Hydrolysis of casein, starch, hippurate, esculin, gelatin	−	−
Hydrogen sulfide production from cysteine	−	−
Growth in the presence of 1% glycine	nd	+
Growth in the presence of 1% bile	nd	−
Anaerobic growth with NO_3^-, Fe(III), DMSO, SO_4^- [b]	−	−
Formation of coccoid bodies in older cultures	+	+
Selenite reduction	nd	−
Pigment formation from aromatic amino acids	−	−
Urease, sulfatase, indole	nd	−
Alkaline reaction in litmus milk	nd	−

[a]For symbols see standard definitions; nd, not determined.

[b]Very slow ferric iron-dependent growth in the absence of oxygen has been reported (Guerin and Blakemore, 1992).

10% (v/v) dimethyl sulfoxide, with subsequent freezing in liquid nitrogen and storage at −80°C.

Procedures for Testing Special Characters

The most conspicuous trait of *Magnetospirillum* species is their magnetic sensitivity, which can be easily checked in living cells by phase-contrast microscopy in the presence of a permanent magnet, where magnetospirilla will orient and swim parallel to the magnetic field lines. Magnetic reaction of cultures can also be checked by placing a drop of cell suspension onto the top of a magnetic stirrer and watching for the characteristic "flickering", as the light scattering of suspensions of magnetic cells is affected by changing magnetic fields (Schüler et al., 1995). By electron microscopy, intracellular magnetosome crystals are easily revealed in unstained cells as electron-dense inclusions.

A *Magnetospirillum*-specific pair of primers for the PCR-amplification of a 16S rRNA gene fragment has been proposed (Burgess et al., 1993), but these were found to also be homologous to several unrelated, nonmagnetic *Alphaproteobacteria* in a recent database search (D. Schüler, unpublished). Tests for oxygen tolerance and catalase and oxidase activities are further useful diagnostic features.

Differentiation of the genus *Magnetospirillum* from other genera

The intracellular magnetosome formation and magnetic reaction clearly distinguishes *Magnetospirillum* from other microaerophilic, spiral-shaped bacteria from freshwater.

Magnetospirillum species are most closely related (94–96% 16S rDNA sequence similarity) to several nonmagnetic, photosynthetic, nonsulfur purple *Alphaproteobacteria* of the genus *Phaeospirillum* (*P. fulvum* and *P. molischianum*; Imhoff et al., 1998), with which they share similarities in cell morphology and flagellation, the presence of intracytoplasmic membranes, and the microaerophilic nature of their chemoorganotrophic growth. However, *Magnetospirillum* strains are unable to grow photosynthetically and lack the characteristic photosynthetic pigments (bacteriochlorophyll, carotenoids) of the *Phaeospirillum* species.

Magnetospirillum species are phylogenetically only distantly related to other, mostly uncultured vibrioid, rod-shaped, and coccoid magnetotactic bacteria, and can be distinguished by cell morphology and the shape, size, and arrangement of the magnetosome crystals (Spring and Schleifer, 1995).

Taxonomic Comments

The first magnetic spirillum isolated by R. Blakemore was originally described as *Aquaspirillum magnetotacticum* (Maratea and Blakemore, 1981). However, 16S rRNA gene sequence analysis of *A. magnetotacticum* and the newly isolated magnetic strain MSR-1 demonstrated their affiliation with the *Alphaproteobacteria*, while the type species of *Aquaspirillum* falls in the *Betaproteobacteria*. Moreover, magnetic spirilla differ from known *Aquaspirillum* strains in a number of morphological and physiological features such as the presence of magnetic inclusions and the type of flagellation, suggesting classification in a separate genus. Therefore, the new genus *Magnetospirillum* was proposed with the type

strain *M. gryphiswaldense* MSR-1, and *A. magnetotacticum* was transferred to *Magnetospirillum* as *M. magnetotacticum* (see Tables BXII.α.7 and BXII.α.8) (Schleifer et al., 1991).

List of species of the genus Magnetospirillum

1. **Magnetospirillum gryphiswaldense** Schleifer, Schüler and Ludwig 1992, 291[VP] (Effective publication: Schleifer, Schüler and Ludwig *in* Schleifer, Schüler, Spring, Weizenegger, Amann, Ludwig and Köhler 1991, 384.)
gry.phis.wal.den'se. L. adj. *gryphiswaldense* the Latin name of Greifswald, a town in Germany where the organism was isolated.

Helical spirilla, 0.7 × 3–4 µm. Catalase and oxidase positive. Microaerophilic, but grows prolifically in agitated liquid medium[1] exposed to air if large inocula (1/10) are used. Growth rates are 0.3–0.1 h^{-1}. Isolated by D. Schüler from sediments of a small river (Ryck) near Greifswald, Germany.

The mol% G + C of the DNA is: 62.7 (HPLC) (Sakane and Yokota, 1994).

Type strain: MSR-1, DSM 6361.

GenBank accession number (16S rRNA): Y10109.

2. **Magnetospirillum magnetotacticum** (Maratea and Blakemore 1981) Schleifer, Schüler and Ludwig 1992, 291[VP] (Effective publication: Schleifer, Schüler and Ludwig *in* Schleifer, Schüler, Spring, Weizenegger, Amann, Ludwig and Köhler 1991, 385) (*Aquaspirillum magnetotacticum* Maratea and Blakemore 1981, 454.)
mag.ne.to.tac' ti.cum. Gr. n. *magnes* magnet, comb. form *magneto-* Gr. adj. *taktikos* showing orientation or movement directed by a force or agent; *magnetotacticum* capable of orientation with respect to a magnet.

Helical spirilla, 0.4–0.7 × 3–4 µm. Microaerophilic. No growth of magnetic cells in liquid cultures with free gas exchange to air. Very weak ferric iron-dependent growth in the absence of oxygen has been reported (Guerin and Blakemore, 1992). Nitrate is reduced to N_2 with transient accumulation of nitrous oxide but without nitrite accumulation (Bazylinski and Blakemore, 1983b). Grows in a defined mineral medium[2]. Vitamins are not strictly required for growth, but deletion of vitamins from the growth medium results in a pleomorphic appearance (Blakemore et al., 1979). Catalase, oxidase, urease, sulfatase, and indole are negative. Oxidase test is faintly positive with toluene-treated cells (Maratea and Blakemore, 1981). Isolated by R.P. Blakemore at the University of Illinois from sediments collected in Cedar Swamp, Woods Hole, Massachusetts (USA).

The mol% G + C of the DNA is: 63 (HPLC) (Sakane and Yokota, 1994).

Type strain: MS-1, ATCC 31 632, DSM 3856.

GenBank accession number (16S rRNA): Y10110.

Other Organisms

Several magnetic spirilla isolates have been identified as *Magnetospirillum* species based on cell morphology, ultrastructure, and phylogenetic analysis, and form a monophyletic group including *M. magnetotacticum* and *M. gryphiswaldense* within the *Alphaproteobacteria*. However, their taxonomic characterization is incomplete and they are not yet validly described.

The *Magnetospirillum* strains MGT-1 (GenBank accession number of the 16S rRNA gene sequence: D17515) and AMB-1 (D17514) were isolated from freshwater ponds in Tokyo, Japan (Burgess et al., 1993). Sequence similarities of the 16S rRNA genes of MGT-1 and AMB-1 to that of *M. gryphiswaldense* are 95.0% and 95.8%, respectively, and to that of *M. magnetotacticum* are 99.0% and 99.4% (Schüler et al., 1999). MGT-1 and AMB-1 were reported to have increased oxygen tolerance and to form colonies on agar surfaces exposed to air (Burgess et al., 1993). Seven *Magnetospirillum* strains (MSM-1, 3, 4, 6, 7, 8, 9) were isolated from a freshwater pond in Iowa, USA (EMBL-accession numbers for the sequences of the 16S rRNA genes of the *Magnetospirillum* strains MSM-3, MSM-4, and MSM-6 are Y17389, Y17390, and Y17391, respectively). While five of the isolates were very similar to either *M. gryphiswaldense* or *M. magnetotacticum* by 16S rRNA gene sequence analysis (>99.7%), two new isolates (MSM-3, MSM-4) are likely to represent new species (Schüler et al., 1999). A total of six different sequences was obtained from a single sample site, indicating a significant microdiversity of natural populations of magnetic spirilla.

1. *M. gryphiswaldense* medium (mod. after Schüler and Baeuerlein, 1996) contains per liter: KH_2PO_4, 0.5 g; Na-acetate, 1.0 g; soybean peptone (E. Merck), 1.0 g; NH_4Cl, 0.1 g; $MgSO_4 \cdot 7H_20$, 0.1 g; yeast extract, 0.1 g; agar (for semisolid medium), 2 g; Fe(III) citrate, 50 µM (final concentration). Dissolve and autoclave at 121°C for 15 min. For liquid cultures, inoculate with 1/10 vol and agitate at 100 rpm.

2. *M. magnetotacticum* medium (DSM 380) contains per liter: Vitamin solution (Wolin et al., 1963), 10 ml; trace elements (Wolin et al., 1963), 5 ml; Fe(III) quinate solution, 2 ml; resazurine, 0.5 mg; KH_2PO_4, 0.68 g; $NaNO_3$, 0.12 g; Na-thioglycolate, 0.05 g; L(+)-tartaric acid, 0.3 g; succinic acid, 0.37 g; Na-acetate, 0.05 g; agar (for solid medium), 13.0 g. Dissolve components in the order given, adjust pH to 6.75 with NaOH. Ferric quinate solution, 0.01 M (per liter): $FeCl_3 \cdot 6H_2O$, 4.5 g; quinic acid, 1.9 g, Dissolve and autoclave at 121°C for 15 min. Liquid medium: Purge medium with N_2 gas for 10 min. Under the same atmosphere, anaerobically fill tubes to 1/3 of their volume and seal. Autoclave at 121°C for 15 min. Before inoculation, add sterile air (with hypodermic syringe through the rubber closure) to 1% O_2 concentration in the gas phase.

Genus V. **Phaeospirillum** *Imhoff, Petri, and Süling 1998, 796*[VP]

JOHANNES F. IMHOFF

Phae.o.spi.ril′lum. Gr. adj. *phaeos* brown; M.L. neut. n. *Spirillum* a bacterial genus; M.L. neut. n. *Phaeospirillum* brown *Spirillum.*

Cells are vibrioid to spiral shaped, motile by means of polar flagella and multiply by binary fission. **Gram negative and belong to the *Alphaproteobacteria*.** Internal photosynthetic membranes are lamellar stacks forming a sharp angle with the cytoplasmic membrane. Photosynthetic pigments are **bacteriochlorophyll *a*** (esterified with phytol) and **carotenoids of the spirilloxanthin series**, with spirilloxanthin itself lacking. **Ubiquinones and menaquinones with nine isoprene units (Q-9 and MK-9)** are present. **Major cellular fatty acids are $C_{18:1}$, $C_{16:1}$, and $C_{16:0}$**, with $C_{18:1}$ as dominant component (44–55% of total fatty acids).

Cells grow preferentially photoheterotrophically under anoxic conditions in the light. **Chemotrophic growth is possible at very low oxygen tensions in the dark.** Growth factors may be required. **Mesophilic freshwater bacteria with preference for neutral pH.** Habitat: stagnant and anoxic freshwater habitats.

The mol% G + C of the DNA is: 60.5–65.3.

Type species: **Phaeospirillum fulvum** (van Niel 1944) Imhoff, Petri, and Süling 1998, 797 (*Rhodospirillum fulvum* van Niel 1944, 108.)

FURTHER DESCRIPTIVE INFORMATION

Phaeospirillum species are very sensitive to oxygen and do not grow under oxic conditions in the dark (Pfennig, 1969b). They do grow, however, under microoxic conditions in the dark, provided the oxygen tension is lower than 1.5 kPa for *Phaeospirillum fulvum* and 1.0 kPa for *Phaeospirillum molischianum* (Lehmann, 1976). These bacteria are unable to induce a second electron transport chain in the presence of oxygen and depend on microoxic conditions in which the internal membrane system and the light-driven electron transport chain are fully expressed. The cells are fully pigmented under these growth conditions (Lehmann, 1976).

Ammonia assimilation is mediated by the glutamine synthetase/glutamate synthase reactions, which are NADH-dependent in *Phaeospirillum molischianum* and *Phaeospirillum fulvum* (Brown and Herbert, 1977).

ENRICHMENT AND ISOLATION PROCEDURES

Media and growth conditions applied for *Rhodospirillum* species are also suitable for *Phaeospirillum* species, if the oxygen partial pressure is adequately reduced. This can be achieved by addition of 0.05% sodium ascorbate to the growth media in completely filled screw-capped bottles. A recipe for a mineral medium appropriate for cultivation of *Phaeospirillum* species is given with the description of the genus *Rhodospirillum.* Higher fatty acids such as pelargonate and caprylate (concentrations below 0.04% at pH 7.5) provide selective conditions for enrichment of *P. fulvum* and *P. molischianum.* Benzoate may be used for selective enrichment of *P. fulvum.* Standard techniques for isolation of anaerobic bacteria in agar dilution series and on agar plates can be applied to *Phaeospirillum* species (Biebl and Pfennig, 1981; Imhoff, 1988; Imhoff and Trüper, 1992), if care is taken to establish and maintain oxygen-free conditions.

MAINTENANCE PROCEDURES

Cultures can be preserved by standard techniques in liquid nitrogen or at −80°C in a mechanical freezer.

DIFFERENTIATION OF THE GENUS *PHAEOSPIRILLUM* FROM OTHER GENERA

Besides 16S rDNA sequence similarities (Kawasaki et al., 1993b; Imhoff et al., 1998), the size and sequences of the small-size cytochromes c_2 (Ambler et al., 1979), quinone, and fatty acid composition and other properties also distinguish *Phaeospirillum* and *Rhodospirillum* species (see Tables BXII.α.1 and BXII.α.2 in the chapter describing the genus *Rhodospirillum*).

TAXONOMIC COMMENTS

Phaeospirillum species have previously been included in the genus *Rhodospirillum.* Based on significant differences in chemotaxonomic properties and 16S rDNA sequences, they have been transferred into the new genus *Phaeospirillum* (Imhoff et al., 1998). The name *Phaeospirillum* was first proposed by Kluyver and van Niel (1936) for brown-colored, phototrophic, spiral-shaped bacteria but was not included in the Approved List of Names and therefore lost standing in nomenclature. The name was revived (Imhoff et al., 1998). Both *Phaeospirillum* species have highly similar 16S rDNA sequences (greater than 99% similarity) that would allow their treatment as a single species. This was not proposed because of the well-recognized phenotypic differences between the two species. The phylogenetic relationships of these bacteria based on 16S rDNA sequences are shown in Fig. 1 (p. 124) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A.

DIFFERENTIATION OF THE SPECIES OF THE GENUS *PHAEOSPIRILLUM*

Phaeospirillum molischianum and *Phaeospirillum fulvum* can be distinguished from each other primarily by cell size, growth factor requirements, and fatty acid composition (Table BXII.α.1 in the description of the genus *Rhodospirillum*). The utilization of benzoate is a characteristic and distinguishing property of *Phaeospirillum fulvum* (Table BXII.α.2 in the description of the genus *Rhodospirillum*).

List of species of the genus Phaeospirillum

1. **Phaeospirillum fulvum** (van Niel 1944) Imhoff, Petri, and Süling 1998, 797[VP] (*Rhodospirillum fulvum* van Niel 1944, 108.)

   ful′vum. M.L. neut. adj. *fulvum* deep or reddish yellow, tawny.

   Cells are vibrioid shaped to spiral, 0.5–0.7 × 3.5 µm; one complete turn of a spiral is 1.0–1.6 µm wide. Internal photosynthetic membranes are present as lamellar stacks forming a sharp angle to the cytoplasmic membrane. Anaerobic liquid cultures are deep brown. Photosynthetic pig-

ments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series. Spirilloxanthin is lacking, but the biosynthetic precursors lycopene and rhodopin are present as major components.

Cells grow preferentially photoheterotrophically under anoxic conditions in the light with various organic compounds as carbon and electron sources. Chemotrophic growth at very low oxygen tensions is possible. Unable to adapt to oxic growth conditions. Under microoxic conditions cells are fully pigmented. Carbon sources utilized are shown in Table BXII.α.2 in the description of the genus *Rhodospirillum*. Ammonia and N_2 are used as nitrogen source. Sulfate can be used as sole sulfur source. For optimal development, the addition of ascorbate or thioglycolate as a reductant may be necessary. *p*-Aminobenzoic acid is required as a growth factor.

Mesophilic freshwater bacterium with optimum growth at 25–30°C and pH 7.3 (pH range: 6.0–8.5). Habitat: stagnant and anoxic freshwater habitats that are exposed to the light.

The mol% G + C of the DNA is: 64.3–65.3 (Bd) and 62.1–62.8 (T_m).

Type strain: Pfennig 1360, ATCC 15798, DSM 113.

GenBank accession number (16S rRNA): M14433, M59065.

2. **Phaeospirillum molischianum** (Giesberger 1947) Imhoff, Petri, and Süling 1998, 797[VP] (*Rhodospirillum molischianum* Giesberger 1947, 142.)
mo.li'schi.a'num. M.L. neut. adj. *molischianum* pertaining to Molisch, named for H. Molisch, an Austrian botanist.

Cells are vibrioid to spiral shaped, 0.7–1.0 × 4–6 μm or even longer; one complete turn of a spiral is 1.5–2.5 μm wide. Internal photosynthetic membranes are present as lamellar stacks forming a sharp angle to the cytoplasmic membrane (Fig. BXII.α.14). Anaerobic liquid cultures are brown-orange to brown-red or dark brown. Absorption maxima of living cells are at 375, 465, 488–491, 520–528, 590–595, 803–807, and 850–855 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series. Spirilloxanthin is lacking, but the biosynthetic precursors lycopene and rhodopin are present as major components. Cells grow preferentially photoheterotrophically under anoxic conditions in the light with various organic compounds as carbon and electron sources. Chemotrophic growth at very low oxygen tensions is possible, but the ability to adapt to oxic growth conditions is lacking. Under microoxic conditions cells are fully pigmented. Carbon sources utilized are shown in Table BXII.α.2 in the description of the genus *Rhodospirillum*. Malonate is not used. Ammonia, N_2, and some amino acids are used as nitrogen sources. For optimal development the addition of ascorbate or thioglycolate as a reductant may be necessary. Complex mixtures of amino acids, such as yeast extract and vitamin-free Casamino acids, stimulate growth considerably and may be required.

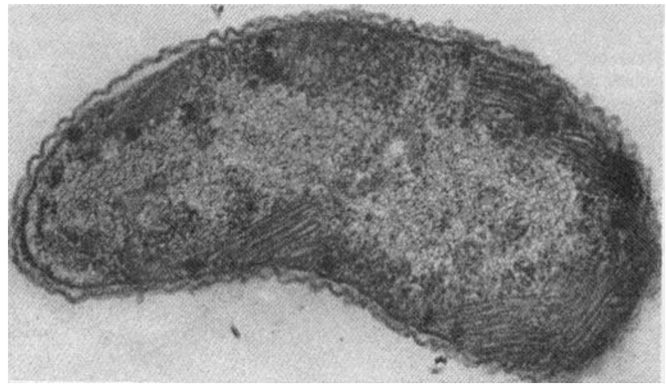

FIGURE BXII.α.14. *Phaeospirillum molischianum* grown anaerobically in the light. Note the position and the lamellar stack type of the intracytoplasmic membrane system. × 90,000. (Courtesy of G. Drews.)

Mesophilic freshwater bacterium with optimal growth at 30°C and pH 7.3 (pH range: 6.0–8.5). Habitat: stagnant and anoxic freshwater habitats that are exposed to the light.

The mol% G + C of the DNA is: 60.5–64.8 (Bd) and 62.1–62.6 (T_m).

Type strain: ATCC 14031, DSM 120, NCIB 9957, NTHC 131.

GenBank accession number (16S rRNA): M59067.

Genus VI. **Rhodocista** *Kawasaki, Hoshino, Kuraishi and Yamasato 1994b, 182[VP] (Effective publication: Kawasaki, Hoshino, Kuraishi and Yamasato 1992, 548)*

JOHANNES F. IMHOFF

Rho.do.ci'sta. L. fem. n. *rhodon* the rose; L. fem. n. *cista* a basket; M.L. fem. n. *Rhodocista* the rose basket.

Cells are vibrioid to spiral in shape, motile by means of a long polar flagellum. **Gram negative. Belong to the *Alphaproteobacteria*.** Internal photosynthetic membranes occur as lamellae lying parallel to the cytoplasmic membrane. Photosynthetic pigments are **bacteriochlorophyll *a*** and **carotenoids of the spirilloxanthin series**. **Ubiquinone with nine isoprene units (Q-9) is present.**

Cells grow preferentially photoheterotrophically under anoxic conditions in the light. **Chemotrophic growth under oxic conditions in the dark is possible.**

The mol% G + C of the DNA is: 69.9.

Type species: **Rhodocista centenaria** Kawasaki, Hoshino, Kuraishi and Yamasato 1994b, 182 (Effective publication: Kawasaki, Hoshino, Kuraishi and Yamasato 1992, 548) (*Rhodospirillum centenum* Favinger, Stadtwald and Gest 1994, 182.)

FURTHER DESCRIPTIVE INFORMATION

When grown in liquid culture, *R. centenaria* cells are motile by means of a single polar flagellum (Favinger et al., 1989). On solid media, however, numerous lateral, peritrichous flagella that enable rapid movement on agar surfaces are produced. The kind of swarming motility observed with *R. centenaria* has not yet been observed in other phototrophic purple nonsulfur bacteria, and enables very rapid light-directed motility across the agar surface, which appears to be a true phototactic behavior (Ragatz et al.,

1995). It has also been shown that photo-induced cyclic electron flow is required for the photo-tactical response and that phototaxis is controlled by respiration (Romagnoli et al., 1997). The type strain (ATCC 43720) is not phototactically active (Nickens et al., 1996).

Absorption spectra of cultures grown anaerobically in the light or aerobically in the dark are almost identical, which demonstrates the absence of oxygen repression of photopigment synthesis that is common to most of the anoxygenic phototrophic purple bacteria (Yildiz et al., 1991).

Out of 13 strains under investigation, all were sensitive to rifampicin and streptomycin but highly resistant to neomycin and kanamycin (Nickens et al., 1996).

Enrichment and Isolation Procedures

R. centenaria appears to be widely distributed in warm waters and has been repeatedly isolated from a variety of hot springs with the source water temperature between 34 and 58°C (Nickens et al., 1996). Most of the strains have been isolated with dinitrogen as sole nitrogen source and under anoxic conditions, but after transient exposure to air. Incubation at temperatures between 40 and 45°C under anoxic conditions in the light, in media suitable for freshwater purple nonsulfur bacteria, and with N_2 as the sole nitrogen source, provides selective conditions for the enrichment of *Rhodocista centenaria* (Nickens et al., 1996). Standard techniques for the isolation of anaerobic bacteria in agar dilution series and on agar plates can be applied (Biebl and Pfennig, 1981; Imhoff and Trüper, 1992).

Maintenance Procedures

Cultures are well preserved by standard techniques in liquid nitrogen, by lyophilization or storage at -80°C in a mechanical freezer.

Differentiation of the genus *Rhodocista* from other genera

Differential characteristics and phylogenetic relationships based on 16S rDNA sequences are shown in Table BXII.α.1 and Table BXII.α.2 in the description of the genus *Rhodospirillum* and Fig. 1 (p. 124) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A.

Taxonomic Comments

Until recently, the genus *Rhodospirillum* represented a heterogeneous assemblage of species that were of spiral shape and capable of phototrophic growth. Four halophilic species were classified together with several freshwater species. Because of its spiral shape and phototrophic capacity, *Rhodospirillum centenum* was also assigned to the genus *Rhodospirillum* (Favinger et al., 1989). The anticipated heterogeneity of the genus *Rhodospirillum* became clearly apparent with the 16S rDNA sequence information of most of the known species (Kawasaki et al., 1993b), and these data implied that the spiral-shaped *Alphaproteobacteria* were phylogenetically quite distantly related to each other and did not warrant classification in one and the same genus. Upon recognition of the great genetic distance between *Rhodospirillum rubrum* and *Rhodospirillum centenum*, the latter was transferred to a new genus as *Rhodocista centenaria* (Kawasaki et al., 1992). The phylogenetic relationships of these bacteria based on 16S rDNA sequences are shown in Fig. 1 (p. 124) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A.

List of species of the genus Rhodocista

1. **Rhodocista centenaria** Kawasaki, Hoshino, Kuraishi and Yamasato 1994b, 182[VP] (Effective publication: Kawasaki, Hoshino, Kuraishi and Yamasato 1992, 548) (*Rhodospirillum centenum* Favinger, Stadtwald and Gest 1994, 182.)
cen.ten.a'ri.a. L. fem. adj. *centenaria* relating to a hundred, to commemorate a century after the publication of the first description of a phototrophic bacterium in 1887.

Cells are vibrioid to spiral in shape, 1–2 × 3 μm. In liquid media they are actively motile by means of a single polar flagellum. When grown on agar, peritrichous flagella are induced, conferring swarming motility. Swarming cells exhibit phototactic behavior. Cells are converted to thick-walled cysts, which are resistant to desiccation and heat, under conditions that also favor the formation of poly-β-hydroxybutyrate, especially in aging conditions on agar. Internal photosynthetic membranes are lamellae lying parallel to the cytoplasmic membrane. Color of anaerobically grown cultures is pink. Living cells show absorption maxima at 475–550, 587, 800, and 875 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series. Photopigment synthesis is not significantly affected by molecular oxygen.

Cells grow preferentially photoheterotrophically under anoxic conditions in the light or chemotrophically under oxic conditions in the dark. Pyruvate, lactate, acetate, alanine, aspartate, glutamate, and glutamine are used as carbon sources and electron donors. Butyrate, valerate, caproate, and caprylate also support phototrophic growth when supplemented with bicarbonate (9 mM). Sugars and C4 dicarboxylic acids, including malate, do not support growth. With butyrate as the sole carbon source, the spiral-shaped cells are converted to cysts, which are desiccation and heat resistant. Filter-fixed cysts kept viability at 55°C for 2 d. Ammonia, N_2, glutamate, glutamine, aspartate, and alanine are utilized as nitrogen sources. Biotin and vitamin B_{12} are required as growth factors.

Freshwater bacterium preferring elevated temperatures, with optimal growth at 40–45°C (upper limit 47°C) and pH 6.8 (pH range 5.7–7.0). Ubiquinone with nine isoprene units (Q-9) is the major quinone. Habitat: neutral to alkaline hot spring effluents, warm soils, effluents of paper factories.

The mol% G + C of the DNA is: 69.9 (T_m).
Type strain: ATCC 43720, DSM 9894, IAM 14193.
GenBank accession number (16S rRNA): D12701.

Genus VII. **Rhodospira** *Pfennig, Lünsdorf, Süling and Imhoff 1998, 328[VP] (Effective publication: Pfennig, Lünsdorf, Süling and Imhoff 1997, 44)*

Johannes F. Imhoff

Rho' do.spi' ra. Gr. n. *rhodon* the rose; Gr. n. *spira* the spiral; M.L. fem. n. *Rhodospira* the rose spiral.

Cells are vibrioid to spirilloid in shape, motile by means of flagella and multiply by binary fission. **Gram negative. Belong to the *Alphaproteobacteria*.** Internal photosynthetic membranes are of the vesicular type. Photosynthetic pigments are **bacteriochlorophyll *b*** and **carotenoids**. **Menaquinones and ubiquinones with seven isoprene units (MK-7 and Q-7)** are present. **Major cellular fatty acids are $C_{18:1}$ and $C_{16:0}$**, with $C_{18:1}$ as dominant component (~60% of total fatty acids).

Cells grow preferentially photoheterotrophically under anoxic conditions in the light, but poor growth may also be possible under microoxic conditions in the dark. Growth factors are required. **Marine bacteria** requiring salt for growth.

Habitat: salt marsh sediments and laminated microbial mats.

The mol% G + C of the DNA is: 65.7.

Type species: **Rhodospira trueperi** Pfennig, Lünsdorf, Süling and Imhoff 1998, 328 (Effective publication: Pfennig, Lünsdorf, Süling and Imhoff 1997, 44.)

Further descriptive information

At present, *Rhodospira trueperi* is the only representative of this genus. *R. trueperi* was isolated from a flat laminated microbial mat in a salt marsh near Woods Hole, Massachusetts, USA. The spiral-shaped bacterium is highly motile, has bipolar tufts of flagella, and internal photosynthetic membranes of the vesicular type. Major photosynthetic pigments are bacteriochlorophyll *b* and the carotenoid tetrahydrospirilloxanthin. *R. trueperi*, a marine organism, shows optimum growth in the presence of salt. It utilizes a number of organic substrates as carbon and energy sources, and requires vitamins and sulfide as a reduced sulfur source for growth. In the presence of sulfide, S^0 globules are formed outside the cells. S^0 is not further oxidized to sulfate. *Rhodospira trueperi* has a unique lipid and fatty acid composition (Pfennig et al., 1997). The latter is dominated by $C_{18:1}$ and $C_{16:0}$ and is unique among the spiral-shaped phototrophic *Alphaproteobacteria* (Table BXII.α.1 in the description of the genus *Rhodospirillum*). According to 16S rRNA gene sequence analysis, *Rhodospira trueperi* is most similar to *Roseospira mediosalina*. The phylogenetic relationships of these bacteria based on 16S rDNA sequences are shown in Fig. 1 (p. 124) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A.

Enrichment and Isolation Procedures

Rhodospira trueperi was isolated from a microbial mat in a salt marsh, requires salt for growth, and depends on the presence of sulfide in growth media (Pfennig et al., 1997). Standard techniques for isolation of anaerobic bacteria in agar dilution series can be applied for *Rhodospira* species (Biebl and Pfennig, 1981; Imhoff, 1988; Imhoff and Trüper, 1992), if care is taken to establish and maintain oxygen-free conditions. *Rhodospira trueperi* can be grown on Pfennig's medium for purple sulfur bacteria (see genus *Chromatium*) with the addition of 2% NaCl and vitamins (or yeast extract).

Maintenance Procedures

Cultures can be preserved by standard techniques in liquid nitrogen or at −80°C in a mechanical freezer.

Differentiation of the genus *Rhodospira* from other genera

Rhodospira species are characterized by salt requirements typical of marine bacteria, requirement for sulfide as a reduced sulfur source, unusual absorption spectra due to the presence of bacteriochlorophyll *b*, and presence of ubiquinones and menaquinones with seven isoprene units (see Table BXII.α.1). Major differentiating properties between *Rhodospira trueperi* and other phototrophic *Alphaproteobacteria* are shown in Table BXII.α.1 and carbon sources utilized in Table BXII.α.2 in the description of the genus *Rhodospirillum.* The phylogenetic relationships of these bacteria based on 16S rDNA sequences are shown in Fig. 1 (p. 124) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A.

List of species of the genus Rhodospira

1. **Rhodospira trueperi** Pfennig, Lünsdorf, Süling and Imhoff 1998, 328[VP] (Effective publication: Pfennig, Lünsdorf, Süling and Imhoff 1997, 44.)

true' pe.ri. M.L. gen. n. *trueperi* of Trüper, named for Hans Georg Trüper, a German microbiologist who contributed significantly to our knowledge of the anoxygenic phototrophic bacteria.

Cells vibrioid to spirilloid in shape, 0.6–0.8 × 1.5–3.0 µm, and motile by bipolar tufts of flagella (2–5 fibrils). Internal photosynthetic membranes are of the vesicular type. Anaerobically grown cultures are beige to peach-colored. Living cell suspensions show absorption maxima at 397, 458, 490, 600, 689, 801, 889, and 986 nm. Photosynthetic pigments are bacteriochlorophyll *b* and the carotenoid tetrahydrospirilloxanthin.

Grows photoheterotrophically under strictly anoxic con-

ditions in the light and in the presence of sulfide as a reduced sulfur source. In the presence of sulfide and hydrogen carbonate and under anoxic conditions, acetate, pyruvate, propionate, butyrate, valerate, lactate, fumarate, malate, succinate, and crotonate are used as substrates. Ethanol and cyclohexane carboxylate are not used. Weak growth may occur under microoxic conditions in the dark. Sulfide is oxidized to S^0, which cannot be oxidized further to sulfate. Thiosulfate is not oxidized. Biotin, thiamine, and pantothenate are required as growth factors.

Marine bacterium with optimal growth at 25–30°C, pH 7.3–7.5 and 2% NaCl (in the presence of 0.3% $MgCl_2 \cdot 6H_2O$). Sodium chloride is required for growth, growth range is from 0.5–5.0% NaCl. Habitat: peach-colored layer of a laminated microbial mat of Great Sippewissett Salt Marsh.

The mol% G + C of the DNA is: 65.7 (by chemical analysis).

Type strain: Pfennig 8316, ATCC 700224.

GenBank accession number (16S rRNA): X99671.

Genus VIII. Rhodovibrio *Imhoff, Petri and Süling 1998, 797*[VP]

JOHANNES F. IMHOFF

Rho.do.vi' bri.o. Gr. n. *rhodon* the rose; M.L. masc. n. *Vibrio* a bacterial genus; M.L. masc. n. *Rhodovibrio* the rose *Vibrio*.

Cells are vibrioid to spiral shaped, motile by means of polar flagella and multiply by binary fission. **Gram negative, belonging to the *Alphaproteobacteria*.** Internal photosynthetic membranes are present as vesicles. Photosynthetic pigments are **bacteriochlorophyll *a*** and **carotenoids of the spirilloxanthin series**. **Ubiquinones and menaquinones with 10 isoprene units (Q-10 and MK-10) are present. Major cellular fatty acids are $C_{18:1}$ and $C_{18:0}$.**

Cells grow preferentially photoheterotrophically under anoxic conditions in the light. **Chemotrophic growth is possible under microoxic to oxic conditions in the dark.** Complex nutrients are required. **Halophilic bacteria that require NaCl or sea salt for growth** and have salt optima above seawater salinity. Habitat: anoxic zones of hypersaline environments such as salterns and salt lakes that are exposed to the light.

The mol% G + C of the DNA is: 66–67.

Type species: **Rhodovibrio salinarum** (Nissen and Dundas 1985) Imhoff, Petri and Süling 1998, 797 (*Rhodospirillum salinarum* Nissen and Dundas 1985, 224.)

FURTHER DESCRIPTIVE INFORMATION

Growth of *Rhodovibrio* species depends on hypersaline concentrations of salts. Both species grow well at 2 M NaCl. They show best growth in the presence of 0.1 M Mg^{2+} and can grow in media containing 1 M $MgCl_2$ (Mack et al., 1993). In contrast to *R. sodomensis*, which is tolerant to NaBr up to concentrations of 1.5 M, growth of *R. salinarum* is inhibited at much lower concentrations of NaBr (Mack et al., 1993). In response to the external salinity, glycine betaine and ectoine are accumulated as major and minor components, respectively, of the compatible solutes (Severin et al., 1992; Imhoff, 1992).

R. salinarum and *R. sodomensis* are unique among the spiral-shaped phototrophic *Alphaproteobacteria* in that they do not contain a soluble cytochrome c_2 (Moschettini et al., 1997; Bonora et al., 1998). *R. salinarum*, but not *R. sodomensis*, lacks a branched respiratory chain if grown aerobically in the dark (Moschettini et al., 1997). It contains two different high-potential iron–sulfur proteins (HiPIP), whereas *R. sodomensis* lacks HiPIPs (Bonora et al., 1998).

ENRICHMENT AND ISOLATION PROCEDURES

Rhodovibrio species are characterized by their requirement for high salt concentrations and complex nutrients. Therefore, complex media with salt concentrations of 10% and incubation anaerobically in the light provide selective conditions for the enrichment of *Rhodovibrio* species. Standard techniques for isolation of anaerobic bacteria in agar dilution series and on agar plates can be applied for *Rhodovibrio* species (Imhoff, 1988; Imhoff and Trüper, 1992). The medium of Nissen and Dundas (1984) is suitable for growth of *Rhodovibrio salinarum* and can also be used for *Rhodovibrio sodomensis*. A recipe for this medium is given below.[1]

MAINTENANCE PROCEDURES

Cultures can be preserved by standard techniques in liquid nitrogen, by lyophilization, or storage at −80°C in a mechanical freezer.

DIFFERENTIATION OF THE GENUS *RHODOVIBRIO* FROM OTHER GENERA

Major differentiating properties for *Rhodovibrio* species and other phototrophic spiral-shaped *Alphaproteobacteria* are shown in Table BXII.α.1 in the description of the genus *Rhodospirillum*.

TAXONOMIC COMMENTS

Two species, *Rhodovibrio salinarum* and *Rhodovibrio sodomensis*, are currently recognized (Imhoff et al., 1998). Because of their spiral shape and phototrophic capacity, *Rhodovibrio* species were originally assigned to the genus *Rhodospirillum* (Nissen and Dundas, 1984; Mack et al., 1993). With growing recognition of the high phenotypic and chemotaxonomic diversity of spiral-shaped phototrophic *Alphaproteobacteria* and the great genetic distance between most of these bacteria, a rearrangement of the species of this group became necessary. Several distinct differences between *Rhodovibrio* species and *Rhodospirillum rubrum* led to their reclassification in the new genus *Rhodovibrio* (Imhoff et al., 1998). The genus name *Rhodovibrio* had originally been proposed by Molisch (1907) for bacteria (*Rhodovibrio parvus*) later recognized as belonging to *Rhodopseudomonas palustris*. Because this name was not included in the Approved List of Names, it had no standing in nomenclature and could be revived (Imhoff et al., 1998). The phylogenetic relationships of these bacteria based on 16S rDNA sequences are shown in Fig. 1 (p. 124) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A.

1. The medium contains (g/l): NaCl, 80; $MgCl_2 \cdot 6H_2O$, 0.4; $CaCl_2 \cdot 2H_2O$, 0.1; $(NH_4)_2SO_4$, 0.5; KH_2PO_4, 2.5; sodium acetate, 1; sodium glutamate 1; and trace element solution SLA, 1 ml. The initial pH is adjusted to 7.0 (see also Imhoff, 1988).

Differentiation of the species of the genus *Rhodovibrio*

Major differentiating properties for *Rhodovibrio* species are shown in Table BXII.α.1 in the description of the genus *Rhodospirillum*.

List of species of the genus Rhodovibrio

1. **Rhodovibrio salinarum** (Nissen and Dundas 1985) Imhoff, Petri and Süling 1998, 797[VP] (*Rhodospirillum salinarum* Nissen and Dundas 1985, 224.)
sal.i.na′ rum. L. fem. pl. n. *salinae* saltern or saltworks; M.L. adj. *salinarum* of a saltern.

Cells are rod shaped to spiral, 0.8–0.9 × 1.0–3.5 μm, and motile by means of bipolar flagella. Internal photosynthetic membranes are present as vesicles. Color of anaerobically grown cultures is red. Absorption maxima of living cells are at 380, 490, 520, 550, 595, 800, and 870 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series with spirilloxanthin as the major component.

Growth occurs equally well photoheterotrophically under anoxic conditions in the light and chemoheterotrophically under oxic conditions in the dark. Cells have a complex nutrient requirement and do not grow in the absence of substantial amounts of yeast extract or peptone. In the presence of low amounts of peptone and yeast extract (0.015% each), Casamino acids and lactate support growth, but acetate, citrate, fumarate, glutamate, malate, propionate, pyruvate, succinate, fructose, galactose, glucose, sorbose, sucrose, glycerol, and mannitol do not. Sulfide and S^0 are not used as electron donors for photosynthesis.

Obligately and moderately halophilic bacterium with optimum growth at 42°C (temperature range: 20–45°C), pH 7.5–8.0 and 8–12% NaCl (range 3–24%). Habitat: anoxic zones of hypersaline environments such as salterns and salt lakes that are exposed to the light.

The mol% G + C of the DNA is: 67.4 (Bd) and 68.1 (T_m).
Type strain: ATCC 35394, DSM 9154.
GenBank accession number (16S rRNA): M59069.

2. **Rhodovibrio sodomensis** (Mack, Mandelco, Woese and Madigan 1996) Imhoff, Petri and Süling 1998, 797[VP] (*Rhodospirillum sodomense* Mack, Mandelco, Woese and Madigan 1996, 1189.)
so.do.men′ sis. M.L. masc. adj. *sodomensis* pertaining to the Sea of Sodom, the Talmudic name for the Dead Sea.

Cells vibrio shaped, occasionally true spirilla, 0.6–0.7 × 1.6–2.5 μm and weakly motile, presumably by polar flagella. Internal photosynthetic membranes are of the vesicular type. Photosynthetic cultures appear pink and major absorption maxima of living cells are at 377, 421, 516, 551, 591, and 875–880 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series. A B875 light-harvesting complex (but not a B800/850 complex) is present.

Growth occurs photoheterotrophically under anoxic conditions in the light only in the presence of yeast extract. At low concentrations of yeast extract, growth is stimulated by acetate, malate, pyruvate, or succinate, but not by propionate, butyrate, and citrate. Chemotrophic growth is possible under oxic conditions in the dark with acetate and succinate in the presence of 0.3–0.5% yeast extract. Nitrogen sources used are ammonia and yeast extract, but evidence for N_2 fixation is lacking. Poly-β-hydroxybutyrate is produced as a storage polymer. Complex nutrients are required, and can be supplied with 0.01% yeast extract.

Obligately and moderately halophilic bacterium with optimum growth at 35–40°C (range 25–47°C), pH 7.0, and 12% NaCl (salt range: 6–20% NaCl). Extremely bromide tolerant, growing well if 50–75% of NaCl is replaced by NaBr (up to 1.5 M NaBr). Habitat: anoxic parts of sediments and water of the Dead Sea that are exposed to the light.

The mol% G + C of the DNA is: 66.2–66.6 (T_m).
Type strain: ATCC 51195.
GenBank accession number (16S rRNA): M59072.

Genus IX. **Roseospira** *Imhoff, Petri and Süling 1998, 797*[VP]

Johannes F. Imhoff and Vladimir M. Gorlenko

Ro′se.o.spi′ ra. L. adj. *roseus* rosy; Gr. n. *spira* the spiral; M.L. fem. n. *Roseospira* the rosy spiral.

Cells are vibrioid to spiral shaped, motile by means of polar flagella and multiply by binary fission. **Gram negative, belonging to the *Alphaproteobacteria*.** Internal photosynthetic membranes are present as vesicles. Photosynthetic pigments are **bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series**.

Cells grow preferentially photoheterotrophically under anoxic conditions in the light. Chemotrophic growth is possible under microoxic conditions in the dark. Growth factors are required. **Halophilic bacteria that require NaCl or sea salt for growth**.

Habitat: warm sulfur spring with elevated mineral salts concentration.

The mol% G + C of the DNA is: 66.6.

Type species: **Roseospira mediosalina** (Kompantseva and Gorlenko 1984) Imhoff, Petri and Süling 1998, 798 (*"Rhodospirillum mediosalinum"* Kompantseva and Gorlenko 1984, 780.)

Enrichment and Isolation Procedures

Roseospira mediosalina was isolated from microbial mats of a warm sulfur spring (43–51°C) with elevated mineral salts concentration (2% total salts) and alkaline pH (pH 8.2) (Kompantseva and Gorlenko, 1984). Media and growth conditions applied for *Rhodospirillum* species are also suitable for *Roseospira* species, if appropriate salt concentrations are supplied. A recipe for a mineral salts medium, which can be used if 5% NaCl is added, is given with the description of the genus *Rhodospirillum*. Standard techniques for isolation of anaerobic bacteria in agar dilution series and on agar plates can be applied for *Roseospira* species (Imhoff, 1988; Imhoff and Trüper, 1992). *Roseospira mediosalina* can also be grown on Pfennig's medium for purple sulfur bacteria (see Genus *Chromatium*) with the addition of 5% NaCl and vitamins (or yeast extract).

Maintenance Procedures

Cultures can be preserved by standard techniques in liquid nitrogen, by lyophilization, or storage at −80°C in a mechanical freezer.

Differentiation of the genus *Roseospira* from other genera

Major differentiating properties for *Roseospira mediosalina* and other spiral-shaped phototrophic *Alphaproteobacteria* are shown in Table BXII.α.1 and carbon sources utilized in Table BXII.α.2 in the description of the genus *Rhodospirillum*. The phylogenetic relationships of these bacteria based on 16S rDNA sequences are shown in Fig. 1 (p. 124) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A.

Taxonomic Comments

Because of their spiral shape and phototrophic capacity, *Roseospira* species were originally assigned to the genus *Rhodospirillum*, although DNA homology to *R. rubrum* was insignificant (Kompantseva and Gorlenko, 1984). With growing recognition of the high phenotypic and chemotaxonomic diversity of spiral-shaped phototrophic *Alphaproteobacteria* and the great genetic distance between most of these bacteria (Kawasaki et al., 1993b), a rearrangement of the species of this group became necessary (Imhoff et al., 1998). The great differences between *Roseospira* and *Rhodospirillum* led to their reclassification (Imhoff et al., 1998). The phylogenetic relationships of these bacteria based on 16S rDNA sequences are shown in Fig. 1 (p. 124) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume, 2 Part A.

List of species of the genus Roseospira

1. **Roseospira mediosalina** (Kompantseva and Gorlenko 1984) Imhoff, Petri and Süling 1998, 798[VP] (*"Rhodospirillum mediosalinum"* Kompantseva and Gorlenko 1984, 780.)
me′di.o.sa.li′na. L. adj. *medius* medium; L. neut. n. *salinum* saline, salty; M.L. fem. n. *mediosalina* living at a moderate salinity, moderate halophile.

Cells are vibrioid to spiral shaped, 0.8–1.0 × 2.2–6.0 µm; complete turn of a spiral is 4.0–5.2 µm. They are motile by means of polar flagella and multiply by binary fission. Internal photosynthetic membranes are present as vesicles. Color of cell suspension ranges from pinkish to brownish red. Absorption maxima of living cells occur at 379, 474, 504, 534, 591, 803, and 860 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the normal spirilloxanthin series.

Growth is preferentially photoheterotrophic in the presence of organic substrates. Photolithoautotrophic growth occurs with sulfide. Sulfide is oxidized to S^0, which is deposited outside the cell and not further oxidized. Sulfide tolerance is high (up to 2 mM). Thiosulfate does not serve as an electron donor. Chemotrophic growth is possible under microoxic conditions in the dark in the presence of organic substrates. Fatty acids, butyrate, lactate, pyruvate, amino acids (alanine, aspartate, glutamate), intermediates of the tricarboxylic acid cycle (malate, succinate, fumarate), yeast extract, and Casamino acids are used as carbon sources and electron donors. Benzoate, malonate, tartrate, formate, citrate, alcohols, sugars, and sugar alcohols are not used. Ammonium salts and urea can be utilized as nitrogen sources. Capable of assimilatory sulfate reduction. Storage material is poly-β-hydroxybutyrate. Catalase positive. Thiamine, niacin, and *p*-aminobenzoate are required for growth.

Halophilic bacterium with optimum growth at 30–35°C, pH 7.0, and NaCl concentrations of 4–7% (NaCl range: 0.5–15%). No growth in the absence of salts. No growth above 40°C. Habitat: warm sulfur spring Astara (Azerbaijian) with elevated mineral salts concentration of 2%.

The mol% G + C of the DNA is: 66.6 (T_m).

Type strain: BN 280.

GenBank accession number (16S rRNA): AJ000989.

Genus X. **Roseospirillum** *Glaeser and Overmann 2001, 793^VP (Effective publication: Glaeser and Overmann 1999, 414)*

JOHANNES F. IMHOFF

Ro.se.o.spi.ril′lum. L. adj. *roseus* rosy; M.L. neut. n. *spirillum* the spiral, a bacterial genus; M.L. neut. n. *Roseospirillum* the rosy spiral.

Cells are vibrioid to spiral shaped, motile by means of polar flagella and multiply by binary fission. **Gram negative and belong to the *Alphaproteobacteria*.** Internal photosynthetic membranes are present as lamellar stacks. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids.

Cells grow photolithoautotrophically and photoheterotrophically under anoxic conditions in the light. Chemotrophic growth is possible under microoxic conditions in the dark. Growth factors are required. Marine bacteria that **require NaCl or sea salt for optimum growth**.

Habitat: marine sediments and microbial mats.

The mol% G + C of the DNA is: 71.2.

Type species: **Roseospirillum parvum** Glaeser and Overmann 2001, 793 (Effective publication: Glaeser and Overmann 1999, 414.)

Enrichment and Isolation Procedures

Media and growth conditions applied for *Rhodospirillum* species are also suitable for *Roseospirillum* species, if appropriate salt concentrations are supplied. A recipe of a mineral salts medium that can be used if 1–2% NaCl is added is given with the description of the genus *Rhodospirillum*. Standard techniques for isolation of anaerobic bacteria in agar dilution series and on agar plates can be applied (Imhoff, 1988; Imhoff and Trüper, 1992).

Maintenance Procedures

Cultures can be preserved by standard techniques in liquid nitrogen, by lyophilization or storage at −80°C in a mechanical freezer.

Differentiation of the genus *Roseospirillum* from other genera

Major differentiating properties between *Roseospirillum parvum* and other spiral-shaped phototrophic *Alphaproteobacteria* are shown in Table BXII.α.1, carbon sources utilized in Table BXII.α.2. The phylogenetic relationships of these bacteria based on 16S rDNA sequences are shown in Fig. 1 (p.124) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A.

List of species of the genus Roseospirillum

1. **Roseospirillum parvum** Glaeser and Overmann 2001, 793^VP (Effective publication: Glaeser and Overmann 1999, 414.)
par′vum. M.L. neut. adj. *parvum* small.

Cells are vibrioid to spiral shaped, 0.4–0.6 × 1.8–2.6 µm, motile by means of bipolar flagella and multiply by binary fission. Internal photosynthetic membranes are present as lamellae. Color of a cell suspension is pink to pinkish-red. Absorption maxima of living cells occur at 380, 492, 515, 549, 595, 806, and 911 nm. Photosynthetic pigments are bacteriochlorophyll *a* and the carotenoids spirilloxanthin and lycopenal.

Photolithoautotrophic growth occurs with sulfide and thiosulfate. Sulfide is oxidized to elemental sulfur, which is deposited outside the cells and not further oxidized to sulfate. In the presence of sulfide and bicarbonate, acetate, propionate, butyrate, valerate, oxoglutarate, pyruvate, lactate, succinate, fumarate, malate, fructose, Casamino acids, yeast extract, L-alanine, and L-glutamate were assimilated. Chemotrophic growth is possible under microoxic conditions in the dark (with thiosulfate or with thiosulfate and acetate). Incapable of assimilatory sulfate reduction. Yeast extract is required to supply growth factors.

Marine bacterium with optimum growth at 30°C, pH 7.9, and concentrations of 1–2% NaCl (range: up to more than 6% NaCl).

Habitat: microbial mats of Great Sippewissett Salt Marsh.

The mol% G + C of the DNA is: 71.2 (HPLC).

Type strain: 930I, DSM 12498.

GenBank accession number (16S rRNA): AJ011919.

Genus XI. **Skermanella** *Sly and Stackebrandt 1999, 543^VP*

THE EDITORIAL BOARD

Sker.ma.nel′la. M.L. dim. *-ella* ending; M.L. fem. dim. n. *Skermanella* named after V.B.D. Skerman, who first isolated this bacterium, and in honor of his contribution to bacterial systematics.

Gram negative, with unicellular and multicellular growth phases. Does not form spores. Unicellular phase cells are rod shaped, with rounded or tapered ends and a straight or curved axis. Motile with single polar flagellum and one or more lateral flagella of different wavelengths. **Multicellular phase conglomerates** arise from cells that lose motility, become optically refractile, and **reproduce by multiplanar septation**. No filamentous structures or buds are formed. Obligately chemoorganotrophic and **facultatively anaerobic**, having fermentative metabolism. Belongs to the *Alphaproteobacteria*.

The mol% G + C of the DNA is: 67.2 ± 0.8.

Type species: **Skermanella parooensis** (Skerman, Sly and Williamson 1983) Sly and Stackebrandt 1999, 543 (*Conglomeromonas largomobilis* subsp. *parooensis* Skerman, Sly and Williamson 1983, 307.)

List of species of the genus Skermanella

1. **Skermanella parooensis** (Skerman, Sly and Williamson 1983) Sly and Stackebrandt 1999, 543[VP] (*Conglomeromonas largomobilis* subsp. *parooensis* Skerman, Sly and Williamson 1983, 307.)
pa.roo.en' sis. M.L. fem. (and masc.) adj. *parooensis* belonging/pertaining to the Paroo, referring to the Paroo Channel in southwest Queensland, Australia, the source of the water from which the organism was isolated.

Characteristics are as described for the genus, with the following additions. Cells are 1.0–1.5 × 1.5 µm (peptone yeast extract agar) or 1.0–1.5 × 2–3 µm (lake water agar). Noncapsulated. Separated colonies on peptone yeast extract agar are in conglomerate form. Colonies are apricot-colored, opaque, round, and raised, with a rough surface and irregular edge after 72 h at 28°C. Conglomerates have dry appearance and are difficult to emulsify. Confluent growth of single cells is mucoid and emulsifies easily. Conglomerates have the same or greater diameter as colonies of the unicellular form. Colonies grown in the presence of Congo red do not turn scarlet. Aging cells contain poly-β-hydroxybutyrate inclusions. Optimal temperature: 28°C; range 10–37°C. Growth occurs on peptone yeast-extract agar, 0.1% peptone agar, glucose-ammonium sulfate agar, citrate-ammonium agar, and lake water agar. Slower growth occurs in the presence of 2% NaCl in the conglomerate form. No growth in the presence of 5% NaCl. Catalase, oxidase, aminopeptidase, phosphatase, deoxyribonuclease, and urease are produced. Nitrate reduced to nitrite. Utilizes citrate and malonate. Hydrolyzes Tween 80, but not esculin, chitin, alginate, cellulose, gelatin, or casein. Acid but not gas from cellobiose, galactose, glucose, inositol, lactose, mannitol, mannose, melibiose, and rhamnose. No acid from adonitol, amygdalin, D-arabinose, arabitol, dextrin, dulcitol, erythritol, ethanol, fructose, glycerol, inulin, maltose, melizitose, raffinose, D-ribose, salicin, sorbitol, L-sorbose, starch, sucrose, trehalose, or xylose. Utilizes the following carbon sources: D-arabinose, L-arabinose, D-fructose, gentiobiose, D-galactose, D-glucose, D-lyxose, D-mannitol, D-mannose, melibiose, L-rhamnose, D-ribose, and D-xylose, but not *N*-acetylglucosamine, D-cellobiose, D-gluconate, glycerol, inositol, lactose, maltose, D-sorbitol, or D-trehalose. The type strain was isolated from fresh water.

The mol% G + C of the DNA is: 67.2 ± 0.8.

Type strain: ACM 2042, CIP 106994, DSM 9527, UQM 2042.

GenBank accession number (16S rRNA): X90760.

Genus Incertae Sedis XII. **"Sporospirillum"** *Delaporte 1964, 257*

Bruno Pot and Monique Gillis

Spor.o.spi.ril' lum. Gr. n. *sporos* a seed (spore); Gr. n. *spira* a spiral; M.L. dim. n. *spirillum* a small spiral; M.L. neut. n. *Sporospirillum* a small spore (-forming) spiral.

Rigid, helical bacteria of enormous size, 1.8–4.8 µm in diameter and 40–100 µm in length. Structures that morphologically resemble endospores occur within the cells, but their thermal resistance has not been determined. **The spore-like structures have the ability to rotate and to migrate within the cytoplasm of the bacteria.** They initially develop near the cell poles and subsequently migrate to the center where they are released after the cell ruptures and disintegrates. The Gram reaction has not been reported. The cells are **motile, but no organs of locomotion are evident**. The relationship of the cells to oxygen is unknown. Occur in the intestinal contents of tadpoles. Have not been isolated. A type strain has not been designated.

The mol% G + C of the DNA is: not determined.

Type species: **"Sporospirillum bisporum"** Delaporte 1964, 260.

Acknowledgments

We sincerely acknowledge Dr. N.R. Krieg for kindly providing the template text upon which this chapter was based.

List of species of the genus "Sporospirillum"

1. **"Sporospirillum bisporum"** Delaporte 1964, 260.
bi.spo' rum. L. adv. *bis* twice; G. n. *sporos* a seed; M.L. gen. pl. n. *bisporum* of two seeds (spores).

Cell diameter is 3.5–4.8 µm. Cell length is 50–90 µm. Diameter of helix is 11–15 µm. Wavelength is 27–35 µm. An endospore (2–4 × 10–14 µm) occurs at each pole.

The mol% G + C of the DNA is: not determined.

Deposited strain: none designated.

2. **"Sporospirillum gyrini"** Delaporte 1964, 259.
gy.ri' ni. L. n. *gyrinus* a tadpole; L. gen. n. *gyrini* of a tadpole.

Cell diameter is 1.8–2.6 µm. Cell length is 40–100 µm. Diameter of helix is 3–6 µm. Wavelength is 13–20 µm. A single endospore is present, 2 × 5–7 µm.

The mol% G + C of the DNA is: not determined.

Deposited strain: none designated.

3. **"Sporospirillum praeclarum"** (Collin 1913) Delaporte 1964, 259 (*Spirillum praeclarum* Collin 1913, 62.)
prae.cla' rum. L. adj. *praeclarum* distinguished, famous.

Cell diameter is 3.0–4.0 µm. Cell length is 50–100 µm. Diameter of helix is 5–10 µm. Wavelength is 17–23 µm. A single endospore is present, 3–4 × 9–12 µm. A type strain has not been designated.

The mol% G + C of the DNA is: not determined.

Deposited strain: none designated.

Family II. **Acetobacteraceae** Gillis and De Ley 1980, 23[VP]

MARTIN SIEVERS AND JEAN SWINGS

A.ce.to.bac.te.ra' ce.ae. M.L. masc. n. *Acetobacter* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Acetobacteraceae* the *Acetobacter* family.

The family *Acetobacteraceae*, the Gram-negative, aerobic, acetic acid bacteria, has undergone many taxonomic changes in respect to their genus status. Several species of acetic acid bacteria were newly described. Relationships among the acetic acid bacteria were studied genotypically by DNA–rRNA hybridization, DNA–DNA hybridization, and ribosomal RNA gene sequences (5S rRNA, 16S rRNA, and 23S rRNA). Changes at the generic level in the classification of some acetic acid bacteria are given in Table BXII.α.9. Phenotypic characteristics of six genera are shown in Table BXII.α.10. *Gluconacetobacter*, *Acidomonas*, and *Asaia* as well as *Gluconobacter* species, possess Q-10 ubiquinone as the major quinone component. The Q-10 equipped species contain in addition minor amounts of ubiquinone of the Q-9 type. The ubiquinone system of *Acetobacter pasteurianus*, *Acetobacter pomorum*, and *Acetobacter aceti* is Q-9 along with minor components of ubiquinone of the Q-8 type.

Type genus: **Acetobacter** Beijerinck 1898, 215.

FURTHER DESCRIPTIVE INFORMATION

Sugar metabolism Acetic acid bacteria catabolize sugars by means of the cytoplasmic hexose monophosphate pathway. Glycolysis is absent due to lack of phosphofructokinase (Leisinger, 1965; Attwood et al., 1991). The Entner–Doudoroff pathway occurs only in cellulose-synthesizing *Gluconacetobacter* strains, where it appears to be more active than the hexose monophosphate cycle (White and Wang, 1964a, b). The ability to grow on glycerol is due to gluconeogenesis. Specific activities of the key enzymes of the gluconeogenic pathway such as fructose bisphosphatase, fructose bisphosphate aldolase, triosephosphate isomerase, and glycerophosphate dehydrogenase have been described for *Gluconacetobacter diazotrophicus* (Alvarez and Martínez-Drets, 1995). Strains that are able to grow on Hoyer's medium[1] with ethanol as the sole source of carbon and $(NH_4)_2SO_4$ as the only source of nitrogen utilize the glyoxylate bypass (Leisinger, 1965; De Ley et al., 1984).

Alcohol and aldehyde dehydrogenases of acetic acid bacteria The oxidizing systems of acetic acid bacteria are shown in Table BXII.α.11. Acetic acid bacteria oxidize ethanol to acetic acid by two successive catalytic reactions of a membrane-bound alcohol dehydrogenase (ADH) and a membrane-bound aldehyde dehydrogenase (ALDH). The enzymes are bound to the cytoplasmic membrane and face the periplasmic space. The ADH and ALDH complexes are tightly linked to the respiratory chain,

1. Hoyer's medium with ethanol consists of (per liter of distilled water): ethanol (99.8 %), 20 ml; $(NH_4)_2SO_4$, 1.0 g; K_2HPO_4, 0.1 g; KH_2PO_4, 0.9 g; $MgSO_4 \cdot 7H_2O$, 0.25 g; and $FeCl_3$, 0.005 g.

Raffinose	−	nd	−	−	−	+
Cellular fatty acid type	$C_{18:1\ \omega7}$	$C_{18:1\ \omega7}$	$C_{18:1\ \omega7}$	$C_{18:1\ \omega7}$	$C_{18:1\ \omega7}$	$C_{18:1\ \omega7}$
Ubiquinone type	Q-9	Q-10	Q-10	Q-10	Q-10	Q-10
DNA base composition (mol% G + C)	52–60	63–66	59–61	55–66	54–63	56–57

[a]Symbols: +, 90% or more of the strains positive; w, weakly positive reaction; −, 90% or more of the strains negative.

[b]*Asaia* does not produce acetic acid from ethanol with the exception of one strain producing acid weakly (Yamada et al., 2000).

[c]Overoxidation of acetate to CO_2 and H_2O depends on acetate concentration in the medium.

[d] *A. pomorum* assimilates methanol weakly (Sokollek et al., 1998b).

TABLE BXII.α.11. Oxidizing capacity of acetic acid bacteria

Substrate	Product	Enzyme
Ethanol	Acetic acid	Alcohol dehydrogenase, aldehyde dehydrogenase
iso-Butanol	*iso*-Butyric acid	Alcohol dehydrogenase, aldehyde dehydrogenase
α-Acetolactate	Acetoin	α-Acetolactate decarboxylase
D-Glycerol	Dihydroxyacetone	Glycerol dehydrogenase
D-Mannitol	D-Fructose	D-Mannitol dehydrogenase
D-Sorbitol	L-Sorbose	D-Sorbitol dehydrogenase
D-Glucose	D-Gluconic acid	D-Glucose dehydrogenase
D-Gluconic acid	2-Keto-D-gluconic acid	D-Gluconate dehydrogenase
D-Gluconic acid	5-Keto-D-gluconic acid	D-Gluconate dehydrogenase
2-Keto-D-gluconic acid	2,5-Diketo-D-gluconic acid	2-Keto-D-gluconate dehydrogenase
L-Sorbose	L-Sorbosone	L-Sorbose dehydrogenase
L-Sorbosone	2-Keto-D-gulonic acid	L-Sorbosone dehydrogenase
D-Fructose	5-Keto-D-fructose	D-Fructose dehydrogenase

which transfers electrons via ubiquinone and a terminal ubiquinol oxidase to oxygen as final electron acceptor.

The ADH complex in acetic acid bacteria is composed of two or three subunits. The molecular weight of the subunits estimated by SDS-PAGE are 72, 44, and 15 kDa in *Gluconobacter oxydans* (Kondo and Horinouchi, 1997b), 72, 50, and 15 kDa in *Acetobacter aceti* (Inoue et al., 1989, 1992; Matsushita et al., 1992d), 78, 48, and 20 in *Acetobacter pasteurianus* (Kondo et al., 1995), 80, 54, and 8 kDa in *Acidomonas methanolica* (Frébortová et al., 1997), 72 and 44 kDa in *"Acetobacter polyoxogenes"* (Tayama et al., 1989; Tamaki et al., 1991), and 80 and 49 kDa in *Gluconacetobacter europaeus* (Thurner, 1997). The larger subunit of the ADH possesses a heme C and a pyrroloquinoline quinone (PQQ) as cofactors and requires Ca^{2+} to be active, according to the catalytic mechanism given by Anthony (1996) and Goodwin and Anthony (1998). The second subunit is a cytochrome *c*. The third and smallest subunit of the three-component ADH is discussed to protect the catalytic subunit from proteolysis and to keep the correct conformation of the ADH complex for electron transport on the periplasmic surface (Kondo et al., 1995). The genes encoding the dehydrogenase subunit and the cytochrome *c* subunit of ADH are clustered in the same transcription polarity and were cotranscribed. The cytochrome *c* subunit of the ADH complex of *Gluconobacter oxydans* has an additional function: it is a component of the non-energy-generating cyanide-insensitive bypass terminal oxidase in the respiratory chain (Matsushita et al., 1994). Thus, the cytochrome *c* subunit gene of *Gluconobacter oxydans* is transcribed independently from the dehydrogenase subunit gene (Matsushita et al., 1989). The ADH activity of *Acetobacter pasteurianus* is induced by ethanol. The ADH gene cluster utilizes two different promoters for its expression, in response to the presence or absence of ethanol in the culture medium (Takemura et al., 1993). Since ethanol is the major substrate for energy generation in acetic acid bacteria through the ADH and ALDH reactions, the role of the function of ethanol in regulatory mechanisms is to be elucidated. Transcription of the gene encoding the enzyme arylesterase, which is related in ethylacetate formation from acetic acid and ethanol, is induced by ethanol in *Acetobacter pasteurianus* (Kashima et al., 1999). In vinegar, esters weaken the strong smell of acetic acid (Kashima et al., 1999).

The ALDH complex of acetic acid bacteria, which catalyzes the oxidation of acetaldehyde to acetic acid, is composed of two

or three subunits. The molecular masses are 86 and 55 kDa for *Gluconobacter oxydans*, 78, 45, and 14 kDa for *Acetobacter aceti*, and 75 and 19 kDa for *"A. polyoxogenes"* (Tamaki et al., 1989; Matsushita et al., 1994). The ALDH from *Gluconacetobacter europaeus* is composed of three subunits with molecular masses of 79, 49, and 17 kDa. The aldehyde dehydrogenase complex is organized as an operon. The larger catalytic subunit contains heme *b* and a pterin molybdenum instead of PQQ. The middle subunit is a cytochrome *c* with three heme *c* binding sites. The smallest subunit contains two [2Fe-2S] clusters (Thurner, 1997; Thurner et al., 1997). The catalytic subunit of the ALDH of *Gluconacetobacter europaeus* differs by nine amino acids from the corresponding protein of *"A. polyoxogenes"*. Each gene of the ADH and ALDH subunits contains a signal sequence encoding for a leader peptide, responsible for translocation of the proteins through the cytoplasmic membrane. The ADH and ALDH of acetic acid bacteria have a broad substrate specificity and oxidize straight and branched chain alcohols and aldehydes into the corresponding carboxylic acids.

Alcohol and aldehyde dehydrogenases dependent on $NAD(P)^+$ have been isolated and characterized from the cytoplasm of acetic acid bacteria. The $NAD(P)^+$-dependent enzymes show an activity optimum at alkaline pH with much lower specific activities than those of quinoprotein enzymes, which show activity optimum at acidic pH (Matsushita et al., 1994).

Aldehydes produced during food processing can react with amino groups to form colored materials. ADH can scavenge aldehydes and carbonyl residues and since carboxylic acids react little with amino acids, the addition of acetic acid bacteria prevents coloration of food and reduces off-flavors (Nomura et al., 1995a). For instance, to reduce the stale flavor of cooked rice, rice grains have been incubated with a freeze-dried powder of acetic acid bacteria at 50°C, which resulted in a decrease of *n*-hexanol in the rice (Nomura et al., 1995b). Another example of the use of acetic acid bacteria to reduce off-flavors in food involves the cloning and expression of the gene that encodes α-acetolactate decarboxylase from *Gluconacetobacter xylinus* in brewer's yeast: during beer fermentation, brewer's yeasts produce α-acetolactate, which is converted to diacetyl by slow nonenzymatic oxidative decarboxylation. Diacetyl causes off-flavors in beer. The α-acetolactate decarboxylase of *Gluconacetobacter xylinus* converts the α-acetolactate directly to acetoin, which has no effect on the flavor of beer (Yamano et al., 1994).

Acetobacter, *Gluconacetobacter*, and *Acidomonas* are, in contrast to *Gluconobacter*, equipped with a complete tricarboxylic acid (TCA) cycle. The amount of TCA cycle enzymes in cells is correlated with the energy requirement of the cells (Rault-Leonardon et al., 1995). Key enzymes of the TCA cycle are influenced by different intermediate metabolites; an example is the citrate synthase of *Gluconacetobacter europaeus*, which is activated by acetate (Sievers et al., 1997). *Gluconacetobacter* and *Acetobacter* species producing high concentrations of acetic acid are not able to keep the internal pH constant and need additional ATP for internal protection against acetate and H^+ (Menzel and Gottschalk, 1985). Bacteria have to use acid-resistant systems like genes that are induced by environmental stimuli even if the cytoplasm is acidified by low external pH (Kobayashi et al., 2000). As shown for *Acetobacter aceti* and *Gluconobacter oxydans*, eight acetate-specific stress proteins (Asps) were overexpressed in both species during growth in the presence of acetate. Three Asps were similar and five Asps were different in both species analyzed by two-dimensional gel electrophoresis of total protein extracts (Lasko et al., 1997). The acetate-activating enzyme, acetyl-CoA synthetase, has been purified from the cytoplasm of *Gluconacetobacter europaeus* and *Gluconobacter oxydans*. The native acetyl-CoA synthetase of *Gluconacetobacter europaeus* and *Gluconobacter oxydans* has a molecular mass near 150 kDa and is composed of two identical subunits with a molecular mass near 75 kDa, suggesting that the enzyme is a dimer. Due to the instability of the enzyme, 15% glycerol was included in the buffer system used. The activity of the acetyl-CoA synthetase was inhibited by AMP, ADP, and Na-citrate (M. Sievers, F. Tschudin, and M. Teuber, unpublished results). The activity of this enzyme is increased significantly in *Acetobacter* cells when acetate is consumed. Addition of glycerol to the culture medium of *"Acetobacter rancens"* increased acetate oxidation (Saeki et al., 1999). The genes responsible for acetic acid resistance in *Acetobacter aceti* are described by Fukaya et al. (1990) and Fukaya et al. (1993).

Respiratory chains Acetic acid bacteria are oxidase negative, with the exception of *Acidomonas methanolica*, which is oxidase positive during growth on methanol. The respiratory chain in *Gluconobacter* consists of cytochrome *c*, ubiquinone, and cytochrome *o* as a terminal ubiquinol oxidase; it also has a cyanide-insensitive alternative terminal ubiquinol oxidase. The respiratory chain in *Acetobacter* and *Gluconacetobacter* has cytochrome *c*, ubiquinone, and a terminal ubiquinol oxidase of the cytochrome a_1, cytochrome *d*, or cytochrome *o* type (Matsushita et al., 1994). The respiratory chain of *Acidomonas methanolica* contains two different terminal oxidases, viz. a cytochrome *c* oxidase and an ubiquinol oxidase (Matsushita et al., 1992c). Under methylotrophic conditions, *Acidomonas methanolica* produces a cytochrome *co* terminal cytochrome *c* oxidase (Chan and Anthony, 1991). When grown under nonmethylotrophic conditions, however, *Acidomonas methanolica* produces cytochrome *o* as the terminal ubiquinol oxidase (Matsushita et al., 1994). Cytochrome *o* from *Acetobacter aceti* and *Acidomonas methanolica* contains heme *o* (Puustinen and Wikström, 1991) and heme *b* in a 1:1 ratio (Matsushita et al., 1992b). One cell type of *Acetobacter aceti* forms smooth-surfaced colonies, while the other cell type of *Acetobacter aceti* forms rough-surfaced colonies. Cells of the former type predominate in shaking cultures, while cells of the latter type predominate in static cultures. There is a difference in the terminal oxidase, which is cytochrome a_1 in cells in shaking culture, but cytochrome *o* in cells grown statically (Matsushita et al., 1992a, 1994). Cytochrome a_1 has a higher affinity for oxygen than cytochrome *o* (Matsushita et al., 1992b), which results in enhanced growth of smooth-surfaced cells of *Acetobacter aceti* in shaking culture. The two different types of colonies of *Acetobacter aceti* with their corresponding types of cytochrome are shown in Fig. BXII.α.15 (Matsushita et al., 1994).

α-Amino acid ester hydrolase The α-amino acid ester hydrolase from *"Acetobacter turbidans"* ATCC 9325 is a beta-lactam antibiotic acylase capable of hydrolyzing beta-lactam antibiotics (cephalexin, ampicillin). The enzyme also catalyzes the transfer of the acyl group from α-amino acid esters to 7-aminocephem and 6-penam compounds. *"Acetobacter turbidans"* ATCC 9325 was described by Takahashi et al. (1972, 1974) as an acetic acid bacterium able to synthesize cephalosporins. The gene *aehA* (AF439262) encodes a dimeric protein with subunits of 70 kDa and an N-terminal leader sequence of 40 amino acids. The α-amino acid ester hydrolase has the motif GXSYXG in the active site, which is found in serine proteases, suggesting that the enzyme is a serine hydrolase (Polderman-Tijmes et al., 2002).

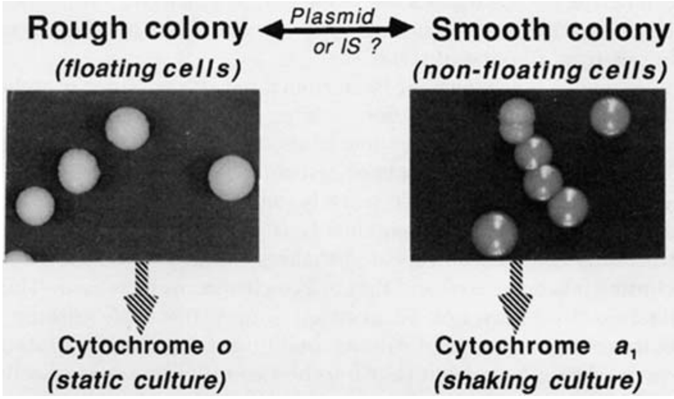

FIGURE BXII.α.15. Two different types of colonies of *Acetobacter aceti* from cells grown in static and shaking cultures. Cells forming rough-surfaced colonies can grow floating on the surface of the culture and thus predominate in static cultures. Cells forming smooth-surfaced colonies are incapable of floating and thus grow only in shaking cultures. The two types of cells produce cytochrome *o* and cytochrome a_1, respectively, as the terminal oxidase. (Reproduced with permission from K. Matsushita et al., Advances in Microbial Physiology, *36:* 247–301, 1994, ©Academic Press Limited, London.)

Production of cellulose and acetan The production of cellulose by *Gluconacetobacter xylinus* has been regarded as the model system for the study of biochemistry and genetics of cellulose biogenesis and is described by Ross et al. (1991), Cannon and Anderson (1991), and Delmer and Amor (1995). The rate of cellulose production in *Gluconacetobacter xylinus* is proportional to the rate of cell growth, and the yield is dependent on the source of carbon (Embuscado et al., 1994; Oikawa et al., 1995). The cellulose production by *Gluconacetobacter xylinus* strains is enhanced by the addition of small amounts of cellulase (endo-β-1,4-glucanase) from *Bacillus subtilis* to the production culture and the amount of produced acetan is reduced (Tonouchi et al., 1995). Activators for the bacterial cellulose production were compounds like caffeine and related xanthines. The suggested target for these activators was the diguanyl cyclic phosphodiesterase whose inhibition favors the cellulose biosynthesis (Fontana et al., 1991). The produced cellulose is of high purity. Products from bacterial cellulose include wound dressings, skin substitutions, high-quality additives for paper, fiber glass filter sheets, chewing gum, food stabilizers, and acoustic diaphragms for audio instruments (Ross et al., 1991). A mechanical separation method and an alkali treatment for the isolation of bacterial cellulose with removal of bacterial cells were developed (Embuscado et al., 1996).

Gluconacetobacter xylinus secretes long β-1,4 glucan chains in a diameter of 1.5 nm from pores along the longitudinal axis of the cell. These glucans aggregate into 3–4-nm microfibrils by crystallization with subsequent assembly to ribbons in the surrounding medium (Cannon and Anderson, 1991; Ross et al., 1991). The membrane-bound cellulose synthase uses UDP-glucose directly as a substrate and catalyzes the polymerization of the glucose residues to β-1,4 glucan (Saxena et al., 1990). The genes coding for cellulose production are organized in the form of an operon. An operon (*acs*) consisting of three genes is functional for the final steps in cellulose biosynthesis in *Gluconacetobacter xylinus* ATCC 53582. The first gene (*acsAB*) codes for the 168-kDa cellulose synthase, the second gene (*acsC*) codes for a 138-kDa pore-protein, and the third gene (*acsD*) of the operon codes for a 17-kDa protein, which is involved in the crystallization of the microfibrils (Saxena et al., 1994). An additional gene encoding cellulolytic activity (*acsAII*) that is similar to the *acsAB* gene product was detected upstream of the cellulose-synthesizing operon in a *Gluconacetobacter xylinus* strain (Saxena and Brown, 1995). In the *bcs* operon from *Gluconacetobacter xylinus* 1306-3 and BPR 2001 a difference in the numbers of open reading frames coding for cellulose synthase is observed in comparison to the *acs* operon (Wong et al., 1990; Nakai et al., 1998). The first two of the four open reading frames of the *bcs* operon encodes the cellulose synthase subunit A (*bcsA*) and B (*bcsB*). In addition, two open reading frames ORF1 and ORF2 are located upstream of the *bcs* operon. The gene product of ORF1 is identified as cellulase (Standal et al., 1994). The presence of cellulase enhances the production of cellulose, and the integration of IS *1031*A in ORF2 causes the inability to produce cellulose. The promoter of the *bcs* operon upstream from *bcsA* and downstream from ORF1 encoding CMCase is overlapping with the ORF2 (Nakai et al., 1998).

The cellulose synthase is activated by cyclic diguanylic acid (c-di-GMP), which acts as an allosteric effector and stimulates the enzyme reaction rate up to 200-fold (Ross et al., 1987). The enzymes diguanylate cyclase and phosphodiesterase A catalyze the synthesis and degradation, respectively, of c-di-GMP and thus have regulatory effects on cellulose biosynthesis. The genes encoding isoenzymes for phosphodiesterase A and diguanylate cyclase are organized on three unlinked homologous operons (Tal et al., 1998).

A conserved UDP-glucose/UDP-*N*-acetylglucosamine binding motif exists among glycosyltransferases using UDP-glucose or UDP-*N*-acetylglucosamine as a substrate (Delmer and Amor, 1995). Cotton and rice contain amino acid sequences homologous to bacterial sequences of the catalytic part of the cellulose synthase (Pear et al., 1996).

Gluconacetobacter xylinus synthesizes a cellulose mat, which covers the surface of the growth medium in static cultures, whereas round balls of cellulose are formed in shaking cultures. Aeration of cultures of *Gluconacetobacter xylinus* strains by stirring or shaking gives rise to the formation of spontaneous non-cellulose-producing mutants (Ross et al., 1991). This phenomenon is also observed by *Gluconacetobacter europaeus* strains. The Cel^- mutants are stable during passages of cultivations in static and shaken cultures.

Acetan, an acidic exopolysaccharide that is related to xanthan, has been isolated from the culture medium of *Gluconacetobacter xylinus* (Couso et al., 1987). Acetan contains glucose, mannose, glucuronic acid, and rhamnose in a molar ratio of 4:1:1:1. The described structure is composed of a pentasaccharide side chain Rha(1-6)Glc (β1-6)Glc(α1-4)GlcA(β1-2)Man, which is α-1,3-linked to every second glucose residue of the β-1,4 glucan chain (Couso et al., 1987). Genes encoding UDP-glucose dehydrogenase, UDP-glycosyl transferase, GDP-mannosyl transferase, and phosphomannose isomerase/GDP-mannose pyrophosphorylase of the acetan biosynthetic pathway have been identified and sequenced from *Gluconacetobacter xylinus* (Griffin et al., 1994, 1996, 1997; Petroni and Ielpi, 1996).

Nitrogen fixation Diazotrophy, the ability to fix free nitrogen gas (N_2) into cell material by reducing it to ammonium, occurs in species of more than 100 genera of *Bacteria* and *Archaea*. Proteins for nitrogen fixation (*nif*) have common structures and

functions, while the degree of linkage and arrangement of specific *nif* and associated genes vary considerably in many diazotrophs (Lee et al., 2000). Among the acetic acid bacteria, *Gluconacetobacter diazotrophicus*, *Gluconacetobacter johannae*, and *Gluconacetobacter azotocaptans* were able to fix molecular nitrogen. The *nifH* gene sequence encoding the Fe protein of the nitrogenase and *nifHDK* genes of *Gluconacetobacter diazotrophicus* are highly similar to those of other nitrogen-fixing bacteria, particularly with other diazotrophic members of the *Alphaproteobacteria* (Franke et al., 1998; Sevilla et al., 1998). The *nifA* and *nifB* genes are adjacent and located upstream from the *nifHDK* genes. The *nifA* gene encoding the transcriptional activator for expression of *nif* genes is repressed at high ammonium concentrations (Teixeira et al., 1999). The cluster of *nif*, *fix*, and associated genes of *Gluconacetobacter diazotrophicus* is about 30.5 kb in size and encodes for 33 proteins with a molecular mass sum up to 1095.5 kDa (Lee et al., 2000). Individual gene products of the cluster of *nif*, *fix*, and associated genes like *mcpA*, which is involved in chemotaxis, are similar to those in species of *Rhizobiaceae* or in *Rhodobacter capsulatus* (Lee et al., 2000).

Insertion sequences Insertion sequences integrated in the genome of acetic acid bacteria are responsible for genetic instability leading to deficiencies in physiological properties like inactivation of alcohol dehydrogenase and loss of cellulose and acetan synthesis. IS elements characterized from acetic acid bacteria are listed in Table BXII.α.12.

The reported IS elements are widely distributed in acetic acid bacteria. Their copy numbers are from 1 to about 16 with the exception of IS*1380*, whose copy number is about 100. The distribution of IS elements in *Gluconacetobacter xylinus*, *Acetobacter pasteurianus*, *Acetobacter aceti*, *Gluconacetobacter europaeus*, *Gluconacetobacter intermedius*, *"A. polyoxogenes"*, *Gluconobacter oxydans*, and *Gluconobacter cerinus* indicates frequent horizontal and vertical gene transfer between strains of acetic acid bacteria. The IS *1031* family, consisting of IS*1031*A to IS*1031*D (Coucheron, 1993) and the related IS elements IS *1032* (Iversen et al., 1994) and IS*12528* (Kondo and Horinouchi, 1997a) are members of the heterogeneous IS*5* group in the higher IS*4* family based on conserved transposase motifs (Rezsöhazy et al., 1993). Additional insertion elements are present in the chromosome of *Acetobacter pasteurianus* NCIB 7214. The strain contains five copies of IS*12528* (Kondo and Horinouchi, 1997a), 10 copies of IS *1452* (Kondo and Horinouchi, 1997c), and 100 copies of IS*1380* (Takemura et al., 1991) with a total insertion element length of 188.5 kb, which is over 6% of the nucleotide sequence of the genome (Kondo and Horinouchi, 1997a). Similarly, *Acetobacter aceti* 1023 contains one copy of IS*12528*, three copies of IS*1452*, and 100 copies of IS*1380* with a total length of 175 kb, corresponding to 6% of the chromosome (Kondo and Horinouchi, 1997a).

Plasmids and phages A variety of plasmids has been reported from strains of *Acetobacter*, *Gluconacetobacter*, and *Gluconobacter*, and genetic transformation systems and plasmid vectors for acetic acid bacteria have been established. An overview of the genetics of *Acetobacter* with respect to acetic acid fermentation has been given by Beppu (1993). Conjugal transfer systems by using broad host-range plasmids based on RK2 replicon as vectors for acetic acid bacteria have been described (Valla et al., 1985; Blatny et al., 1997). For example, plasmid p21R1 (RK2-derivate carrying the gene encoding for levansucrase) was introduced in *Gluconacetobacter diazotrophicus*. In the recombinant bacterium, levansucrase production was increased about fourfold due to the low copy number of p21R1 (Hernández et al., 1999). Electroporation systems for *Gluconobacter oxydans* (Creaven et al., 1994) and *Gluconacetobacter xylinus* (Hall et al., 1992) with heterologous plasmids that gave transformation frequencies of up to 10^5 transformants/µg of DNA have been developed. An efficient electroporation method for transformation of *"A. polyoxogenes"* with plasmid DNA was adapted to the cultivation parameters of this organism (Tayama et al., 1994).

Introduction of the ALDH gene from *"A. polyoxogenes"* in *Gluconacetobacter xylinus* enhanced the production of acetic acid by overexpression of the cloned gene (Fukaya et al., 1989). The

IS*12528*	*Gluconobacter oxydans* IFO 12528	D86632	Alcohol oxidation	Dehydrogenase subunit of the alcohol dehydrogenase complex	TMA	904	18	Kondo and Horinouchi (1997a)

[a]Preferred target site M = A,C; R = A,G.

[b]IS*1031*A is 87.1% homolog to IS*1031*C and IS*1031*D from *G. xylinus* ATCC 23769 (Coucheron, 1993).

1440-bp plasmid pAP12875 isolated from *Acetobacter pasteurianus* contains two open reading frames, of which one has similarity to the replicon protein of pVT736-1 from *Actinobacillus actinomycetemcomitans* and the 32-kDa protein of phage Pf3 from *Pseudomonas aeruginosa* (Fomenkov et al., 1995). Plasmid pAH4 was characterized from a cellulose-producing *Acetobacter* (*Gluconacetobacter*) strain; it consisted of 4002 bp, contained an A–T rich region, and encoded four open reading frames. A shuttle vector system of *Escherichia coli* and this strain was constructed by connecting pAH4 to pUC18 (Tonouchi et al., 1994). Mobilization regions of plasmid pAEU601 (3818 bp) from *Gluconacetobacter europaeus* DSM 6160 have DNA similarities to plasmids RSF1010 from *E. coli* and pTF1 from *Thiobacillus ferrooxidans*, contributing to the broad distribution of pAEU601 in *Gluconacetobacter europaeus* strains via conjugation events (Boesch, 1998). Shuttle vectors (Amp^r) for cloning and expression of genes in *Gluconacetobacter europaeus*, *Gluconacetobacter intermedius*, and *E. coli* were constructed by ligation of pJK2-1 from *Gluconacetobacter europaeus* and pUC18 (Trček et al., 2000).

Lysogenic phage Acm1 from *Acidomonas methanolica* has been described and characterized (Wünsche et al., 1983; Mamat et al., 1995). Phage particles from vinegar fermentations, with hexagonal and icosaedric heads, were morphologically characterized and proved to belong to group A and C of Bradley (Bradley, 1967), respectively (Teuber et al., 1987a; Stamm et al., 1989; Defives et al., 1990; Sellmer et al., 1992). Seven morphologically different types of phage particles from vinegar fermentations with hexagonal heads were identified based on head size, tail length, and diameter by Sellmer et al. (1992). Head sizes varied between 60 and 110 nm, the corresponding tail length ranged from 99 to 360 nm, and tail diameter ranged from 14 to 31 nm (Sellmer et al., 1992). *Gluconacetobacter europaeus* does not grow well in soft agar; consequently, the classical plaque test is not suitable to enumerate infective bacteriophages from vinegar fermentations (Sievers and Teuber, 1995). Restriction-modification systems have been detected in *Acetobacter* and *Gluconacetobacter* strains and further characterized (Tagami et al., 1988; Suzuki et al., 1996; Coucheron, 1997; Nwankwo et al., 1997).

Taxonomic Comments

Phylogenetic affiliations of *Acetobacter*, *Gluconacetobacter*, *Acidomonas*, *Asaia*, and *Gluconobacter* species and related acidophilic bacteria have been studied on the basis of 5S (Bulygina et al., 1992) and 16S rRNA sequences (Sievers et al., 1994a, 1995a; Kishimoto et al., 1995b; Yamada et al., 1997, 2000; Sokollek et al., 1998b; Franke et al., 1999; Schüller et al., 2000; Lisdiyanti et al., 2001a). All of the 16S rRNA sequences show nucleotide deletions in their loop helices V1, V2, and V3, which are characteristic for the *Alphaproteobacteria*. The clustering of *Gluconacetobacter*, *Acetobacter*, and *Gluconobacter* in the *Alphaproteobacteria* had already been shown by Gillis and De Ley (1980) based on RNA–DNA hybridization studies. All species of the six genera of acetic acid bacteria *Acetobacteraceae*, together with *Acidisphaera rubrifaciens*, *Rhodopila globiformis*, *Acidocella*, *Acidiphilium*, and *Roseococcus thiosulfatophilus* as phylogenetic neighbors, formed a cluster with a distinct line of descent (Fig. BXII.α.16). These organisms were characterized by an acidophilic phenotype with the exception of *Roseococcus thiosulfatophilus*. These acidophilic bacteria became adapted to acidic environments after branching off from the common ancestor of the *Alphaproteobacteria* (Kishimoto et al., 1995b). A phylogenetic tree reflecting the close relationships of *Acetobacter*, *Gluconacetobacter*, *Acidomonas*, *Asaia*, and *Gluconobacter* based on the maximum parsimony analysis is shown in Fig. BXII.α.17. Phylogenetically, the acetic acid bacteria form four major clusters, one containing the *Gluconacetobacter* species with a subcluster comprising *Gluconacetobacter europaeus*, *Gluconacetobacter xylinus*, *Gluconacetobacter intermedius*, *Gluconacetobacter oboediens*, *Gluconacetobacter entanii*, *Gluconacetobacter hansenii*, and one

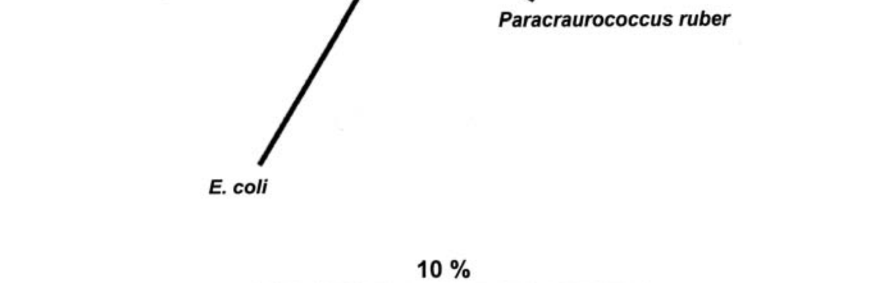

FIGURE BXII.α.16. Phylogenetic tree based on maximum parsimony analysis reflecting the distant relationships of the *Acetobacter–Gluconobacter* cluster and their close relatives among members of the *Alphaproteobacteria*. The topology of the tree was evaluated by applying distance matrix and maximum likelihood analyses. The lengths of the edges indicate the extremes of high and low phylogenetic distances among the members of the particular group. The bar indicates 10% estimated sequence difference. (Courtesy of Wolfgang Ludwig, TU Munich, Germany.)

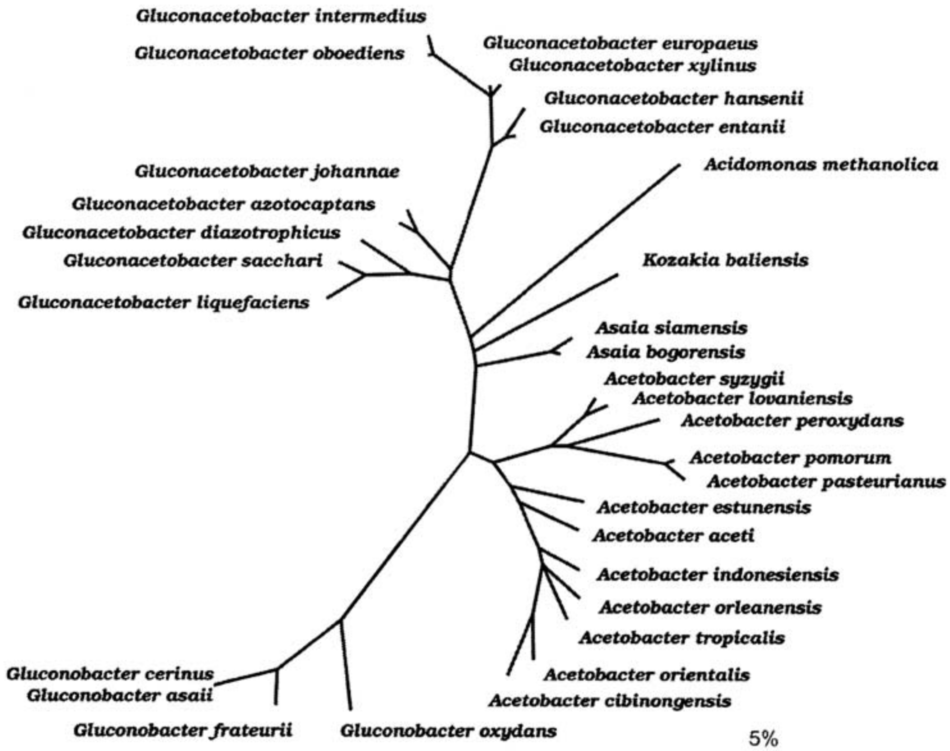

FIGURE BXII.α.17. Phylogenetic tree reflecting the close relationships of the species *Gluconacetobacter, Acidomonas methanolica, Asaia, Acetobacter,* and *Gluconobacter*. The tree is based on the results of a maximum parsimony analysis. The topology of the resulting tree were evaluated by applying the treeing methods (distance matrix, maximum parsimony, and maximum likelihood) to various data sets. The bar indicates 5% estimated sequence difference. (Courtesy of Wolfgang Ludwig, TU Munich, Germany.)

subcluster comprising *Gluconacetobacter sacchari*, *Gluconacetobacter liquefaciens*, *Gluconacetobacter diazotrophicus*, *Gluconacetobacter azotocaptans*, *Gluconacetobacter johannae*, and a second cluster containing *Acetobacter syzygii*, *Acetobacter lovaniensis*, *Acetobacter peroxydans*, *Acetobacter pomorum*, *Acetobacter pasteurianus*, *Acetobacter estunensis*, *Acetobacter aceti*, *Acetobacter indonesiensis*, *Acetobacter orleanensis*, *Acetobacter tropicalis*, *Acetobacter orientalis*, *Acetobacter cibinongensis*, and a third cluster comprising *Gluconobacter oxydans*, *Gluconobacter asaii*, *Gluconobacter cerinus*, and *Gluconobacter frateurii*. *Kozakia baliensis* formed a sublineage separated from *Asaia bogorensis* and *Asaia siamensis*. *Acidomonas methanolica* represents a distinct phylogenetic line and the separate branching of this organism is supported by the majority of the treeing analyses. The overall 16S rRNA sequence similarity values of the type species of five genera of acetic acid bacteria are given in Table BXII.α.13. The 16S rRNA sequence similarity between the species of the genus *Gluconacetobacter* is above 96.5%. *Gluconacetobacter europaeus*, *Gluconacetobacter xylinus*, *Gluconacetobacter intermedius*, and *Gluconacetobacter oboediens* are closely related by sharing over 99% 16S rRNA sequence similarities. Within the genus *Acetobacter*, the overall 16S rRNA sequence similarities are above 95.8% and less than 96,6% with those of other genera. Within the genus *Gluconobacter*, the overall 16S rRNA sequence similarities are 97.0–98.8%. *Gluconobacter* is well separated from the other genera by numerical analyses of protein gel electrophoregrams (Gosselé et al., 1983a, b; Sievers and Teuber, 1995) and by phenotypic features (Gosselé et al., 1983a, b). Two cellulose-producing *Gluconacetobacter* strains (ITDI 2.1 and PA 2.2) involved in nata de coco production were characterized by Bernardo et al. (1998). Based on 16S rDNA sequence analysis, strain ITDI 2.1 is closely related to *Gluconacetobacter xylinus* and strain PA 2.2 to *Gluconacetobacter hansenii*; these strains are discussed as new subspecies under these species designations (Bernardo et al., 1998).

The 16S–23S rDNA intergenic spacer regions of *Gluconacetobacter europaeus*, *Gluconacetobacter intermedius*, and *Gluconacetobacter xylinus* contain genes encoding for two tRNA molecules specific for L-isoleucine and L-alanine. The tRNAIle and tRNAAla sequences are identical in these species. *Gluconacetobacter* seems to contain four copies of the *rrn* operons on its chromosome. Downstream from the tRNAAla gene a boxA with the nucleotide sequence TGCTCTTTGATA and a putative boxB consisting of 30 nucleotides with short inverted repeats are present in the spacer regions of these species (Sievers et al., 1996). These antitermination sequences are necessary to prevent premature termination of the precursor rRNA (Condon et al., 1995).

PCR-RFLP of the 16S rDNA with *Taq*I and *Rsa*I allows identification of acetic acid bacteria on genus level and in some cases at species level (Ruiz et al., 2000). 16S–23S rDNA intergenic spacer restriction patterns can be used to identify strains of acetic acid bacteria due to the variability of these sequences. The type strains of *Gluconacetobacter europaeus*, *Gluconacetobacter intermedius*, and *Gluconacetobacter xylinus* with a high percentage of 16S rDNA similarity have different sequences of their 16S–23S rDNA intergenic spacer regions (Sievers et al., 1996).

For characterization of cultures producing high percentage spirit, wine, and cider vinegar, plasmid profiling has been used to allow definite conclusions regarding origin, stability, and composition of the *Gluconacetobacter europaeus* strains isolated from

submerged fermentations carried out in acetators and trickle generators (Teuber et al., 1987b; Mariette et al., 1991). Plasmid profile analysis showed that acetators (suspensions of *Gluconacetobacter europaeus*) harbored only one dominant strain, whereas trickle generators (with a microflora in the form of biofilms on mechanical supports such as wooden chips) demonstrated a highly complex strain composition with spirit as substrate (Sievers and Teuber, 1995). Industrial submerged vinegar fermentations are initiated by inoculation with "seed vinegar", a microbiologically undefined fermentation broth from previous fermentations. The lack of defined pure starter cultures is due to the problems in the isolation, culture maintenance, determination of viable counts, and strain preservation of *Gluconacetobacter europaeus* strains responsible for high acid (up to 17% acetic acid) production. Sokollek and Hammes (1997) produced a starter culture of an acetic acid bacterium isolated from an industrial acetator with red wine as substrate for vinegar fermentation. The organism required no acetic acid for growth and is classified as *Gluconacetobacter oboediens* (Sokollek et al., 1998b). The frozen and lyophilized strain LTH 2460 was turned into a starter preparation by revitalization steps and stepwise adjustment of the growing culture to the acetic acid and ethanol composition of the medium used in industrial fermentation (Sokollek and Hammes, 1997). The use of a starter culture leads from spontaneous fermentation to a microbiologically controlled fermentation in vinegar production and reduces the time to start the acetator. RAPD (random amplified polymorphic DNA) analysis with a suitable primer (AGCGGGCGTA or CGCGTGCCCA or GTGGTGGTGGTGGTG) for the PCR was used for characterization of genotypically different strains from spirit vinegar fermentations (Trček et al., 1997). On a strain/species level, electrophoretic protein profiles (Kersters and De Ley, 1975) of total cell protein extracts and their computerized evaluation are very useful for the definition of different phenons within the species *Gluconacetobacter europaeus* and *Gluconacetobacter intermedius* (Sievers and Teuber, 1995; Boesch et al., 1998). Numerical analysis of protein gel electrophoregrams of a wide variety of *Acetobacter* strains has been used for classificatory changes at species level within the genus *Gluconacetobacter* (Gosselé et al., 1983b). Electrophoretic mobilities of metabolic enzymes (multilocus enzyme electrophoresis) have been used to measure genotypic diversity of natural populations (Selander et al., 1986). This technique was applied to *Gluconacetobacter diazotrophicus* strains isolated from sucrose-rich host plants and mealy bugs to determine their degree of genetic relationships (Caballero-Mellado and Martínez-Romero, 1994; Caballero-Mellado et al., 1995). Nitrogen-fixing *Acetobacter* (*Gluconacetobacter*) strains isolated from a new host plant *Eleusine coracana* (finger millet) were characterized upon RAPD profiles grouping into two genetically related clusters (Loganathan et al., 1999). Pulsed-field gel electrophoresis with *Xba*I as restriction enzyme (electrophoresis for 24.5 h at 200 V in 1% agarose with a pulse time ramped from 5 to 40 s) is an appropriate tool for differentiation among strains of acetic acid bacteria.

Enrichment and isolation procedures A standard medium for enrichment and isolation of acetic acid bacteria, with the exception of *Gluconacetobacter europaeus* and *Gluconacetobacter entanii*, contains (per liter of distilled water) yeast extract, 5.0 g; peptone, 3.0 g; D-glucose, 0.5 g; ethanol (99.8%), 15 ml; cycloheximide, 0.1 g; and 12 g agar. The enrichment medium for the isolation of acetic acid bacteria, especially for *Asaia*, whose growth is inhibited by 0.35% acetic acid, is composed of (per liter of distilled water): D-sorbitol, 20 g; peptone, 5 g; yeast extract, 3 g; and cycloheximide, 0.1g; adjusted to pH 3.5 with hydrochloric acid (Yamada et al., 2000).

Differentiation of acetic acid bacteria from other genera Acetic acid bacteria (with the exception of *Asaia*) oxidize ethanol aerobically to acetic acid. Acetic acid is accumulated in the medium. After the complete oxidation of ethanol, *Acetobacter*, *Gluconacetobacter*, and *Acidomonas* oxidize acetic acid further to CO_2 and H_2O. This phenomenon provides a rapid phenotypic differentiation of the overoxidation capacity by use of the chalk–ethanol test of Carr and Passmore (1979). All species of acetic acid bacteria with the exception of *Gluconacetobacter europaeus*, *Gluconacetobacter entanii*, *Asaia bogorensis*, and *Asaia siamensis* grow well to moderately on the modified medium.[2] The acetic acid that is initially formed dissolves the calcium carbonate; then further oxidation of the acetic acid by *Acetobacter* and *Gluconacetobacter* leads gradually to a return of the chalk. This medium is used for isolation of acetic acid bacteria from flowers and fruits. A final concentration of 0.01% cycloheximide (stock-solution dissolved in ethanol) is used to prevent growth of most yeast cells.

Frateuria resembles *Acetobacter*, *Gluconacetobacter*, *Acidomonas*, and *Gluconobacter* in its ability to oxidize ethanol to acetic acid. *Frateuria* is not able to overoxidize acetate, but, in contrast to *Gluconobacter* oxidizes lactate to CO_2 and H_2O. *Frateuria* contains ubiquinone of the Q-8 type. Colonies of *Acidiphilium* are light brown, pale pink, red, or violet due to the presence of carotinoids and bacteriochlorophyll *a*. Some strains of *Acidiphilium* produce no bacteriochlorophyll *a*. Growth of *Acidiphilium* is inhibited in contrast to acetic acid bacteria in the presence of 0.25 mM acetate. *Acidiphilium acidophilum* (*Thiobacillus acidophilus*) can be differentiated from acetic acid bacteria by its ability to grow in mineral medium at pH values of 2–4 in the presence of H_2SO_4. *Acidocella* can be differentiated from other genera by its ability to use diaminobutane, 4-aminobutyrate, and 5-aminovalerate as carbon and energy source. *Rhodopila globiformis* grows phototrophically under anaerobic conditions. *R. globiformis* is able to grow photoheterotrophically using ethanol as electron donor and carbon source. The cell shape of *R. globiformis* is spherical. *Roseococcus thiosulfatophilus* contains bacteriochlorophyll *a* and is obligately aerobic. *R. thiosulfatophilus* can be differentiated from acetic acid bacteria by its formation of pink cocci, its oxidation of thiosulfate to sulfate, and its inability to use ethanol, D-mannitol, and D-fructose as carbon sources. *Ketogulonigenium vulgare* is oxidase positive and, in contrast to acetic acid bacteria, not able to grow at pH 4.5. The truncated stem-loop structure in the 16S RNA at position 1241–1296 in the *E. coli* numbering system distinguishes *Ketogulonigenium vulgare* from acetic acid bacteria and some other members of the *Alphaproteobacteria* (Urbance et al., 2001).

In the following chapters, we describe the genera *Gluconacetobacter*, *Acetobacter*, *Acidomonas*, *Asaia*, and *Gluconobacter* of the family *Acetobacteraceae*, which differ in respect to genetic and physiological properties like 16S rRNA sequence similarity, phylogenetic positioning, DNA–DNA similarity, ubiquinone type, oxidation of acetic acid to carbon dioxide and water, and tolerance to acetic acid.

---

2. Medium for the chalk-ethanol test (per liter of distilled water): glucose, 0.5 g; yeast extract, 5.0 g; peptone, 3.0 g; calcium carbonate, 15.0 g; agar, 12.0 g; and ethanol (99.8%), 15 ml (sterilized by filtration and added after sterilization of the basal medium).

Genus I. **Acetobacter** Beijerinck 1898, 215[AL]

Martin Sievers and Jean Swings

A.ce.to.bac′ter. L. n. *acetum* vinegar; M.L. n. *bacter* masc. equivalent of Gr. neut. n. *bakterion* rod; M.L.masc. n. *Acetobacter* vinegar rod.

Cells **ellipsoidal to rod shaped**, straight or slightly curved, 0.6–0.9 × 1.0–4.0 μm, occurring singly, in pairs, or in chains. **Motile or nonmotile; if motile, the flagella are peritrichous**. Endospores are not formed. Gram negative. **Obligately aerobic**; metabolism is strictly respiratory with oxygen as the terminal electron acceptor. Never fermentative. Form pale colonies; most strains produce no pigments. A minority of strains produces brown water-soluble pigments or show pink colonies due to the production of porphyrins. Usually catalase positive. Oxidase negative. Absence of gelatin liquefaction, indole production, and H_2S formation. **Oxidizes ethanol to acetic acid. Acetate is oxidized to CO_2 and H_2O**. The best carbon sources for growth are ethanol, glycerol, and glucose. Some strains require *p*-aminobenzoic acid, niacin, thiamin, or pantothenic acid as growth factors. Neither lactose nor starch is hydrolyzed. No production of 2,5-diketo-D-gluconate from D-glucose. Chemoorganotrophs. Optimum temperature is 30°C. Some strains reduce nitrate to nitrite. **The pH optimum for growth is 4.0–6.0. Possesses ubiquinone of the Q-9 type as major quinone**. The predominant fatty acid in *Acetobacter* is the $C_{18:1\ \omega7}$ straight-chain unsaturated acid. ***Acetobacter* species occur in flowers, fruits, palm wine, vinegar, kefir, and fermented foods and can cause infections in grape wine, sake, tequila, cocoa wine, cider, beer, and fermented meat**. *Acetobacter* is not known to have any pathogenic effect toward humans and animals.

The mol% G + C of the DNA is: 50.5–60.3.

Type species: **Acetobacter aceti** (Pasteur 1864) Beijerinck 1898 (*Mycoderma aceti* Pasteur 1864, 125; *Acetobacter aceti* subsp. *aceti* (Pasteur 1864) De Ley and Frateur 1974.)

Further descriptive information

Cultivation media *Acetobacter aceti*, *A. pasteurianus*, *A. pomorum*, *A. orleanensis*, *A. peroxydans*, and *A. estunensis* grow well on standard medium (MYP).[1] *Acetobacter indonesiensis* and *Acetobacter tropicalis* are not able to utilize D-mannitol and were cultivated on a basal medium containing glucose, glycerol, and ethanol. Acetic acid bacteria are mesophilic strains with optimal temperature for growth at 28–30°C. Thermotolerant *Acetobacter* spp. capable of producing acetic acid at temperatures of about 37°C have been described (Ohmori et al., 1980; Saeki et al., 1997; Lu et al., 1999).

Maintenance Procedures

Strains of *Acetobacter* can be maintained for 2 weeks at 4°C on agar media used for cultivation. *Acetobacter* strains can be frozen and kept at −75°C in the presence of 24% (v/v) glycerol.

1. MYP medium (g/l distilled water): D-mannitol, 25.0; yeast extract, 5.0; peptone, 3.0; agar, 12.0.

Differentiation of the species of the genus *Acetobacter*

Characteristics of the species of the genus *Acetobacter* are given in Table BXII.α.14.

[c]Nitrate reduction was tested from nitrate peptone water (per liter of distilled water, pH 7.0: peptone, 10 g; KNO_3, 2 g) (Franke et al., 1999).

List of species of the genus Acetobacter

1. **Acetobacter aceti** (Pasteur 1864) Beijerinck 1898[AL] (*Mycoderma aceti* Pasteur 1864, 125; *Acetobacter aceti* subsp. *aceti* (Pasteur 1864) De Ley and Frateur 1974.)
a.ce′ti. L. n. *acetum* vinegar; L. gen. n. *aceti* of vinegar.

Cell morphology and colonial characteristics are as described for the genus. All strains are ketogenic toward glycerol and sorbitol and most strains toward D-mannitol. Both 2-keto- and 5-ketogluconic acids are synthesized from D-glucose. 2,5-Diketogluconic acid is not produced. All strains acidify ethanol, *n*-propanol, *n*-butanol, D-xylose, D-mannose, and D-glucose. Ethanol, glycerol, D-mannitol, Na-acetate, and Na-D,L-lactate are good carbon sources for growth. All strains require growth factors in the presence of D-mannitol. Most strains utilize L-alanine and L-proline as a source of nitrogen in the presence of D-mannitol (De Ley et al., 1984). The level of 16S rRNA sequence similarity is 96.6–98.0% between *A. aceti* DSM 3508 and the type strains of the other *Acetobacter* species.

The mol% G + C of the DNA is: 56.2–57.2 (T_m).

Type strain: ATCC 15973, DSM 3508, IMET 10732, JCM 7641, NCIB 8621.

GenBank accession number (16S rRNA): D30768, X74066.

2. **Acetobacter cibinongensis** Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2002, 3[VP] (Effective publication: Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2001a, 130.)
ci.bi.non′gen.sis. N.L. adj. *cibinongensis* derived from Cibinong, West Java, Indonesia.

A. cibinongensis is closely related to *Acetobacter orientalis* sharing 99.1–99.3% 16S rRNA sequence similarity by DNA–DNA similarity values of 12–25%. Strains produce D-gluconate and 2-keto-D-gluconate from D-glucose. Acid is produced from D-glucose, ethanol, and *n*-propanol. Acid production from L-arabinose, D-xylose, D-galactose, and D-mannose is strain dependent. *A. cibinongensis* does not produce acid from D-fructose, L-sorbose, D-arabinose, D-mannitol, D-sorbitol, glycerol, and lactose. Weakly positive for growth at 42°C, at pH 3.0 and pH 9.0, in the presence of 20% glucose, and in the presence of 10% ethanol (Lisdiyanti et al., 2001a). The level of 16S rRNA sequence similarity is 96.8–99.0% between *A. cibinongensis* IFO 16605 and the type strains of the other *Acetobacter* species. *A. cibinongensis* was isolated from fruit (mountain soursop) and curd of tufu in Indonesia.

The mol% G + C of the DNA is: 53.8–54.5 (T_m).

Type strain: IFO 16605, JCM 11196, NRIC 0482.

GenBank accession number (16S rRNA): AB052710.

3. **Acetobacter estunensis** (Carr 1958) Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2001b, 263[VP] (Effective publication: Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2000, 162) *Acetobacter pasteurianus* subsp. *estunensis* (Carr 1958) De Ley and Frateur 1974, 278; *"Acetobacter estunenses"* (sic) Carr 1958, 157.
es.tun.en′sis. M.L. adj. *estunensis* probably named after the old English name of the village Long Ashton, where J.G. Carr isolated the type strain.

A. estunensis was described by Carr (1958) as *"Acetobacter estunense"*. The name, *"A. estunense"*, implies that this organism is distinct from any species described by Frateur (Carr, 1958). *A. estunensis* oxidizes glucose to gluconate; 2-ketogluconate is produced but not 5-ketogluconate. Acid is produced from D-mannose and D-xylose but not from D-galactose, D-arabinose, L-arabinose, D-fructose, L-sorbose, D-mannitol, D-sorbitol, glycerol, sucrose, or lactose. *A. estunensis* IFO 13751 contains 89.2% ubiquinone of the Q-9 type and 10.8% of the Q-8 type. *A. estunensis* IFO 13751 was isolated from cider. *A. estunensis* produced pellicles, which are not composed of cellulose since they dissolved after being boiled in 5% NaOH (Lisdiyanti et al., 2000). *A. estunensis* IFO 13751 showed 16S rRNA sequence similarity values of 96.3–97.9% to the type strains of other *Acetobacter* species.

The mol% G + C of the DNA is: 59.3–59.7 (T_m).

Type strain: ATCC 23753, DSM 4493, IFO 13751, LMG 1626, NCIMB 8935.

GenBank accession number (16S rRNA): AB032349.

4. **Acetobacter indonesiensis** Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2001b, 263[VP] (Effective publication: Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2000, 162.)
in.do.ne.si.en′sis. M.L. adj. *indonesiensis* referring to Indonesia where most strains studied were isolated.

A. indonesiensis cells are rod shaped, 1.8–2.0 × 0.8–1.0 µm, occurring singly, in pairs, or in chains. Colonies are circular, convex, glistening, and nonpigmented on basal medium containing 1.0% glucose, 1.0% glycerol, 1.0% ethanol, 1.0% peptone, 0.5% yeast extract, and 1.5% agar (Lisdiyanti et al., 2000). No growth on D-mannitol. Oxidizes glucose to gluconate; 2-ketogluconate is produced but not 5-ketogluconate. Does not produce acid from D-arabinose, D-fructose, L-sorbose, D-mannitol, D-sorbitol, glycerol, sucrose, or lactose. Acid production from D-mannose, D-galactose, L-arabinose, and D-xylose is strain dependent. No ketogenesis from glycerol. *A. indonesiensis* IFO 16471 contains 86% ubiquinone of the Q-9 type and 14% of the Q-10 type (Lisdiyanti et al., 2000). The level of 16S rRNA sequence similarity is 96.4–98.6% between *A. indonesiensis* NRIC 0313 and the type strains of other *Acetobacter* species. *A. indonesiensis* was isolated from Indonesian fruits like banana, papaya, zirzak, and mango. *A. indonesiensis* IFO 16471 was obtained from the fruit of zirzak (*Annona muricata*).

The mol% G + C of the DNA is: 53.3–55.1 (T_m).

Type strain: IFO 16471, NRIC 0313.

GenBank accession number (16S rRNA): AB032356.

5. **Acetobacter lovaniensis** (Frateur 1950) Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2001b, 263[VP] (Effective publication: Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2000, 162 (*Acetobacter pasteurianus* subsp. *lovaniensis* (Frateur 1950) De Ley and Frateur 1974, 278; *"Acetobacter lovaniense"* (sic) Frateur 1950, 336.)
lo.va.ni.en′sis. M.L. adj. *lovaniensis* referring to the city Louvain (Lovanium), in Belgium, where the type strain was isolated and studied by J. Frateur.

Acetobacter lovaniensis includes *A. pasteurianus* IFO 13753 and IFO 3284, *A. aceti* AJ 2913 and AJ 2914, and several Indonesian isolates from fruits (palm seed and starfruit) and fermented foods (nata de coco, moromi soya, palm

wine, and pickle) (Lisdiyanti et al., 2000). *A. lovaniensis* oxidizes glucose to gluconate. 2-ketogluconate and 5-ketogluconate are not produced. Does not produce acid from D-fructose, L-sorbose, D-mannitol, D-sorbitol, glycerol, sucrose, or lactose. Acid production from D-mannose, D-galactose, L-arabinose, and D-xylose is strain dependent. *A. lovaniensis* IFO 13753 contains 84.9% ubiquinone of the Q-9 type, 8.6% of the Q-8 type, and 6.5% of the Q-10 type (Lisdiyanti et al., 2000). The level of 16S rRNA sequence similarity is 97.0–99.4% between *A. lovaniensis* IFO 13753 and the type strains of other *Acetobacter* species.

The mol% G + C of the DNA is: 57–59 (T_m).

Type strain: ATCC 12875, DSM 4491, IFO 13753, LMG 1579, NCIMB 8620.

GenBank accession number (16S rRNA): AB032351.

6. **Acetobacter orientalis** Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2002, 3[VP] (Effective publication: Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2001a, 130.)
o.ri.en′ ta.lis. M.L. adj. *orientalis* "oriental", referring to the region where the strains were isolated.

A. orientalis cells are rod shaped, 2.0–3.0 × 0.6–0.8 μm. Colonies are circular, convex, glistening, and nonpigmented on basal medium pH 6.8 containing 1.0% glucose, 1.0% glycerol, 1.0% ethanol, 1.0% peptone, 0.5% yeast extract, and 1.5% agar (Lisdiyanti et al., 2001a). Strains produce D-gluconate and 2-keto-D-gluconate from D-glucose. Acid is produced from D-glucose, ethanol, and *n*-propanol. Acid production from L-arabinose, D-xylose, D-galactose, and D-mannose is strain dependent. *A. tropicalis* does not produce acid from D-fructose, L-sorbose, D-arabinose, D-mannitol, D-sorbitol, glycerol, and lactose. Weakly positive for growth at 42°C, at pH 3.0 and pH 9.0, in the presence of 20% glucose, and in the presence of 10% ethanol (Lisdiyanti et al., 2001a). *Acetobacter orientalis* was isolated from canna flower, fruits (starfruit and coconut), and fermented foods (curd of tofu and tempeh) in Indonesia. The level of 16S rRNA sequence similarity is 96.8–99.0% between *A. orientalis* IFO 16606 and the type strains of the other *Acetobacter* species.

The mol% G + C of the DNA is: 52–52.8 (T_m).

Type strain: IFO 16606, JCM 11195, NRIC 0481.

GenBank accession number (16S rRNA): AB052706.

7. **Acetobacter orleanensis** (Henneberg 1906) Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2001b, 263[VP] (Effective publication: Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2000, 161) (*Acetobacter aceti* subsp. *orleanensis* (Henneberg 1906) De Ley and Frateur 1974, 278; *"Bacterium orleanense"* Henneberg 1906, 106.)
or.le.an.en′ sis. M.L. adj. *orleanensis* referring to the city Orleans and the "Orleans method" for vinegar production.

A. orleanensis includes strains of *A. pasteurianus* IFO 13752, IFO 3170, and IFO 3223, *Gluconacetobacter hansenii* IFO 3296, and six Indonesian isolates from fruits (guava and sapodilla) and fermented foods (nata de coco) (Lisdiyanti et al., 2000). *A orleanensis* oxidizes glucose to gluconate; 2-ketogluconate is produced but not 5-ketogluconate. Does not produce acid from D-arabinose, D-fructose, L-sorbose, D-mannitol, D-sorbitol, glycerol, sucrose, or lactose. Acid production from D-mannose, D-galactose, L-arabinose, and D-xylose is strain dependent. *A. orleanensis* IFO 13752 contains 81.0% ubiquinone of the Q-9 type, 14.2% of the Q-8 type, and 4.8% of the Q-10 type. The level of 16S rRNA sequence similarity is 95.9–98.7% between *A. orleanensis* IFO 13752 and the type strains of other *Acetobacter* species.

The mol% G + C of the DNA is: 56.5–58.7 (T_m).

Type strain: ATCC 12876, DSM4492, IFO 13752, LMG 1583, NCIMB 8622.

GenBank accession number (16S rRNA): AB032350.

8. **Acetobacter pasteurianus** (Hansen 1879) Beijerinck 1916, 1199[AL] (*Mycoderma pasteurianum* Hansen 1879, 230; *Acetobacter pasteurianum* (sic) Beijerinck 1916, 1199; *Acetobacter pasteurianus* subsp. *ascendens* (Henneberg 1898) De Ley and Frateur 1974, 278; *Acetobacter pasteurianus* subsp. *paradoxus* (Frateur 1950) De Ley and Frateur 1974, 278.)
pas.teur.i.a′ nus. M.L. adj. *pasteurianus* of Pasteur; named after Louis Pasteur (1822–1895), French chemist and bacteriologist.

The cell morphology and colonial characteristics are as described for the genus. Not all strains are able to grow on GYC medium (5% D-glucose, 1% yeast extract, 3% $CaCO_3$, 1.5% agar). Most strains are negative for ketogenesis from glycerol and formation of 5-ketogluconic acid from D-glucose. Some strains are weakly catalase positive. Most strains produce acid from ethanol, *n*-propanol, and *n*-butanol, but not always from D-glucose. All strains require growth factors in the presence of D-mannitol (De Ley et al., 1984). *A. pasteurianus* was found in different kefir grains as milk adapted biotype at numbers varying between 3 × 10^3 and 3 × 10^6 CFU/g (Häfliger et al., 1991a, b). *A. pasteurianus* growing in kefir utilizes L-alanine and L-proline as nitrogen and carbon sources (Häfliger et al., 1991b). The level of 16S rRNA sequence similarity is 95.9–99.4% between *A. pasteurianus* DSM 3509 and the type strains of the other *Acetobacter* species.

The mol% G + C of the DNA is: 51.8–53 (T_m).

Type strain: ATCC 33445, DSM 3509, IMET 10733, LMD 22.1.

GenBank accession number (16S rRNA): X71863.

9. **Acetobacter peroxydans** Visser′ t Hooft 1925, 225[VP]
per.ox′ y.dans. L. pref. *per* very; M.L. part. adj. *oxydans* acid-giving, oxidizing; M.L. part. adj. *peroxydans* strongly oxidizing.

Strain IFO 13755 is the type species and was isolated from ditch water. *A. peroxydans* IFO 13755 oxidizes ethanol, acetate, and lactate but does not produce acid from different carbon sources (D-glucose, D-mannose, D-galactose, D-arabinose, L-arabinose, D-xylose, D-fructose, DL-sorbose, D-mannitol, D-sorbitol, glycerol, sucrose, lactose). Does not produce 2-ketogluconate or 5-ketogluconate. Catalase negative. Peroxidase positive. The level of DNA relatedness of *A. peroxydans* IFO 13755 with other strains of *Acetobacter* is above 46%. The level of 16S rRNA sequence similarity is 96.5–97.9% between *A. peroxydans* IFO 13755 and the type strains of other *Acetobacter* species.

The mol% G + C of the DNA is: 60.3 (T_m).

Type strain: IFO 13755, ATCC 12874, LMG 1635, NCIMB 8618.

GenBank accession number (16S rRNA): AB032352.

10. **Acetobacter pomorum** Sokollek, Hertel and Hammes 1998b, 940[VP]
po.mo′rum. L. n. *pomum* fruit; L. gen. pl. n. *pomorum* of the fruits.

Cells are 0.8–1.2 × 1.3–1.6 μm, nonmotile, and occur mainly in pairs. Colonies are round, regular, convex, soft to liquid, glossy, and beige with a diameter of 0.8–1.5 mm on RAE agar (1a/2e). Plates of RAE agar are prepared by using the double layer technique as described by Entani et al. (1985) with 0.5% agar in the bottom layer and 1% agar in the top layer. RAE agar (1a/2e) is composed of 4% glucose, 1% yeast extract, 1% peptone, 0.338% $Na_2HPO_4 \cdot 2H_2O$, 0.15% citric acid·H_2O, 1% (v/v) acetic acid, and 2% (v/v) ethanol, in both agar layers (Sokollek and Hammes, 1997). Cells grow on 3% (v/v) ethanol in the presence of acetic acid levels as high as 4% (w/v). Growth occurs in the presence of 30% (w/v) glucose with a weak gluconic acid formation (<10 g/l). 5- and 2-keto-gluconic acid are not formed from glucose. Carbon sources include methanol, ethanol, *n*-propanol, D-glucose, D-fructose, D-maltose, D-ribose, D-xylose, D-sorbitol, D-mannitol, and glycerol. No growth occurs on sucrose, L-lactate, and D-gluconate. Dihydroxyacetone is formed from glycerol. Cellulose is not synthesized. *A. pomorum* DSM 11825 was isolated from a submerged cider vinegar fermentation. The level of 16S rRNA sequence similarity is 96.2–99.4% between *A. pomorum* DSM 11825 and the type strains of the other *Acetobacter* species.

The mol% G + C of the DNA is: 50.5 (T_m).
Type strain: DSM 11825, LTH 2458.
GenBank accession number (16S rRNA): AJ001632.

11. **Acetobacter syzygii** Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2002, 3[VP] (Effective publication: Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2001a, 129.)
sy.zy′gi.i. L. gen. *syzygii* derived from N.L. neut. n. *syzygium* referring to the name of the fruit of the Malay rose apple (*Syzygium malaccense*) from which the type strain was isolated.

A. syzygii IFO 16604 is closely related to *A. lovaniensis* IFO 13753 sharing 99.4% 16S rRNA sequence similarity by DNA–DNA similarity value of 38%. Strains of *A. syzygii* produce acids from D-glucose, ethanol, and *n*-propanol. 2 keto-D-gluconate is not formed. Acid production from L-arabinose, D-xylose, and D-mannose is strain dependent. Weakly positive for growth at 42°C, at pH 3.0 and pH 9.0, in the presence of 20% glucose, and in the presence of 10% ethanol (Lisdiyanti et al., 2001a). The level of 16S rRNA sequence similarity is 96.9–99.4% between *A. syzygii* IFO 16604 and the type strains of the other *Acetobacter* species.

The mol% G + C of the DNA is: 54.3–55.4 (T_m).
Type strain: IFO 16604, JCM 11197, NRIC 0483.
GenBank accession number (16S rRNA): AB052712.

12. **Acetobacter tropicalis** Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2001b, 263[VP] (Effective publication: Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura and Komagata 2000, 163.)
tro.pi.ca′lis. M.L. adj. *tropicalis* referring to the tropical region where the strains were isolated.

A. tropicalis cells are rod shaped, 1.8–2.0 × 0.5–0.7 μm, occurring singly, in pairs, or in chains. Colonies are circular, convex, glistening, and nonpigmented on basal medium containing 1.0% glucose, 1.0% glycerol, 1.0% ethanol, 1.0% peptone, 0.5% yeast extract, and 1.5% agar (Lisdiyanti et al., 2000). No growth on D-mannitol. Oxidizes glucose to gluconate; 2-ketogluconate is produced but not 5-ketogluconate. Does not produce acid from D-arabinose, D-fructose, L-sorbose, D-mannitol, D-sorbitol, glycerol, sucrose, or lactose. Acid production from D-mannose, D-galactose, L-arabinose, and D-xylose is positive to weak reaction. No ketogenesis from glycerol. The major quinone is Q-9 (86–100%). *A. tropicalis* IFO 16470 showed 16S rRNA sequence similarity values of 96.4–98.7% to the type strains of other *Acetobacter* species. *A. tropicalis* IFO 16470 was isolated from coconut (*Coccos nucifera*).

The mol% G + C of the DNA is: 55.2–56.6 (T_m).
Type strain: IFO 16470, NRIC 0312.
GenBank accession number (16S rRNA): AB032354, AB032355.

Genus II. **Acidiphilium** *Harrison 1981, 331*[VP] *emend. Kishimoto, Kosako, Wakao, Tano and Hiraishi 1995b, 90*

Akira Hiraishi and Johannes F. Imhoff

A.ci.di.phi′li.um. M.L. n. *acidum* an acid; Gr. adj. *philus* loving; M.L. neut. n. *Acidiphilium* acid lover.

Cells are straight rods, 0.3–1.2 × 4.2 μm, multiply by binary fission and exhibit a pleomorphic tendency at varied pH values and in the presence of different carbon sources. Motile by means of polar, subpolar, and lateral flagella. Do not form spores or capsules. Gram negative. **16S rRNA structures and signatures conform to the *Alphaproteobacteria*.** Cell suspensions and colonies are white to cream, yellow, pink, red, or brown. **Strictly aerobic, chemoorganotrophic and chemolithotrophic bacteria containing photosynthetic pigments**, categorized into the aerobic bacteriochlorophyll-containing bacteria. **Main photosynthetic pigments are zinc-chelated bacteriochlorophyll (Zn-BChl) *a* and the carotenoid spirilloxanthin.** Grow with simple organic compounds, such as sugars, as electron donors and carbon sources. **Growth is inhibited in the presence of 0.6% yeast extract and low concentrations of acetate (0.25 mM) and lactate (2 mM).** One species is a facultative chemolithotroph utilizing elemental sulfur as electron donor. Fe^{2+} does not serve as the electron donor for chemolithotrophic growth but has stimulatory effects on heterotrophic growth. Catalase is positive and oxidase negative or weakly positive. Mesophilic and **obligately acidophilic bacteria** growing in the pH range of 2.0–5.9 (but not at pH 6.1 and above). **Straight-chain monounsaturated $C_{18:1}$ acid is the major component of cellular fatty acids. Ubiquinones with ten isoprene (Q-10) units are present.**

The mol% G + C of the DNA is: 62.9–68.1.
Type species: **Acidiphilium cryptum** Harrison 1981, 331.

Further descriptive information

Phylogenetic analyses based on 16S rDNA sequence information have shown that *Acidiphilium* species form a major cluster in the *Alphaproteobacteria*, together with members of the acidophilic chemotrophic bacteria of the genera, *Acidocella*, *Acetobacter*, and *Gluconobacter*, and the acidophilic anoxygenic phototrophic bacterium *Rhodopila* (Sievers et al., 1994a; Kishimoto et al., 1995b). This cluster is deeply branched off from the *Alphaproteobacteria*. (See Fig. 1 p. 136 in the essay "Aerobic Bacteria Containing Bacteriochlorophyll and Belonging to the *Alphaproteobacteria*", Volume 2, Part A.)

Cells of *Acidiphilium* species are straight or slightly curved rods with rounded ends (Figs. BXII.α.18 and BXII.α.19). They vary in size from 0.4–0.8 × 1.0–3.0 μm under optimal growth conditions, but cell size and shape are influenced by the kind and concentration of carbon source and by physico-chemical growth conditions (the range of cell size is shown in the generic description). Swollen cells and filaments (>10 μm long) frequently occur when growing in nutrient-rich media, and this tendency is most pronounced in *Acidiphilium rubrum*. The swollen cells contain discrete, refractive, sudanophilic granules that are possibly poly-β-hydroxybutyrate granules. Electron microscopy of negatively stained cells shows that motile cells have single polar or subpolar flagellum (Fig. BXII.α.20). Two lateral flagella are occasionally found in *Acidiphilium cryptum* (Harrison, 1989) and *Acidiphilium multivorum*. Thin-section electron microscopy shows that any type of intracytoplasmic membrane systems is absent in the cells (Matsuzawa et al., 2000) (Fig. BXII.α.21). Polyphosphate granules as well as poly-β-hydroxybutyrate granules are frequently observed.

Acidiphilium species are strictly aerobic, chemoorganoheterotrophic bacteria (a single species is chemolithotrophic) that require high acidity for growth. They grow in the pH range of 2.5–5.9, some as low as 1.5–2.0, but not at pH 6.1 and above. Growth rates vary remarkably among the species. The type species *A. cryptum* and its closest relatives, *A. multivorum* and *A. organovorum*, exhibit a doubling time of 3–9 h, whereas *A. acidophilum* and *A. rubrum* grow much more slowly with a doubling time of more than 10 h under optimal growth conditions. *Acidiphilium* species use simple organic compounds as carbon and energy sources for growth. The following sugars and sugar alcohols are good substrates supporting growth of all species: L-arabinose, D-xylose, D-ribose, D-glucose, D-galactose, D-fructose, sucrose, glycerol, arabitol, and mannitol. *Acidiphilium* species utilize the pentose phosphate and Entner–Doudroff pathways for glucose metabolism and lack the Embden–Meyerhoff–Parnas pathway (Shuttleworth et al., 1985). None of the strains uses the following carbon sources: L-rhamnose, cellobiose, trehalose, melibiose, formate, butanol, acetate, propionate, butyrate, valerate, caproate, lactate, pyruvate, glycolate, oxalate, DL-β-hydroxybutyrate, benzoate, *p*-hydroxybenzoate, glycine, cysteine, and lysine. Growth of *Acidiphilium* species in glucose-mineral media is inhibited by low concentrations of acetate or lactate. In addition, succinate and fumarate inhibit growth of some species. Yeast extract at a low concentration of less than 0.1% (w/v) enhances growth of *Acidiphilium* species, but at 0.3% and above it has inhibitory effects on the growth (Harrison, 1981; Kishimoto et al., 1990). This is due to the effects of organic acids contained in the yeast extract (Kishimoto et al., 1990). Trypticase and peptone have similar inhibitory effects.

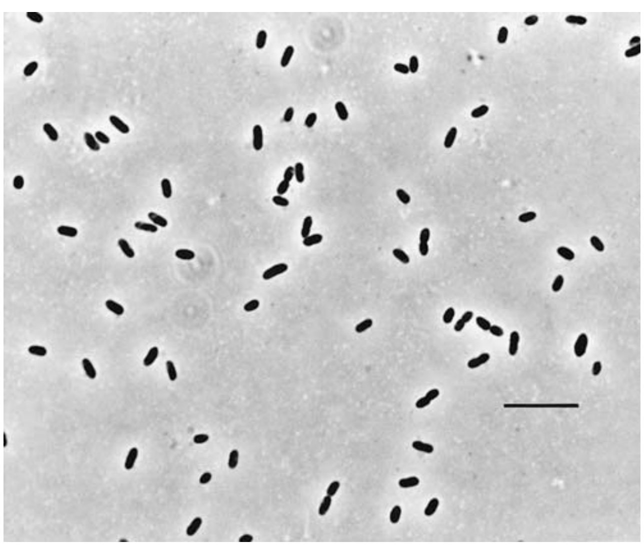

FIGURE BXII.α.18. Phase-contrast photomicrograph showing general cell morphology of *Acidiphilium cryptum* Bar = 5 μm.

A. acidophilum is the only species that exhibits chemolithotrophic growth with reduced sulfur compounds as energy sources, but other species may have the ability to oxidize elemental sulfur to sulfate (Harrison, 1981). A number of studies have demonstrated sulfur-dependent chemolithotrophy of and sulfur oxidation by *A. acidophilum* (Guay and Silver, 1975; Harrison, 1981; Pronk et al., 1990; Meulenberg et al., 1992; Hiraishi et al., 1998).

All species are capable of growth on high concentrations of metals, such as 100 mM Fe^{2+} and 100 mM Al^{3+}. *A. rubrum* may accumulate Fe as magnetite (Itoh et al., 1998; Matsuzawa et al., 2000). All species also exhibit high resistance to heavy metals such as copper, nickel, and zinc (Mahapatra and Banerjee, 1996). However, neither Fe^{2+} nor other metal ions can serve as an electron donor for chemolithotrophic growth. However, the addition of ferrous ion stimulates heterotrophic growth significantly. Some strains of *Acidiphilium* species, including *A. cryptum* are capable of coupling the reduction of Fe(III) to the oxidation of a variety of substrates under aerobic or anaerobic conditions (Johnson and McGinness, 1991; Pronk and Johnson, 1992; Johnson, 1998; Küsel et al., 1999). They may co-respire oxygen and Fe(III) under oxic conditions.

A. multivorum has the ability to oxidize arsenite to arsenate, whereas all other species lack this property (Wakao et al., 1994). *A. multivorum* has a number of plasmids of different sizes, one of which is 56 kbp and encodes its arsenic resistance. The arsenic resistance (*ars*) operon from the *A. multivorum* plasmid was cloned and sequenced (Suzuki et al., 1998). This cluster contained five genes in the following order: *arsR*, *arsD*, *arsA*, *arsB*, *arsC*, and the deduced amino acid sequences of all the gene products are homologous to the amino acid sequences of the *ars* gene products of the *Escherichia coli* plasmids. The *ars* operon cloned from *A. multivorum* conferred resistance to arsenate and arsenite upon *E. coli*.

One of the most outstanding characteristics of *Acidiphilium* species is the production of photopigments with Zn-BChl *a* as the major component (for abbreviations for metal-substituted bacteriochlorophylls [BChls] see Takaichi et al., 1999). The chemical structure of Zn-BChl *a* isolated from *Acidiphilium* is the same as Mg-BChl *a* esterified with phytol, except the occurrence of Zn in place of Mg as the central metal (Wakao et al., 1996;

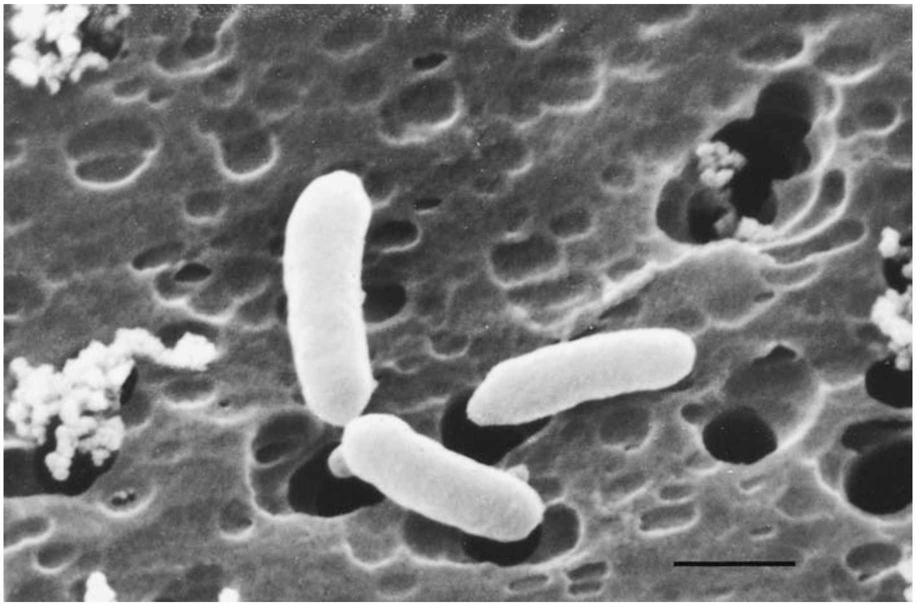

FIGURE BXII.α.19. Scanning electron photomicrograph showing general cell morphology of *Acidiphilium rubrum* ATCC 35905. Bar = 0.9 µm.

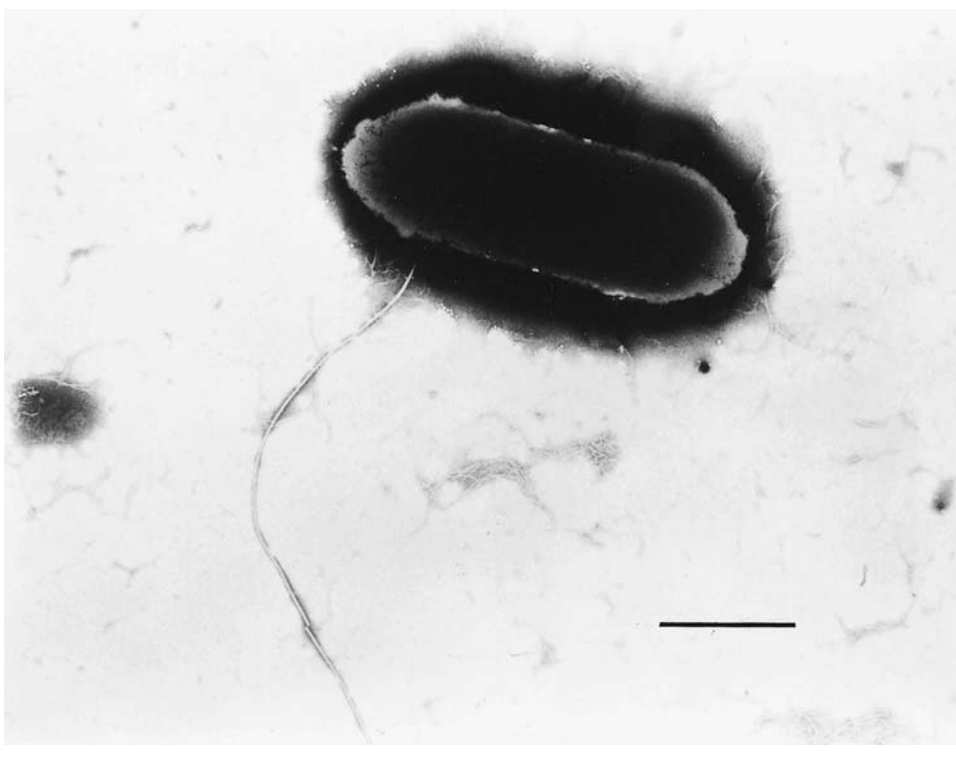

FIGURE BXII.α.20. Electron photomicrograph of a negatively stained cell of *Acidiphilium cryptum* ATCC 33463 having a subpolar flagellum. Bar = 0.5 µm. (Reprinted with permission from A. Hiraishi and K. Shimada, Journal of General Applied Microbiology *47:* 161–180, 2001, ©Japan Society for Bioscience, Biotechnology, and Agrochemistry.)

Kobayashi et al., 1998). The dominant occurrence of Zn-BChl *a* is indicated by an absorption maximum at 763 nm in the acetone-methanol extract, which is blue-shifted by 7 nm compared to the absorption maximum of Mg-BChl *a* in the corresponding near infrared region. Among the *Acidiphilium* species so far established, *A. rubrum* is most remarkable for Zn-BChl *a* production and contains 0.8–1.0 nmol of Zn-BChl *a* per mg dry weight of cells under optimal growth conditions. The cellular content of Zn-BChl *a* varies depending on environmental conditions. The production of Zn-BChl *a* occurs only under oxic-dark conditions,

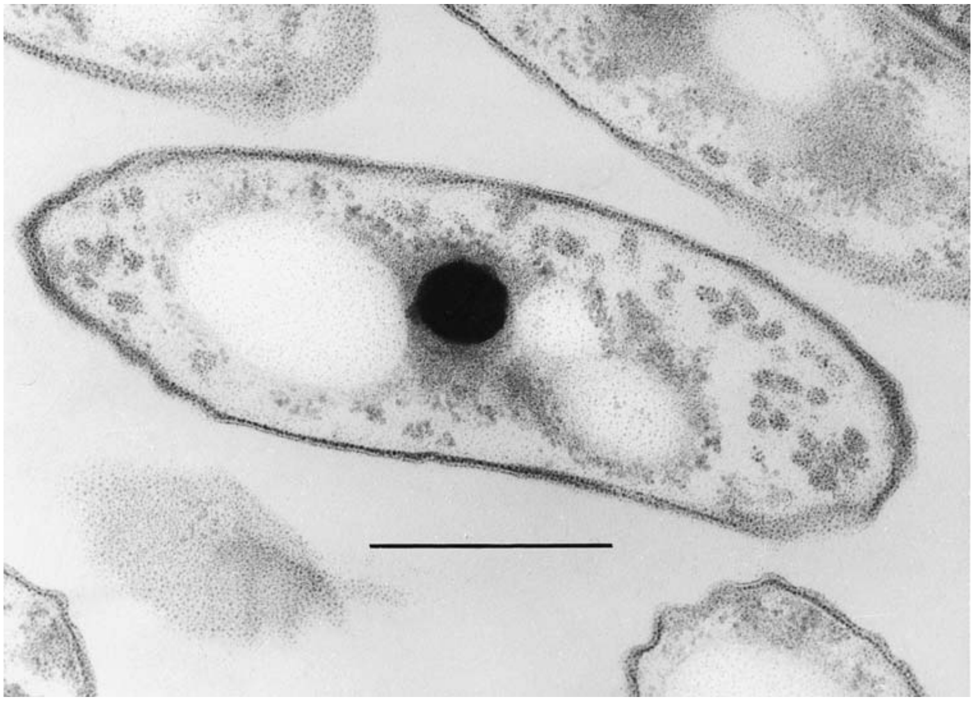

FIGURE BXII.α.21. Thin-section electron photomicrograph of cells of *Acidiphilium rubrum* ATCC 35905. Bar = 0.5 μm.

indicating the strong requirement of energy produced via aerobic respiratory electron transport for pigment production. Light inhibits photopigment production even under optimal growth conditions, as is the case in other genera of aerobic bacteriochlorophyll-containing bacteria. *Acidiphilium* species produce Mg-BChl *a* and bacteriopheophytin (BPhe) in addition to Zn-BChl *a*, but Zn-BChl *a* always predominates. The molar ratio of Zn-BChl *a*:Mg-BChl *a*:BPhe in the cells is relatively constant among the species; e.g., *A. rubrum* produces them at a molar ratio of 13:2:1 (Wakao et al., 1996; Hiraishi et al., 1998). In *A. rubrum*, a single set of magnesium chelatase homologs catalyzes the insertion of only Mg^{2+} into protoporphyrin IX to yield magnesium protoporphyrin IX monomethyl, and Zn-BChl *a* may be formed by a substitution of Zn^{2+} for Mg^{2+} at a step in the bacteriochlorophyll biosynthesis after formation of magnesium protoporphyrin IX monomethyl ester (Masuda et al., 1999).

Membrane preparations of *A. rubrum* have absorption maxima at 377, 486, 515, 549, 590, 792, and 864 nm. A much lower absorption maximum at around 800 nm compared to the maximum at 864 nm indicates that the cells contain light-harvesting complex I together with the photosynthetic reaction center but lack the peripheral light-harvesting complex LH II, like cells of the anoxygenic phototrophic bacterium *Rhodospirillum rubrum*. Spirilloxanthin is the sole carotenoid component of the antenna complex. Unlike other genera of aerobic bacteriochlorophyll-containing bacteria, such as *Erythrobacter* and *Porphyrobacter*, *Acidiphilium* contains no membrane-free polar carotenoids.

Photosynthetic activities were examined by light-induced absorption changes of the membrane-bound pigments of *A. rubrum* (Wakao et al., 1996). The light-induced difference spectrum showed absorption changes at around 800 and 850 nm, caused by activities of the monomer and special pair BChl molecules in the reaction center complex, respectively. The peak positions assigned to the monomer and special pair BChls are blue-shifted by 7 and 25 nm, respectively, compared to the analogous positions found in *R. rubrum*. This suggests the involvement of Zn-BChl *a*, instead of Mg-BChl *a*, in the photochemical reaction. Although representative species of *Acidiphilium* have been shown to contain a fully active photochemical reaction center, they neither grow anaerobically in the light nor produce photopigments under anoxic or oxygen-limited conditions. The biological significance of the photosynthetic system in *Acidiphilium* has not been fully understood, but it has been shown that light enhances $^{14}CO_2$ incorporation into cells of *A. rubrum* under oxic conditions (Kishimoto et al., 1995a).

Nagashima et al. (1997b) have demonstrated that *Acidiphilium* species contain the *puf* operon, an assemblage of genes coding for α and β polypeptides of the light-harvesting complex LH I, the L and M subunits of photosynthetic reaction center proteins, and the membrane-bound cytochrome *c* subunit. The *puf* operon of *A. rubrum* consists of *pufB*, *-A*, *-L*, *-M*, and *-C* as found in general in anoxygenic phototrophic purple bacteria. A comparative analysis of deduced amino acid sequences showed that His L168, which is highly conserved in the L subunit in the anoxygenic phototrophic bacteria, is replaced by glutamic acid in *Acidiphilium*. This residue was suggested to locate closely to the special pair of BChl molecules and to be involved in the stabilization and function of Zn-BChl *a*, if the three dimensional structures of the *Blastochloris viridis* and *Rhodobacter sphaeroides* reaction centers were taken into account for comparison. A continuous stretch of amino acid sequences of the L and M subunits of *Acidiphilium* species is highly conserved, and a phylogenetic tree based on these amino acid sequences is basically consistent with the 16S rDNA sequence-based tree in the genealogical relationships between *Acidiphilium* and other phototrophic purple bacteria (Hiraishi et al., 1998).

Acidiphilium species contain high amounts (33–43% of the total lipids) of phosphorus-free lipoamino acids in their cell membranes. Two major lipoamino acids were isolated from *A. organovorum* and identified as being α-*N*-3-hydroxystearylornithinyltaurine and α-*N*-3-hydroxystearylornithine, to which $C_{18:1}$ fatty acid is linked by an ester-linkage (Kishimoto et al., 1993a). In addition to these lipids, bisphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, and phosphatidylcholine are present as the major phospholipids. Straight-chain monounsaturated $C_{18:1}$ acid is the major component of whole-cell fatty acids, constituting of 40–90% of the total content (Kishimoto et al., 1993a; Wakao et al., 1994). A considerable amount of cyclopropane $C_{19:0}$ acid (5–21%) is also present.

Acidiphilium species (including new isolates of acidophilic heterotrophic bacteria that most likely belong to this genus) have been isolated from acidic mineral environments, such as pyritic mine drainage, pyritic coal refuse, copper and uranium mine tailings, acidic hot springs, and acidic soil (Tuttle et al., 1968; Manning, 1975; Wichlacz and Unz, 1981; Wichlacz et al., 1986; Kishimoto and Tano, 1987; Harrison, 1989; Wakao et al., 1994; Banerjee et al., 1996; A. Hiraishi, unpublished data). Also, as several strains of *Acidiphilium* species were isolated or found as contaminants from cultures of the iron-oxidizing chemolithotroph *Thiobacillus ferrooxidans* (Guay and Silver, 1975; Harrison et al., 1980; Harrison, 1981, 1989; Johnson and Kelso, 1983; Lobos et al., 1986), they may aid leaching through the consumption of organic matter inhibitory to the growth and activity of *T. ferrooxidans*. Although most *Acidiphilium* species are obligately heterotrophic, their natural habitats seem to be oligotrophic environments with poor organic matter. The ability of *Acidiphilium* to perform photosynthesis with Zn-BChl *a* may be an advantage to grow and survive in such oligotrophic acidic environments. Zn-BChl *a* is much more stable under acidic conditions than Mg-BChl *a* and chlorophylls (Wakao et al., 1996). Therefore, it is likely that the capacity for photosynthesis with Zn-BChl *a* of *Acidiphilium* is a result of its adaptation to acidic mineral environments. In addition, the ability of *Acidiphilium* species to reduce Fe(III), using a variety of organic substrates indicates that they may be of ecological significance in the biogeochemical cycling of iron at oxic-anoxic interfaces in acidic environments.

Enrichment and Isolation Procedures

A suitable medium for growth of *Acidiphilium* contains, per liter of distilled water: 2 g $(NH_4)_2SO_4$, 1 g KH_2PO_4, 0.5 g $MgSO_4{\cdot}7H_2O$, 0.05 g $CaCl_2{\cdot}2H_2O$, and 1 ml trace element solution SL8 (Biebl and Pfennig, 1978), to which are added 0.1% glucose and 0.01% yeast extract (Difco Laboratories). The organic supplements are autoclaved separately. For solid media separately autoclaved 1.5% agar is added; alternatively, 0.6% gellan gum can be used (Kishimoto and Tano, 1987). For isolation and enrichment of *Acidiphilium* from the environment, the medium should be adjusted to pH 2.0–2.5 to minimize growth of fungi and facultatively acidophilic bacteria. Although *Acidocella* strains are frequently recovered on isolation media, it is possible to differentiate colonies of *Acidiphilium* from those of *Acidocella* by pigmentation when the media are incubated for more than one week.

Maintenance Procedures

Cultures are well preserved in liquid nitrogen, by lyophilization, or at −80°C in a mechanical freezer.

Differentiation of the genus *Acidiphilium* from other genera

The genus *Acidiphilium* is separated from other genera of aerobic acidophilic heterotrophic bacteria by its phylogenetic position and its outstanding physiological and chemotaxonomic characteristics. Differential characteristics of *Acidiphilium* and phenotypically related genera are indicated in Table BXII.α.15.

Taxonomic Comments

The genus *Acidiphilium* was first monotypic with *A. cryptum* as the type species (Harrison, 1983). Later, several species including *A. angustum*, *A. facilis*, *A. organovorum*, and *A. rubrum* (Lobos et al., 1986; Wichlacz et al., 1986) were identified as new members of this genus. A phylogenetic analysis based on 5S rRNA sequences showed a close relationship between *A. cryptum* and *Thiobacillus acidophilus* (Lane et al., 1985). Information about the phylogeny and photosynthetic features of *Acidiphilium* has increasingly been accumulated in the 1990s. Wakao et al. (1993) reported that some members of *Acidiphilium* including the type species *A. cryptum* produced BChls. This report was the first to demonstrate the occurrence of photosynthetic pigments in *Acidiphilium* species. Similar observations were reported by Kishimoto et al. (1995a). Phylogenetic analyses based on 16S rDNA sequences revealed that all species of *Acidiphilium* form a major phylogenetic cluster in the *Alphaproteobacteria* (Lane et al., 1992; Sievers et al., 1994a) and that the BChl-producing species were genetically distant from the non-BChl-producing ones (Kishimoto et al., 1995b). This finding led to the proposal to remove the non-BChl producing species (i.e., *Acidiphilium facilis* and *Acidiphilium aminolytica*) from the genus *Acidiphilium* and to transfer them into the new genus *Acidocella* (Kishimoto et al., 1995b). The emended description of *Acidiphilium* only includes aerobic BChl-containing bacteria.

Acidiphilium angustum and *A. rubrum* were described as distinct species by Wichlacz et al. (1986) based mainly on phenotypic data. However, these two species have been shown to be indistinguishable by 16S rDNA sequencing and genomic DNA–DNA hybridization (Wakao et al., 1994; Kishimoto et al., 1995a; Hiraishi et al., 1998; Table BXII.α.16) and in addition are phenotypically quite similar to each other. These data strongly suggest that the two species names are subjective synonyms. Here we propose to unite *A. angustum* and *A. rubrum* in a single species, retaining the name *A. rubrum*.

Thiobacillus acidophilus (Guay and Silver, 1975) was not included in the Approved List of Bacterial Names (Skerman et al., 1980). After reexamination of the characteristics of *Thiobacillus acidophilus* and confirmation that this bacterium was a facultative chemolithotroph growing equally with elemental sulfur or glucose as the sole energy source, Harrison (1983) revived this name. However, phylogenetic analyses based on small-subunit rRNA sequences showed that *Thiobacillus acidophilus* was more closely related to members of the genus *Acidiphilium* than to any other species of *Thiobacillus* (Lane et al., 1985, 1992; Kishimoto et al., 1995b). Therefore, based on the phylogenetic evidence and the finding that this bacterium contains Zn-BChl *a* and the *puf* genes, as the other *Acidiphilium* species, the transfer of *Thiobacillus acidophilus* to the genus *Acidiphilium* as *Acidiphilium acidophilum* comb. nov. was proposed (Hiraishi et al., 1998).

A. organovorum	64	10	9–26	53–56	100

[a]Data from Wakao et al. (1994) and Hiraishi et al. (1998).

Hiraishi, A. and S. Shimada. 2001. Aerobic anoxygenic photosynthetic bacteria with zinc-bacteriochlorophyll. J. Gen. Appl. Microbiol. *47*: 161–180.

Shimada, K. 1995. Aerobic anoxygenic phototrophs. *In* Blankenship, Madigan and Bauer (Editors), Anoxygenic Photosynthetic Bacteria, Kluwer Academic Publishers, Dordrecht. pp. 105–122.

Differentiation of the species of the genus *Acidiphilium*

The differential characteristics of the species of *Acidiphilium* are indicated in Table BXII.α.17. Data on genomic DNA relatedness among the species are presented in Table BXII.α.16. Genetically, *Acidiphilium* species can be classified into two subgroups, one of which consists of *A. cryptum*, *A. multivorum*, and *A. organovorum* (*A. cryptum* subgroup) and one of which includes *A. acidophilum* and *A. rubrum* (*A. rubrum* subgroup). The levels of 16S rDNA sequence similarity and DNA–DNA hybridization between the two subgroups are 94–95% and 8–26%, respectively. Species differentiation in the former subgroup is problematic because of only small phenotypic and genetic differences among the species of this subgroup (Tables BXII.α.16 and BXII.α.17). It is impossible to separate *A. cryptum*, *A. multivorum*, and *A. organovorum* by 16S rDNA sequencing (>99.5% interspecies similarity). In addition, genomic DNA–DNA reassociation levels among the three species are relatively high (43–63%). The diagnostic characteristics useful for the identification of the species include growth inhibition by different concentrations of glucose, yeast extract, and trypticase and carbon nutrition (fumarate, succinate, sorbitol, and inositol). However, since the available phenotypic information has been derived from studies of only limited numbers of strains, DNA–DNA hybridization assays are required for the ultimate identification at the species level.

List of species of the genus Acidiphilium

1. **Acidiphilium cryptum** Harrison 1981, 331[VP]
cryp' tum. Gr. adj. *kryptos* hidden.

Cells are straight rods, 0.3–0.6 × 0.6–1.5 μm under optimal growth conditions, occurring singly or in pairs. Motile by means of a single polar, or subpolar, flagellum or by two lateral flagella; some strains appear to be nonmotile. Colonies on agar media are circular (1–3 mm in diameter after one week of incubation), smooth, convex, slightly translucent, and white to cream, and turn pink to light brown after continued incubation. Aerobic, chemoorganoheterotrophic bacteria having a respiratory type of metabolism with oxygen as terminal electron acceptor. Some strains may grow with Fe(III) as the terminal electron acceptor under both oxic and anoxic conditions. Carbon sources utilized are listed in Table BXII.α.17. D-Glucose, D-fructose, and some other sugars support good growth. Growth is inhibited by the presence of 1% glucose, 0.3% yeast extract, and 1% trypticase. Growth factors are required and this requirement is satisfied by 0.01% yeast extract. Ammonium salts are used as nitrogen source. Catalase is produced. Oxidase reaction is weakly positive or absent. Urease is negative. Arsenite oxidation is negative. Susceptible to ampicillin, chloramphenicol, rifampin, tetracycline, but resistant to josamycin, lincomycin, penicillin, and streptomycin. Optimal growth occurs at 30–37°C (range: 15–42°C) and at pH 3.0–3.5 (range: pH 2.0–5.9). No growth occurs at 42°C or with 3% NaCl. Habitat: Originally isolated from an iron-oxidizing culture of *Thiobacillus ferrooxidans* and found in strongly acidic environments, including mine water.

Mol% G + C content of DNA	67.3–68.3	62.9–63.2	63.2–63.4	66.2–68.1	67.4

[a]Symbols: +, 90% or more of strains positive; −, 90% or more of strains negative; d, 11–89% of strains positive; nd, not determined

[b]Data from Wakao et al. (1994) and Hiraishi et al. (1998).

The mol% G + C of the DNA is: 68–70 (T_m), 69 (Bd), 67.3–67.5 (HPLC).

Type strain: Lhet2, ATCC 33463, DSM 2389.

GenBank accession number (16S rRNA): D30773.

2. **Acidiphilium acidophilum** (Harrison 1983) Hiraishi, Nagashima, Matsuura, Shimada, Takaichi, Wakao and Katayama 1998,1396[VP] (*Thiobacillus acidophilus* (Guay and Silver 1975) Harrison 1983.)

a.ci.do'phi.lum. L. adj. *acidus* sour; M.L. neut. n. *acidum* acid; Gr. adj. *philus* loving; M.L. adj. *acidophilum* acid-loving.

Cells are rod-shaped, 0.5–0.8 × 1.0–1.5 µm , occurring singly, mainly in pairs and rarely chains. Motile by means of single polar flagella or nonmotile. Colonies on agar media are small (1–2 mm in diameter after one week of incubation), round, smooth, convex, slightly translucent, and cream colored; if cells age, they become pink to light brown. Strictly aerobic; facultatively chemolithotroph and mixotroph, growing with elemental sulfur as an energy source. Thiosulfate, trithionate, and tetrathionate also serve as electron donor. Neither sulfite, sulfide, nor ferrous ion is used as electron donor. Polyhedral inclusion bodies (carboxysomes) are present in elemental sulfur-growing cells. Carbon sources utilized are listed in Table BXII.α.17. D-Glucose, D-fructose, and some other sugars support good growth. Growth is inhibited by the presence of 1% glucose, 0.3% yeast extract, or 1% trypticase. No growth factor is required. Ammonium salts are utilized as nitrogen source. Catalase positive. Oxidase negative. Arsenite oxidation is negative. Optimal growth occurs at 25–30°C (range: 15–35°C) and at pH 3.0–3.5 (range: pH 1.5–6.0). No growth occurs in the presence of 3% NaCl. Habitat: Originally isolated from an iron-oxidizing culture of *Thiobacillus ferrooxidans* and found in strongly acidic environments including mine drainage.

The mol% G + C of the DNA is: 62.9–63.2 (T_m).

Type strain: ATCC 27807 (DSM 700).

GenBank accession number (16S rRNA): D86511.

3. **Acidiphilium multivorum** Wakao, Nagasawa, Matsuura, Matsukura, Matsumoto, Hiraishi, Sakurai and Shiota 1995, 197[VP] (Effective publication: Wakao, Nagasawa, Matsuura, Matsukura, Matsumoto, Hiraishi, Sakurai and Shiota 1994, 156.)

mul.ti.vo'rum. L. adj. *multus* many; L. v. *voro* eat, consume; M.L. adj. *multivorum* devouring many kinds of substances.

Cells are rod-shaped, 0.5–0.9 × 1.5–3.8 µm under optimal growth conditions. Motile by means of single polar, subpolar, or lateral flagellum; some strains appear to be nonmotile. Colonies on agar media are circular (1–2 mm in diameter after 3 days of incubation), smooth, slightly convex, opaque, and white to cream, and turn pink to light brown after continued incubation. Strictly aerobic, chemoorganoheterotrophic bacteria. Carbon sources utilized are listed in Table BXII.α.17. D-Glucose, D-fructose, and some other sugars support good growth. Growth is not inhibited by the presence of 1% glucose, 0.3% yeast extract, or 1% trypticase. Growth factors are required and this requirement is satisfied by 0.01% yeast extract. Ammonium salts and nitrate salts are utilized as nitrogen source. Nitrate is reduced to nitrite. No denitrification. Arsenite oxidation is positive. Catalase and urease positive. Oxidase, DNase, and amino acid carboxylases negative. Hydrogen sulfide produced. Indole not formed. Starch and gelatin are not hydrolyzed. Tween 40 and 60 hydrolyzed. Susceptible to ampicillin, chloramphenicol, penicillin, rifampin, streptomycin, and tetracycline but resistant to josamycin, kanamycin, and lincomycin. Optimal growth occurs at 27–35°C (range: 17–42°C) and at pH 3.2–4.0 (range: pH 1.9–5.6). Growth occurs in the presence of 3% NaCl. Habitat: water and sediments in acidic mine drainage streams.

The mol% G + C of the DNA is: 66.2–68.1 (HPLC).

Type strain: AIU 301, DSM 11245, JCM 8867.

GenBank accession number (16S rRNA): AB006711.

4. **Acidiphilium organovorum** Lobos, Chisolm, Bopp and Holmes 1986, 143[VP]

or.ga.no'vor.um. N.L. n. *organum* organic, compound; L. v. *voro* eat, consume; N.L. adj. *organovorum* devouring organic compounds.

Cells are rod-shaped, 0.5–0.7 × 1.0–1.5 µm under optimal growth conditions, occurring singly, in pairs, and in chains in some cases. Motile by means of polar or subpolar flagella. Colonies on agar media are circular (1–2 mm after 3 days of incubation), smooth, convex, slightly translucent, and white to cream, and turn pink to light brown after continued incubation. Strictly aerobic, chemoorganoheterotrophic bacteria having respiratory type of metabolism with oxygen as terminal electron acceptor. Carbon sources utilized are listed in Table BXII.α.17. D-Glucose, D-fructose, and some other sugars support good growth. Growth is not inhibited by the presence of 1% glucose, 0.3% yeast extract, or 1% trypticase. Growth factors are required, and this requirement is satisfied by 0.01% yeast extract. Ammonium and nitrate salts are utilized as nitrogen source. Catalase and urease positive. Oxidase negative. Arsenite oxidation negative. Susceptible to ampicillin, chloramphenicol, novobiocin, penicillin, rifampin, and tetracycline, but resistant to josamycin, lincomycin, and streptomycin. Optimal growth occurs at 25–30°C (range: 15–42°C) and at pH 3.0–3.5 (range: pH 2.0–6.0). Growth occurs in the presence of 3% NaCl. Habitat: Originally isolated from an iron-oxidizing culture of *Thiobacillus ferrooxidans* and found in acidic mine drainage.

The mol% G + C of the DNA is: is 67.4–67.5 (HPLC).

Type strain: ATCC 43141.

GenBank accession number (16S rRNA): D30775.

5. **Acidiphilium rubrum** Wichlacz, Unz and Langworthy 1986, 200[VP]

ru'brum. L. adj. *rubrum* red colored.

Cells are straight or slightly curved rods, 0.5–0.8 × 1.5–3.2 µm under optimal growth conditions, occurring singly, in pairs, and in chains in some cases. Motile by means of polar or subpolar flagella. Colonies on agar media are small (1 mm in diameter after one week of incubation), round, regular, convex, slightly translucent, and red to violet. Strictly aerobic, chemoorganoheterotrophic bacteria having respiratory type of metabolism. Carbon sources utilized are listed in Table BXII.α.17. D-Glucose, D-fructose, and some other sugars support good growth. Growth is inhibited by the presence of 1% glucose, 0.3% yeast extract, or 1% trypticase. Growth factors are required and this requirement is satisfied by 0.01% yeast extract. Ammonium salts

are utilized as nitrogen source. Catalase positive. Oxidase negative. Arsenite oxidation negative. Optimal growth occurs at 25–30°C (range: 15–35°C) and at pH 3.0–3.5 (range: 2.0–5.9). No growth occurs in the presence of 3% NaCl. Habitat: water and sediments in acidic mine drainage streams.

The mol% G + C of the DNA is: 63 (T_m), 63.2–64.0 (HPLC).

Type strain: OP, ATCC 35905.

GenBank accession number (16S rRNA): D30776.

Genus III. **Acidisphaera** *Hiraishi, Matsuzawa, Kanbe, and Wakao 2000b, 1544*[VP]

Akira Hiraishi

A.ci.di.sphae′ra. M.L. n. *acidum* an acid; M.L. fem. n. *sphaera* sphere; M.L. fem. n. *Acidisphaera* acid (-requiring) coccoid microorganism.

Cells are cocci or coccobacilli, 0.7–0.9 × 0.9–1.6 μm. Nonmotile. Spore and capsules are not formed. Multiply by binary fission. Gram negative. Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Chemoorganotrophic. **Produce bacteriochlorophyll *a* esterified with phytol and carotenoids** as photosynthetic pigments only under aerobic growth conditions in the dark. Light stimulates aerobic growth and viability. Do not grow phototrophically under anoxic conditions in the light. Liquid cultures and colonies on agar media are pink or salmon-pink. Growth occurs with a number of simple organic compounds as electron donor and carbon source. Growth on complex media containing peptone is poor. Sulfide, S^0, thiosulfate, and Fe^{2+} do not serve as electron donors for chemolithotrophic growth. Catalase and oxidase positive. Mesophilic. **Obligately acidophilic**, growing in the pH range of 3.5–6.0 (but not at pH 3.0 or 6.5). Freshwater bacteria that do not require NaCl for optimal growth. **Ubiquinones with ten isoprene units** (Q-10) are present. Members of the class *Alphaproteobacteria*. Isolated from acidic mineral environments including surface water and sediment in acidic hot springs (at 42°C and below) and mine drainage streams.

The mol% G + C of the DNA is: 69–70.

Type species: **Acidisphaera rubrifaciens** Hiraishi, Matsuzawa, Kanbe and Wakao 2000b, 1545.

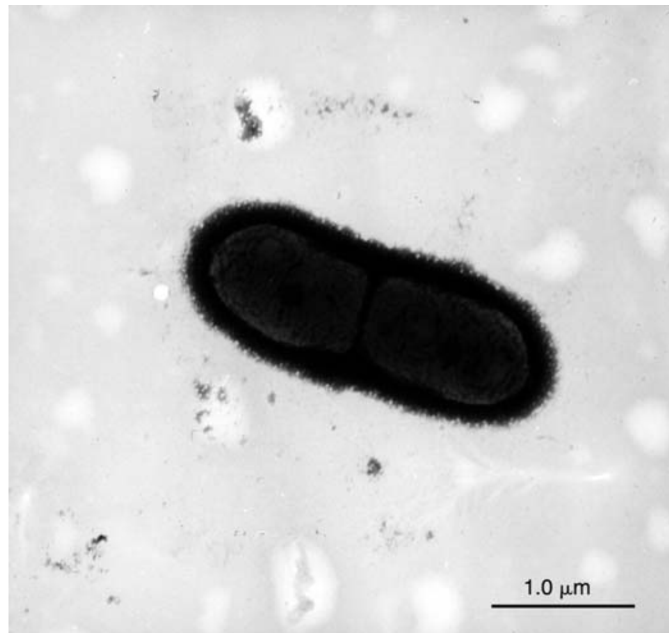

FIGURE BXII.α.22. Electron micrograph showing general cell morphology of *Acidisphaera rubrifaciens* (strain HS-AP3).

Further descriptive information

Cells of *A. rubrifaciens* are cocci, coccobacilli, or short rods and occur singly or in pairs (Fig. BXII.α.22). Motility is not observed at any growth stage. Thin-section electron microscopy shows that cells have typical Gram-negative membranes (Fig. BXII.α.23). Internal photosynthetic membranes are not found. Polyphosphate granules are present.

Colonies grown on agar media are 2 mm in diameter after one week of incubation, and are round, smooth, circular, convex, and salmon pink.

The photosynthetic pigments are magnesium-chelated bacteriochlorophyll (Mg-BChl) *a* esterified with phytol and the carotenoid spirilloxanthin. In addition to this carotenoid component, cells contain much larger amounts of a polar carotenoid that hardly migrates on silica-gel thin-layer chromatography with benzene–acetone (1:1, v/v) as the developing solvent. Membrane preparations from cells grown aerobically in darkness show major absorption maxima at 474–476, 502–503, 545 (shoulder), 590 (shoulder), 801, and 873–874 nm. The very low absorption peak at around 800 nm, compared to the peak at 873–874 nm, suggests that cells contain the core light-harvesting complex (LH I) together with the photosynthetic reaction center, but lack peripheral antenna complexes. The acetone–methanol extract has absorption maxima at 386, 466–467 (shoulder), 494–495, 525–526, and 770 nm, indicating the presence of Mg-BChl *a* but not Zn-BChl *a* as the major photopigment. However, when cells are grown in the presence of 1 mM zinc sulfate, an additional photopigment, Zn-BChl *a*, occurs in a trace amount (1–2% of the amount of Mg-BChl *a*) (Hiraishi et al., 2000b). As with many other species of aerobic BChl-containing bacteria (Shimada, 1995; Yurkov and Beatty, 1998a), aerobic and dark conditions are most favorable for BChl production by *A. rubrifaciens*. BChl production is repressed completely by continuous illumination. The BChl *a* content of *A. rubrifaciens* strains grown under optimal growth conditions in darkness ranges from 35 to 90 nmol/g dry weight of cells (Hiraishi et al., 2000b). A marked increase in BChl content is found under oligotrophic or starvation conditions (A. Hiraishi, unpublished data).

Strains of *A. rubrifaciens* are aerobic chemoorganotrophic bacteria that grow well under aerobic conditions with shaking but do not exhibit phototrophic growth under anaerobic conditions in the light. They have a doubling time of 11–13 h when grown in gluconate-containing liquid medium in darkness. Continuous incandescent illumination stimulates aerobic growth significantly, provided that the preculture is grown in darkness. The

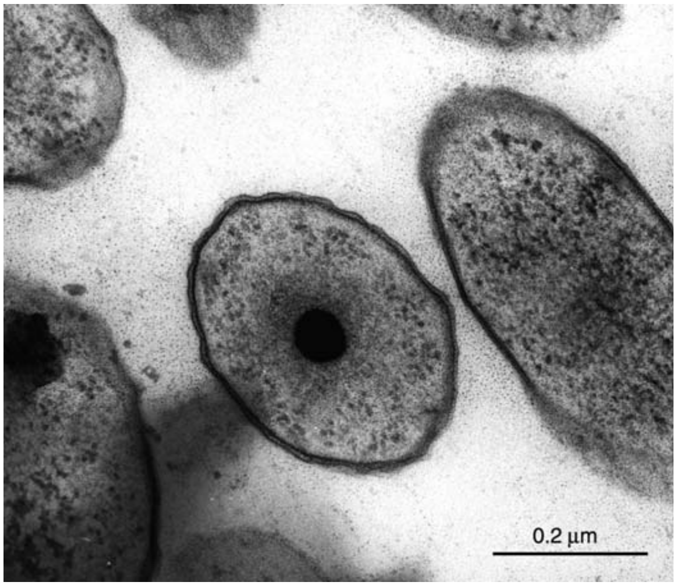

FIGURE BXII.α.23. Thin-section electron micrograph showing ultrastructure of *Acidisphaera rubrifaciens* cells (strain HS-AP3).

growth yield is 1.5–1.8-fold higher in illuminated cultures than in chemotrophic dark cultures. Illumination also enhances the viability of *A. rubrifaciens* cells under starvation conditions, as is the case in some other aerobic BChl-containing bacteria (Shiba, 1984).

The optimum pH for growth is 4.5–5.0. The temperature range for growth is 20–40°C (optimum 30–35°C). Growth is good in the absence of NaCl and is inhibited by adding 3% NaCl.

Catalase and cytochrome oxidase are produced. Hydrolysis of starch, Tween 80, or casein is negative. Nitrate is not reduced to nitrite. Utilization patterns of organic compounds as carbon and energy sources are shown in Tables BXII.α.18 and BXII.α.19. Good carbon sources are gluconate, lactate, malate, and pyruvate. Moderate growth is observed with xylose, galactose, glycerol, sorbitol, ethanol, and some intermediates of the tricarboxylic acid cycle. Little or no growth occurs with maltose, lactose, sucrose, lower fatty acids, citrate, benzoate, amino acids, Casamino acids, or peptone.

The major respiratory quinone, Q-10, accounts for 98–99% of the total quinone contents. The remainder detected is Q-9. Other quinone ring groups, such as menaquinones and rhodoquinones, are not found.

The natural habitats and ecological roles of *A. rubrifaciens* have not yet been fully identified. Strains of *A. rubrifaciens* have so far been isolated from acidic mineral environments including surface water and sediment in acidic hot springs (at 42°C and below) and mine drainage streams (Hiraishi et al., 2000b). In mine drainage environments, *A. rubrifaciens* frequently coexists with members of the genus *Acidiphilium*, another group of acidophilic aerobic BChl-containing bacteria (A. Hiraishi, unpublished observations). In view of its characteristic lifestyle as an acidophilic BChl-producing bacterium, *A. rubrifaciens* appears to have an ecological niche similar to that of *Acidiphilium* species, although the former organism differs from the latter in exhibiting weaker acidophily and lacking Zn-BChl as the main photosynthetic pigment. In sunlight-exposed environments, *A. rubrifaciens* can be viable and survive for a long time without any carbon/energy source. Synthesis and expression of the photosynthetic apparatus in *A. rubrifaciens* may be regarded as a result of its adaptation to oligotrophic and mineral environments like hot springs and mine drainage streams.

Enrichment and Isolation Procedures

A suitable medium for growth and purification of *Acidisphaera* contains (per liter distilled water): $(NH_4)_2SO_4$, 1.0 g; KH_2PO_4, 1.0 g; $MgSO_4 \cdot 7H_2O$, 0.5 g; $CaCl_2 \cdot 2H_2O$, 0.05 g; and trace element solution SL8 (Biebl and Pfennig, 1978), 1.0 ml. To this medium are added (per liter): gluconate, 2.0–3.0 g, and yeast extract (Difco), 1.0 g. The organic supplements are autoclaved separately and combined with the basal medium before use. The final pH of the medium should be 4.0–4.5. For solid media, separately

TABLE BXII.α.18. Differential characteristics of *Acidisphaera* and phenotypically and phylogenetically related genera of BChl-containing bacteria[a]

Characteristic	*Acidisphaera*	*Acidiphilium*[b]	*Craurococcus*[c]	*Paracraurococcus*[c]	*Roseococcus*[d]	*Rhodopila*[e]

[a]For symbols see standard definitions; Q-10, ubiquinone-10; MK-9, menaquinone-9; RQ-9, rhodoquinone-9. Q-9(10), MK-9(10), and RQ-9(10) mean the presence of those quinones with both 9 and 10 isoprene units in the side chain.

[b]Information from Hiraishi et al. (1998).

[c]Information from Saitoh et al. (1998).

[d]Information from Yurkov and Gorlenko (1992) and Yurkov et al. (1994c).

[e]Information from Pfennig (1974).

autoclaved 1.5% agar or 0.6% gellan gum can be used. Enrichment and isolation of *A. rubrifaciens* from the environment are possible using the above-noted medium, but an alternative use of both gluconate (1.0 g/l) and D-xylose (1.0 g/l) as the carbon source may be more effective in some cases. Cultures are incubated aerobically at 30°C in darkness. Although other aerobic acidophilic bacteria and acid tolerant bacteria are frequently recovered in or on isolation media, enriched cultures or colonies of *A. rubrifaciens* are distinguishable by their pink or salmon-pink color.

Maintenance Procedures

Cultures are preserved in liquid nitrogen or by lyophilization. Preservation in a mechanical freezer at −80°C is also possible.

Differentiation of the genus *Acidisphaera* from other genera

The genus *Acidisphaera* is differentiated from other genera of aerobic BChl-containing bacteria by a combination of morphological, physiological, and chemotaxonomic characteristics as indicated in Table BXII.α.18.

Taxonomic Comments

The description of the genus *Acidisphaera* is based on only one species, *A. rubrifaciens* (Hiraishi et al., 2000b). The 16S rDNA sequences of *A. rubrifaciens* strains place them in the major acidophilic cluster of the class *Alphaproteobacteria*, with members of the genera *Acidiphilium*, *Rhodopila*, *Acetobacter*, and *Gluconobacter* as their phylogenetic relatives. The nearest phylogenetic neighbor is the anaerobic phototrophic bacterium *Rhodopila globiformis* (95% similarity).

Before the description of *A. rubrifaciens*, acidophilic aerobic BChl-containing bacteria had been limited to members of the genus *Acidiphilium*, which contain Zn-BChl *a* rather than Mg-BChl *a* as the major photopigment (Wakao et al., 1996; Hiraishi et al., 1998). Thus, *A. rubrifaciens* is the first description of acidophilic aerobic bacteria containing Mg-BChl *a* as the major photopigment. *A. rubrifaciens* is similar to the moderately acidophilic phototrophic bacterium *Rhodopila globiformis* (Pfennig, 1974) in morphology, physiology, and natural habitats, but *A. rubrifaciens* differs clearly from the latter by failing to grow anaerobically in the light. The level of 16S rDNA sequence similarity between *A. rubrifaciens* and *R. globiformis* is low enough to warrant different generic allocations.

TABLE BXII.α.19. Physiological and biochemical characteristics of *Acidisphaera rubrifaciens*[a]

Characteristic	Result/reaction
Optimal temperature (°C) for growth	30–35

Differentiation of the species of the genus *Acidisphaera*

The genus *Acidisphaera* is monotypic, with *A. rubrifaciens* as the type species. General characteristics of *A. rubrifaciens* in terms of physiology and biochemistry are shown in Table BXII.α.19.

List of species of the genus Acidisphaera

1. **Acidisphaera rubrifaciens** Hiraishi, Matsuzawa, Kanbe and Wakao 2000b, 1545[VP]

rub.ri.fac′i.ens. L. adj. *ruber* red; L. v. *facio* make; M.L. part. adj. *rubrifaciens* red-producing.

The characteristics are as described for the genus and as listed in Tables BXII.α.18 and BXII.α.19, with the following additional features. Cells are 0.7–0.9 × 0.9–1.6 μm. No intracytoplasmic membrane systems occur. Polyphosphate granules are present. Cell membranes have absorption maxima at 474–476, 502–503, 545, 590, 801, and 873–874 nm. Acetone-methanol extracts from cells have absorption maxima at 386, 466–467, 494–495, 525–526, and 770 nm. Sprilloxanthin and a polar pigment are the major carotenoids. No hydrolysis of starch, casein and Tween 80 occurs. Gluconate, lactate, malate, and pyruvate are good carbon sources. Other usable carbon sources are galactose, glucose, D-xylose, glycerol, mannitol, sorbitol, fumarate, malate, succinate, and yeast extract. The habitats are strongly acidic mineral environments, including acidic hot springs (at 42°C and below) and pyritic mine drainage.

The mol% G + C of the DNA is: 69.1–69.8 (HPLC).

Type strain: HS-AP3, JCM 10600.

GenBank accession number (16S rRNA): D86512.

Genus IV. Acidocella *Kishimoto, Kosako, Wakao, Tano, and Hiraishi 1996, 362*VP *(Effective publication: Kishimoto, Kosako, Wakao, Tano, and Hiraishi 1995b, 90)*

Akira Hiraishi

A.ci.do.cel′ la. M.L. n. *acidum* an acid; L. n. *cella* a cell; M.L. n. *Acidocella* acid (-requiring) cell.

Straight or slightly curved rods and coccobacilli with rounded or tapered ends, 0.5–0.8 × 1.0–2.0 μm. Motile by means of polar or lateral flagella; some strains are nonmotile. Nonsporeforming and nonencapsulated. Gram negative. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Cell suspensions and colonies are white, cream, or light brown. Photosynthetic pigments and carotenoids are absent. Mesophilic. **Obligately acidophilic, growing in the pH range of 3.0–6.0;** some strains grow at pH 2.5. No growth occurs at pH ≥6.1. **Chemoorganotrophs,** growing with simple organic compounds as carbon and energy sources. **Growth occurs in the presence of either 0.25 mM acetate, 2 mM lactate, or 4 mM succinate.** Catalase positive. **Oxidase negative or weakly positive. A straight-chain monounsaturated $C_{18:1}$ acid is the major component of cellular fatty acids. Ubiquinones with ten isoprene (Q-10) units are present. 16S rRNA structures and signatures conform to species of the *Alphaproteobacteria.*** Inhabit strongly acidic mineral environments.

The mol% G + C of the DNA is: 58–65.

Type species: **Acidocella facilis** (Wichlacz, Unz, and Langworthy 1986) Kishimoto, Kosako, Wakao, Tano, and Hiraishi 1996, 362 (Effective publication: Kishimoto, Kosako, Wakao, Tano, and Hiraishi 1995b, 90) (*Acidiphilium facilis* Wichlacz, Unz, and Langworthy 1986, 200.)

Further descriptive information

Acidocella cells are straight or slightly curved rods with rounded or tapered ends, occurring singly or in pairs (Fig. BXII.α.24). In some cases, they are observed in chains and small flocs. Cells vary from 0.5 to 0.8 μm in width and from 1.0 to 2.0 μm in length under optimal growth conditions. Strains of each species are usually motile, but nonmotile strains are occasionally found. Electron microscopy of negatively stained cells shows that motile cells have polar or lateral flagella (Fig. BXII.α.25). The flagellar arrangement is different from strain to strain; in some cases, cells with polar flagella and with lateral flagella coexist in a single strain.

Colonies on agar media are circular (3–5 mm in diameter after 3 d of incubation), smooth, convex, slightly translucent, and white, cream, or light brown in color. Neither bacteriochlorophylls nor carotenoid pigments are present.

Acidocella species are nutritionally more versatile and exhibit more rapid and luxuriant growth than the phylogenetically and physiologically related *Acidiphilium* species. Most *Acidocella* strains exhibit a doubling time of 2–3 h under optimal growth conditions. The following sugars and sugar alcohols are good substrates supporting growth of all species: L-arabinose, D-xylose, D-ribose, D-glucose, D-galactose, D-fructose, sucrose, glycerol, arabitol, and mannitol. The following compounds are not used as carbon sources: L-rhamnose, maltose, cellobiose, methanol, formate, acetate, propionate, butyrate, valerate, caproate, lactate, and benzoate. As is the case with *Acidiphilium*, acidophilic growth of *Acidocella* strains is inhibited in the presence of high concentrations of organic acids such as acetate, lactate, and succinate when grown in glucose-mineral medium. However, *Acidocella* species are more tolerant to such organic acids at low concentrations.

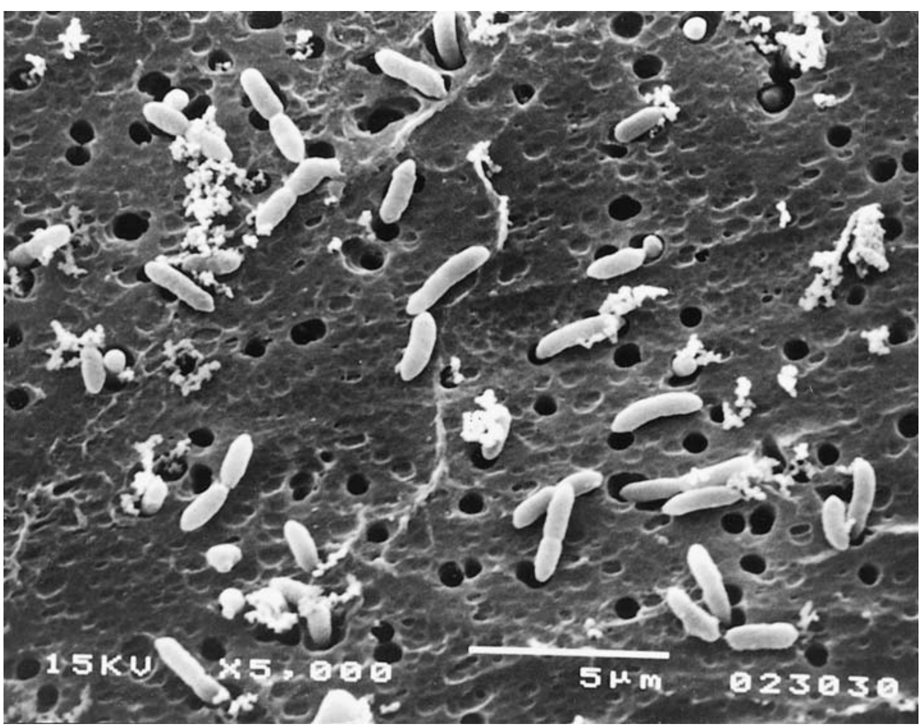

FIGURE BXII.α.24. Scanning electron micrograph showing general cell morphology of *Acidocella facilis* (ATCC 35904T.)

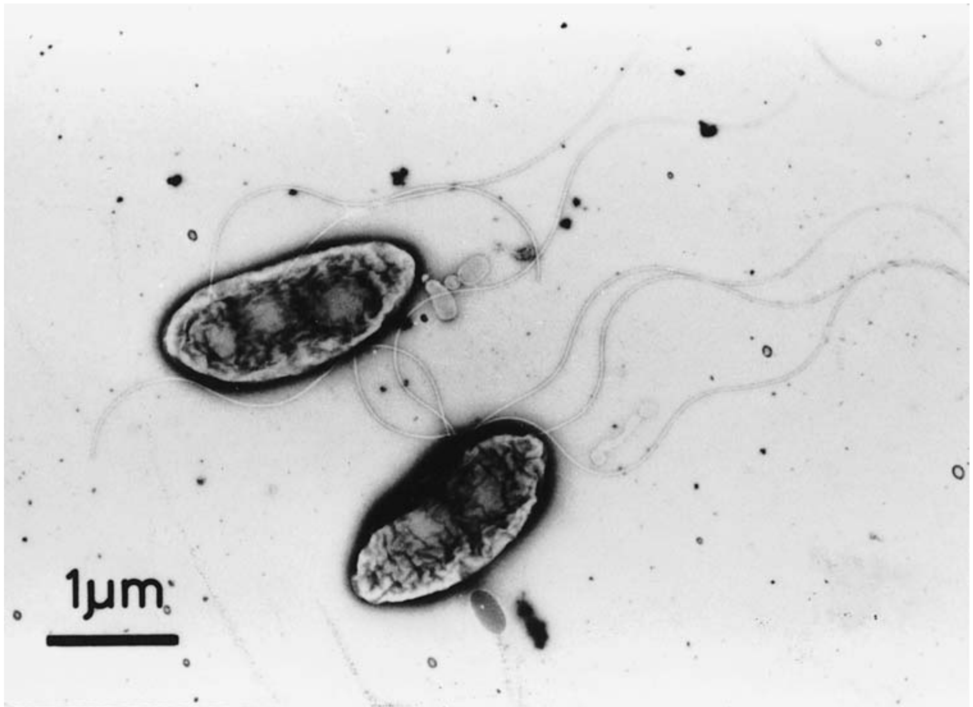

FIGURE BXII.α.25. Electron micrograph of negatively stained cells of *Acidocella facilis* (ATCC 35904^T) having lateral flagella. (Reprinted with permission from K. Inagaki, Nippon Nogeikagaku Kaishi *71:* 1–8, 1997, ©Japan Society for Bioscience, Biotechnology, and Agrochemistry.)

They are capable of growing in the presence of 0.25 mM acetate, 2 mM lactate, 4 mM succinate, or 0.3% yeast extract, each of which has an inhibitory effect on the growth of *Acidiphilium*.

None of the *Acidocella* species grows chemolithotrophically with S^0 or thiosulfate as the energy source. Neither Fe^{2+} nor other metal ions serve as the electron donor for growth. However, the addition of ferrous or aluminum ions stimulates heterotrophic growth significantly. All species are capable of growth in the presence of 100 mM Fe^{2+} and 100 mM Al^{3+}. Growth yields are much higher in the presence of 100 mM Al^{3+} than in the absence of Al^{3+}, and this growth-promoting effect is more pronounced with aluminum sulfate than with aluminum chloride or aluminum phosphate (A. Hiraishi, unpublished). Some strains also exhibit extremely high resistance to heavy metals such as cadmium, copper, nickel, and zinc; however, these metals extend the lag period and generation time for growth. The heavy-metal resistance of *Acidocella* strains may be plasmid-dependent. When *Acidiphilium multivorum* and *Escherichia coli* were subjected to transformation with a plasmid prepared from an *Acidocella* strain, they became more highly resistant to cadmium and zinc (Ghosh et al., 1997).

Acidocella strains, as well as *Acidiphilium* strains, contain high amounts of phosphorus-free lipoamino acids in their cell membranes. Ornithine amide lipids, $C_{18:1}$ fatty acid esters of α-*N*-3-hydroxystearylornithine and α-*N*-3-hydroxystearylornithyltaurine, are the major polar aminolipids (Kishimoto et al., 1993a). In addition to these lipids, phosphatidylglycerol, phosphatidylethanolamine, and phosphatidylcholine are present as the major phospholipids. Bisphosphatidylglycerol is absent. Straight-chain monounsaturated $C_{18:1}$ acid is the major component of whole-cell fatty acids, constituting 57–66% of the total content (Kishimoto et al., 1993b). A considerable amount of cyclopropane $C_{19:0}$ acid (6–21%) is also present. 2-Hydroxymyristic acid is found in these strains. Ubiquinone-10 is the sole respiratory quinone.

The genetic aspects of *Acidocella facilis* have been studied to some degree. The *recA* gene of *A. facilis* has been cloned and sequenced (Inagaki et al., 1993). In the deduced amino acid sequence of the recA protein, *A. facilis* showed a similarity level of 72% to *Thiobacillus ferrooxidans*, 62% to *Escherichia coli*, and 53% to *Bacillus subtilis*.

Like *Acidiphilium* strains, *Acidocella* strains inhabit strongly acidic mineral environments. These organisms have so far been isolated from water and sediment taken from acidic mine drainage streams (Wichlacz et al., 1986; Kishimoto et al., 1993b) and acidic soil from a copper mine (Banerjee et al., 1996). In these environments, *Acidocella* strains frequently coexist with members of the genera *Acidiphilium* and *Acidithiobacillus*. *Acidocella* strains also inhabit acidic hot springs and acidic farm soil, and are the most abundant heterotrophic bacteria isolated from sulfuric acidic tropical soil (I. Nioh, personal communication). Moreover, mud and sewage at slightly acidic pH are possible sources of these organisms (Kishimoto and Tano, 1987; Kishimoto et al., 1993b).

Enrichment and Isolation Procedures

Growth media for *Acidocella* are similar to those for *Acidiphilium*. A suitable medium consists of (per liter of distilled water): $(NH_4)_2SO_4$, 2.0 g; KH_2PO_4, 1.0 g; $MgSO_4 \cdot 7H_2O$, 0.5 g; $CaCl_2 \cdot 2H_2O$, 0.05 g; and trace element solution SL8 of Biebl and Pfennig (1978) (pH 3.0), 1.0 ml. Glucose (3.0 g/l) and yeast

extract (Difco, 0.5 g/l) are added to the medium from autoclaved stock solutions to give final concentrations of 3.0 g/l and 0.5 g/l, respectively. When used as a solidified medium, the medium also contains 1.5% agar (separately autoclaved). Alternatively, 0.6% gellan gum can be used for this purpose (Kishimoto and Tano, 1987). For selective isolation and enrichment of *Acidocella* from the environment, the medium is supplemented with 0.2 mM acetate to inhibit co-growth of *Acidiphilium* and is adjusted to pH 2.5–3.0 to minimize growth of fungi and facultatively acidophilic bacteria.

Maintenance Procedures

Cultures can be preserved in liquid nitrogen or by lyophilization. Preservation in a mechanical freezer at −80°C is also satisfactory.

Differentiation of the genus *Acidocella* from other genera

The genus *Acidocella* is separated from other genera of chemoorganotrophic proteobacteria by its phylogenetic position and its outstanding physiological and chemotaxonomic characteristics. The differential characteristics of the genera *Acidocella* and *Acidiphilium* are indicated in Table BXII.α.20.

TABLE BXII.α.20. Differential characteristics of the genera *Acidocella* and *Acidiphilium*[a]

Characteristic	*Acidocella*	*Acidiphilium*
Cell width, μm	0.5–0.8	0.3–0.8
Pink or yellow pigment	−	D
Photosynthetic pigments	−	+
Growth inhibition by:		
Acetate, 0.25 mM	−	+
Lactate, 2 mM	−	+
Succinate, 4 mM	−	+
Bisphosphatidylglycerol	−	+
2-Hydroxy fatty acid	$C_{14:0}$	−
Mol% G + C of DNA	58–65	63–68

[a]For symbols see standard definitions.

Taxonomic Comments

Phylogenetic analyses based on 16S rDNA sequence information have shown that *Acidocella* species form a major cluster in the *Alphaproteobacteria*, together with the acidophilic, chemotrophic genera *Acidiphilium*, *Acetobacter*, and *Gluconobacter*, and the anaerobic phototrophic acidophile *Rhodopila* (Sievers et al., 1994a; Kishimoto et al., 1995b). The genus *Acidiphilium* is the nearest phylogenetic neighbor. The levels of 16S rDNA sequence similarity between members of the genera *Acidocella* and *Acidiphilium* are 92–94%.

The two established species of the genus *Acidocella*, *A. facilis* and *A. aminolytica*, were originally classified in the genus *Acidiphilium* as *Acidiphilium facilis* and *Acidiphilium aminolytica*, respectively. However, these two species were found to differ from other *Acidiphilium* species in the lack of the ability to produce photosynthetic pigments (Wakao et al., 1993; Kishimoto et al., 1995a) and in some other phenotypic properties (Kishimoto et al., 1995b). Also, phylogenetic analyses based on 16S rDNA sequences revealed that although *A. facilis* and *A. aminolytica* form a monophyletic cluster with other *Acidiphilium* species in the *Alphaproteobacteria*, there was a significant genetic distance at the generic level between the former two species and the latter (Kishimoto et al., 1995b). These findings led to the conclusion that the non-BChl producing species (i.e., *A. facilis* and *A. aminolytica*) should be removed from the genus *Acidiphilium.*

However, the name *Acidocella* is an orthographic error. The first constituent of the name (Acidi-, from *acidum*, acid) is derived from Latin and therefore the connecting vowel to the second constituent (-cella cell) must be -i-. A correction of the name *Acidocella* to *Acidicella* is recommended so as to be in accord with Rule 57c, Note 1 of the International Code of Nomenclature of Bacteria (Lapage et al., 1992). Likewise, the original spelling of the specific epithet, *A. aminolytica*, should be changed to *aminilytica.*

The levels of 16S rDNA sequence similarity and DNA–DNA hybridization between *A. facilis* and *A. aminolytica* are 98% and 10–15%, respectively (Kishimoto et al., 1993b, 1995b).

Acknowledgments

The author is indebted to K. Inagaki for providing the electron micrograph and H.G. Trüper for his valuable advice on bacterial nomenclature.

Differentiation of the species of the genus *Acidocella*

The differential characteristics of the species of *Acidocella* are indicated in Table BXII.α.21.

List of species of the genus Acidocella

1. **Acidocella facilis** (Wichlacz, Unz, and Langworthy 1986) Kishimoto, Kosako, Wakao, Tano, and Hiraishi 1996, 362[VP] (Effective publication: Kishimoto, Kosako, Wakao, Tano, and Hiraishi 1995b, 90) (*Acidiphilium facilis* Wichlacz, Unz, and Langworthy 1986, 200.)

Genus V. **Acidomonas** *Urakami, Tamaoka, Suzuki and Komagata 1989a, 54*[VP]

MARTIN SIEVERS AND JEAN SWINGS

A.ci.do.mo' nas. Gr. adj. *acid* acid; Gr. n. *monas* unit, monad; M.L. fem. n. *Acidomonas* acidophilic monad.

Cells are Gram negative, nonsporeforming, nonmotile, rod shaped, 0.8–1.0 × 1.5–3.0 μm. Cells occur singly, rarely in pairs. Colonies were white to yellow on PYM medium. Strictly aerobic. Facultative methylotroph. Metabolism is respiratory, never fermentative. Optimal temperature for growth is 30°C. Optimal pH for growth is pH 4.0–4.5. Catalase positive. Nitrate is not reduced to nitrite. Oxidizes ethanol to acetic acid. Overoxidizes acetic acid to CO_2 and H_2O. *Acidomonas* contains $C_{18:1}$ straight-chain unsaturated fatty acid as well as $C_{16:0\ 3OH}$ and $C_{16:0\ 2OH}$ as major components of cellular and hydroxy fatty acids, as do the other genera of the family *Acetobacteraceae* (Yamada et al., 1981; Urakami and Komagata, 1987a; Urakami et al., 1989a). The ubiquinone system is Q-10, along with ubiquinone Q-9 and Q-11 as minor components.

The mol% G + C of the DNA is: 62.

Type species: **Acidomonas methanolica** (Uhlig, Karbaum and Steudel 1986) Urakami, Tamaoka, Suzuki and Komagata 1989a, 54 (*Acetobacter methanolicus* Uhlig, Karbaum and Steudel 1986, 321.)

MAINTENANCE PROCEDURES

For cultivation and maintenance of *Acidomonas* a peptone–yeast extract–malt extract agar (PYM medium) is used. The medium is composed of 0.5% peptone, 0.3% yeast extract, 0.3% malt extract, 1.0% glucose, and 2.0% agar; adjusted to pH 4.5 with 1 N HCl (Urakami et al., 1989a).

Cultures were incubated at 30°C. In addition, the medium 569 is used for cultivation of *Acidomonas methanolica*. It is composed of: KNO_3, 1.0 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; $CaCl_2 \cdot 2H_2O$, 0.02 g; Na_2HPO_4, 0.23 g; NaH_2PO_4, 0.07 g; $FeSO_4 \cdot 7H_2O$, 1.0 mg; $CuSO_4 \cdot 5H_2O$, 5.0 mg; H_3BO_3, 10.0 mg; $MnSO_4 \cdot 5H_2O$, 10.0 mg; $ZnSO_4 \cdot 7H_2O$, 70 mg; MoO_3, 10 mg; agar, 12 g; distilled H_2O, 1000 ml; methanol, 10 ml. Sterile-filtrated methanol is added after sterilization of the basal medium. The pH of the medium is 6.8, growth is aerobically at 30°C.

DIFFERENTIATION OF THE GENUS *ACIDOMONAS* FROM OTHER GENERA

Acidomonas can be differentiated from *Acetobacter*, *Gluconacetobacter*, *Asaia*, and *Gluconobacter* by growth on methanol and utilization of methanol.

TAXONOMIC COMMENTS

Acetobacter methanolicus was described by Uhlig et al. (1986) as a new *Acetobacter* species and classified as *Acidomonas methanolica* by Urakami et al. (1989a). It was reclassified in the genus *Acetobacter* by Sievers et al. (1994b) based on the 16S rDNA sequence of the type strain. Due to the current classification of acetic acid bacteria (Table BXII.α.9 in *Acetobacteraceae*), the name *Acidomonas methanolica* is used.

List of species of the genus Acidomonas

1. **Acidomonas methanolica** (Uhlig, Karbaum and Steudel 1986) Urakami, Tamaoka, Suzuki and Komagata 1989a, 54[VP] (*Acetobacter methanolicus* Uhlig, Karbaum and Steudel 1986, 321.)
me.tha.no′ li.cus. L. n. *methanolum* methanol; L. adj. *methanolicus* methanolic, using methanol as a sole carbon source.

Ellipsoidal to rod-shaped cells 0.6–0.8 × 1.0–1.8 μm, occurring singly, in pairs, or rarely in short chains. Cells are usually motile by peritrichous flagellation. Oxidase negative (but under methylotrophic conditions oxidase positive). *A. methanolica* is a facultatively methylotrophic bacterium and utilizes methanol as the sole source of carbon and energy. Methanol is oxidized to formate and fixed by the ribulose monophosphate cycle for biosynthetic purposes (Steudel et al., 1980; Babel, 1984). *A. methanolica* has two independent respiratory chains for methanol and ethanol (Matsushita et al., 1992c). Two different forms of methanol dehydrogenase have been purified from *A. methanolica* containing PQQ as cofactor (Matsushita et al., 1993). Glucose is oxidized to gluconate, but 2-, 5-ketogluconic acid, and 2,5-diketogluconic acid are not produced. No production of dihydroxyacetone from glycerol; γ-pyrones and brown pigments are not formed. *A. methanolica* utilizes methanol, ethanol, acetic acid, D-glucose, glycerol, and pectin as sole carbon sources. Growth did not occur on D-fructose, D-sorbitol, D,L-lactate, sucrose, and lactose. Growth occurs between pH 2.0 and 5.5. Weak growth occurs on D-mannitol and D-mannose. Acid is produced oxidatively from glucose, ethanol, and methanol, but not from D-mannitol, D-xylose, L-arabinose, D-mannose, D-fructose, D-galactose, D-sorbitol, sucrose, and lactose. A medium composed of 0.3% peptone, 0.5% yeast extract, 0.1% D-glucose, and 1.5% methanol (pH adjusted to 5.5) is used for cultivation of the strains.

The mol% G + C of the DNA is: 62 (T_m).

Type strain: TK 0705, ATCC 43581, DSM 5432, IMET 10945; MB 58.

GenBank accession number (16S rRNA): D30770, X77468.

Genus VI. **Asaia** *Yamada, Katsura, Kawasaki, Widyastuti, Saono, Seki, Uchimura and Komagata 2000, 828[VP]*

Martin Sievers and Jean Swings

A.sa′ i.a. M.L. fem. n. *Asaia* derived from Toshinobu Asai, a Japanese bacteriologist who contributed to the systematics of acetic acid bacteria.

Cells are aerobic and rod shaped. Peritrichously flagellated when motile. Does not produce acid from ethanol (with the exception of one strain oxidizing ethanol to acetic acid weakly). Growth is inhibited by 0.35% (v/v) acetic acid. *Asaia* weakly oxidizes acetate and lactate to carbon dioxide and water. No growth on methanol. Growth occurred on mannitol. Produces 2-keto-D-gluconate and 5-keto-D-gluconate but not 2,5-diketo-D-gluconate from D-glucose. Acids are produced from D-glucose, D-fructose, L-sorbose, D-mannitol, and D-sorbitol. The major quinone type is Q-10.

The mol% G + C of the DNA is: 59–61.

Type species: **Asaia bogorensis** Yamada, Katsura, Kawasaki, Widyastuti, Saono, Seki, Uchimura and Komagata 2000, 828.

List of species of the genus Asaia

1. **Asaia bogorensis** Yamada, Katsura, Kawasaki, Widyastuti, Saono, Seki, Uchimura and Komagata 2000, 828[VP]
bo.go.r′ en.sis. M.L. adj. *bogorensis* derived from Bogor, Java, Indonesia, where most of the strains were isolated.

Cells are 0.4–1.0 × 0.8–2.0 μm in size. Colonies are pink-yellowish white, shiny, smooth, and raised with an entire margin on AG agar plates (Yamada et al., 2000). AG medium is composed of 0.1% D-glucose, 1.5% glycerol, 0.5% peptone, 0.5% yeast extract, 0.2% malt extract, 0.7% $CaCO_3$ and 1.5% agar (Yamada et al., 2000). *A. bogorensis* produces acid from D-glucose, D-mannose, D-galactose, D-fructose, L-sorbose, D-xylose, ribitol, *meso*-erythritol, glycerol, and melibiose. No acid production from lactose. *A. bogorensis* produces acid from dulcitol and assimilates dulcitol for growth. Acid production from D-mannitol and D-sorbitol is strain dependent. 16S rRNA sequence similarity value of *A. bogorensis* IFO 16594 with the type strain of *Acidomonas methanolica* is 96.2%.

The mol% G + C of the DNA is: 59–61 (T_m).

Type strain: IFO 16594, JCM 10569, NRIC 0311.

GenBank accession number (16S rRNA): AB025928.

2. **Asaia siamensis** Katsura, Kawasaki, Potacharoen, Saono, Seki, Yamada, Uchimura and Komagata 2001, 562[VP]
si.am′ en.sis. M.L. adj. *siamensis* of Siam, old name of Thailand.

Asaia siamensis was isolated from tropical flowers collected in Thailand and Indonesia. Isolates were cultivated for enrichment on sorbitol and dulcitol medium at pH 3.5 (Yamada et al., 2000). Cells are 0.6–1.0 × 1.0–4.5 μm. Colonies are pink, shiny, smooth, and raised with an entire margin on AG agar plates (Katsura et al., 2001). *A. siamensis* produces acid from different sugars (D-glucose, D-mannose, D-fructose, L-sorbose, D-xylose, D-mannitol, D-sorbitol, glycerol, sucrose) but not from lactose and dulcitol. Strains assimilate dulcitol for growth. Acid production from dulcitol is used for differentiation of *A. bogorensis* from *A. siamensis.* 16S rRNA sequence similarity value of *A. siamensis* IFO 16457 with the type strain of *A. bogorensis* is 99.8% by DNA relatedness of 20% and 33%, respectively.

The mol% G + C of the DNA is: 59–60 (T_m).

Type strain: IFO 16457, JCM 10715, NRIC 0323.

GenBank accession number (16S rRNA): AB035416.

Genus VII. **Craurococcus** *Saitoh, Suzuki and Nishimura 1998, 1044[VP]*

Christopher Rathgeber and Vladimir V. Yurkov

Cra.u.ro.coc' cus. Gr. adj. *crauros* fragile; Gr. n. *coccus* berry; M.L. n. *Craurococcus* fragile coccus.

Cells are coccoid, 0.8–2.0 μm in diameter, nonmotile, Gram negative, and divide by binary fission. Form pink irregular colonies when grown on agar media. **Contain bacteriochlorophyll (Bchl) *a*, spirilloxanthin and carotenoic acids. No growth occurs anaerobically in the light.** Grow heterotrophically under aerobic conditions. Nitrate is reduced to nitrite, dissimilatory denitrification not observed.

The mol% G + C of the DNA is: 70.5.

Type species: **Craurococcus roseus** Saitoh, Suzuki and Nishimura 1998, 1045.

Further descriptive information

C. roseus is the only species presently described within the genus *Craurococcus*. Phylogenetically *Craurococcus* forms a cluster with *Paracraurococcus*, *Roseococcus*, *Rhodopila*, and *Acidiphilium* within the *Alphaproteobacteria* (Saitoh et al., 1998).

C. roseus forms irregular light yellowish-red to pink colonies, less than 1 mm in diameter, on agar medium. Cells of *C. roseus* grown in NPGC medium (Saitoh and Nishimura, 1996) adjusted to pH 7.6 were coccoid. The cell size ranges from 0.8 to 2.0 μm in diameter. Cells are nonmotile, occur singly or in pairs, rarely in tetrads. Spore production has not been observed. Cells accumulate poly-β-hydroxybutyrate (PHB) granules when grown under usual culture conditions. Suspension in aqueous solution free of divalent cations causes cells to lyse (Fig. BXII.α.26). Divalent cations such as Ca^{2+} and Mg^{2+} seem to be necessary to maintain cell structure and prevent cell lysis. In liquid culture, divalent cations (0.1–1.0 g/l of $CaCl_2 \cdot 2H_2O$) are required for growth, and optimal growth occurs in BS-XY (Saitoh and Nishimura, 1996) media supplemented with 0.5 g/l $CaCl_2 \cdot 2H_2O$. Supplemental cations are not required for growth on agar media.

In vivo absorption spectra of *C. roseus* show absorption peaks at 800 and 872 nm, indicating the presence of Bchl *a* organized into reaction center and light-harvesting complexes, respectively. Crude pigment extracts in methanol give absorption spectra peaks at 362, 492, and 607 nm due to the presence of carotenoid pigments, as well as a 770 nm peak due to Bchl *a*. Bchl *a* content in cells is estimated to be 0.13 nmol/mg dry cell weight when

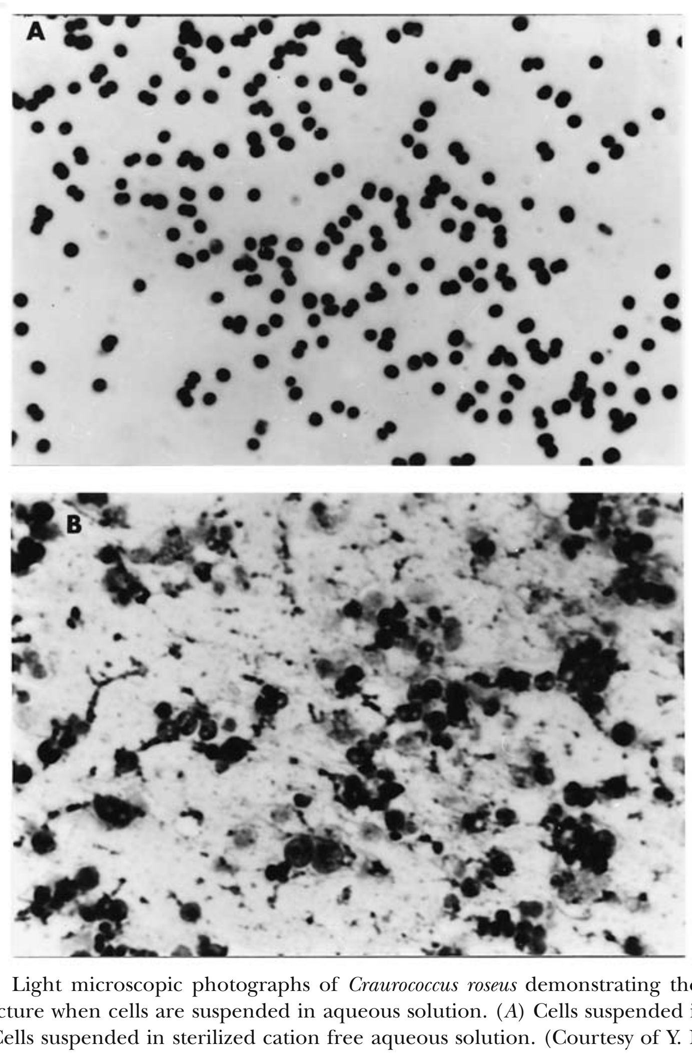

FIGURE BXII.α.26. Light microscopic photographs of *Craurococcus roseus* demonstrating the effect of divalent cations on cell structure when cells are suspended in aqueous solution. (*A*) Cells suspended in sterilized 25 mM $CaCl_2 \cdot 2\,H_2O$. (*B*) Cells suspended in sterilized cation free aqueous solution. (Courtesy of Y. Nishimura.)

grown in NPG medium, and 0.04 nmol/mg dry cell weight when grown in NPGC medium (Saitoh and Nishimura, 1996). Absorption difference spectra (illuminated minus unilluminated) show photochemical activity similar to that found in anaerobic and other aerobic anoxygenic phototrophic bacteria. Carotenoids purified by chromatographic procedures include large amounts of carotenoic acids similar to *Pseudomonas radiora*, and smaller amounts of spirilloxanthin.

The cellular fatty acid composition of *C. roseus* consists of large amounts of octadecanoic acid and small amounts of octadecadienoic acid, 2-hydroxyoctadecanoic acid, 3-hydroxytetradecanoic acid, and 3-hydroxyoctadecanoic acid. Ubiquinone is the only quinone type detected. The major ubiquinone detected is Q-10 (89–96%) and ubiquinones Q-7, Q-8, and Q-9 are present in smaller quantities. Cellular lipids consist of phospholipids of phosphotidylcholine, phosphatidylethanolamine, bisphosphatidyl-glycerol, and phosphatidylglycerol.

C. roseus grows heterotrophically under aerobic conditions. Cultures hydrolyze Tweens 20, 40, 60, and 80, and can utilize several substrates as sole carbon and energy sources for heterotrophic growth. Best growth occurs on D-xylose, fumarate, and L-glutamate. Other carbon sources include glycerol, D-fructose, D-fucose, D-galactose, D-glucose, D-arabinose, L-rhamnose, D-ribose, DL-lactate, malonate, pyruvate, gluconate, and L-malate. *C. roseus* does not show gelatinase or amylase activity.

C. roseus is an obligate aerobe, no growth occurs anaerobically under either illuminated or dark conditions. Light at intensity of about 2000 lux has not been shown to stimulate aerobic growth.

Cells do not require salt for growth, and do not grow in media supplemented with 0.4% NaCl. Cells are susceptible to chloramphenicol, penicillin, streptomycin, and tetracycline, and are resistant to polymixin B. Nicotinic acid and pantothenate are required as growth factors.

C. roseus grows at a mesophilic temperature range between 18°C and 37°C, and optimum growth occurs between 28°C and 32°C. The pH range is narrow, with growth occurring only between pH 7.2 and 8.0. Optimal pH for growth is 7.6.

Enrichment and Isolation Procedures

C. roseus was isolated on a 100-fold dilution of nutrient agar media supplemented with 1.5% agar, from soils found in a parking lot in Nerima Ward, Tokyo.

Maintenance Procedures

Cells are maintained on NPG agar medium at pH 8.0. Long-term storage procedures have not been described.

Differentiation of the genus *Craurococcus* from other genera

The genus *Craurococcus* can be differentiated from other known genera of obligately aerobic phototrophic bacteria based on several characteristics. In a phylogenetic tree derived from 16S rRNA gene sequences, *Craurococcus* forms, with the genus *Paracraurococcus*, a separate line of descent within the *Alphaproteobacteria*. This organism can be differentiated from its closest relatives based on color (yellowish-red to pink colonies) as well as specific absorption spectra characteristics. *C. roseus* is capable of growth over very narrow pH, temperature, and salinity ranges (Table BXII.α.23).

Craurococcus has an unusual requirement for divalent cations (Mg^{2+} or Ca^{2+}) when suspended in aqueous solution. Cell lysis occurs if these divalent cations are not present.

Taxonomic Comments

The 16S rDNA sequence of *C. roseus* showed that the genus *Craurococcus* is most closely related to the genus *Paracraurococcus* and that this line falls within a cluster formed by the genera *Roseococcus*, *Rhodopila*, and *Acidiphilium*. The position of *Craurococcus* is a branch between the genus *Paracraurococcus* and the other members of the cluster, within the *Alphaproteobacteria*.

growth substrates are glycerol, D-fructose, D-fucose, D-galactose, D-glucose, D-arabinose, L-rhamnose, D-ribose, DL-lactate, malonate, pyruvate, gluconate, and L-malate. Hydrolyses Tween 20, 40, 60, and 80, but does not hydrolyze starch or gelatin. No growth on D-mannitol, D-sorbitol, methanol, ethanol, 1,2-propanediol, kerosene, acetate, butyrate, citrate, formate, glycolate, propionate, succinate, phthalate, *p*-hydroxybenzoate, and benzoate.

Optimal growth occurs at pH 7.5 and temperature 28–32°C, NaCl is not required. Incapable of growth at NaCl concentrations of 0.4% and higher. Divalent cations are required for growth. Exhibits oxidase and catalase activity. Reduces nitrate to nitrite. Accumulates poly-β-hydroxybutyrate. Resistant to polymixin B. Susceptible to chloramphenicol, penicillin, streptomycin, and tetracycline. Habitat: soil from a parking lot located in Nerima Ward, Tokyo, Japan.

The mol% G + C of the DNA is: 70.5 (HPLC).

Type strain: NS130, CIP 105707, JCM 9933.

GenBank accession number (16S rRNA): D85828.

Genus VIII. **Gluconacetobacter** *Yamada, Hoshino, and Ishikawa 1998b, 32^VP (Effective publication: Yamada, Hoshino, and Ishikawa 1997, 1249)**

Martin Sievers and Jean Swings

Glu.con.a.ce.to.bac′ter. M.L. n. *acidum, gluconicum* gluconic acid; M.L. n. *bacter* masc. equivalent of Gr. neut. n. *bakterion* rod; M.L. masc. n. *Gluconacetobacter* gluconate-vinegar rod.

Cells **ellipsoidal to rod shaped**, straight or slightly curved, 0.6–1.2 × 1.0–3.0 μm, occurring singly, in pairs, or in short chains. **Motile or nonmotile; if motile, the flagella are peritrichous**. Endospores are not formed. Gram negative. **Obligately aerobic**; metabolism is strictly respiratory with oxygen as the terminal electron acceptor. Never fermentative. Some strains produce thick pellicle-forming colonies. Catalase positive and oxidase negative. Absence of gelatin liquefaction, indole production, and H_2S formation. **Oxidize ethanol to acetic acid**. **Overoxidation of acetate to CO_2 and H_2O depends upon acetate concentration in the medium**. The best carbon sources for growth are ethanol, glucose, and acetate. Acids are formed from glucose and ethanol. Species differ in respect to growth behavior on media with high acetate or glucose concentrations. Optimum temperature is 30°C. **The pH optimum for growth is 2.5–6.0**. **Possesses ubiquinone of the Q-10 type as major quinone**. The predominant fatty acid in *Gluconacetobacter* is the $C_{18:1\ \omega7}$ straight-chain unsaturated acid. ***Gluconacetobacter* species occur in vinegar, tea fungus, sugarcane, mealy bug, flowers, and fruits, and can cause infections in beverages and spirituous liquors**. *Gluconacetobacter* is not known to have any pathogenic effect toward humans and animals.

The mol% G + C of the DNA is: 55–67.

Type species: **Gluconacetobacter liquefaciens** (Asai 1935) Yamada, Hoshino and Ishikawa 1998b, 327 (Effective publication: Yamada, Hoshino and Ishikawa 1997, 1250) (*Acetobacter liquefaciens* (Asai 1935) Gosselé, Swings, Kersters, Pauwels, and De Ley 1983c, 896; *Acetobacter aceti* subsp. *liquefaciens* De Ley and Frateur 1974, 277; *"Gluconobacter liquifaciens"* Asai 1935, 610.)

Further descriptive information

Based on partial base sequences in positions 1220–1375 (*E. coli* numbering system, Brosius et al., 1981) of 16S rRNA genes, the *Gluconacetobacter* species that have Q-10 clustered remotely from the *Acetobacter* and *Gluconobacter* species (Yamada et al., 1997). The levels of overall 16S rRNA sequence similarity between members within the Q-10 equipped *Gluconacetobacter* species are above 96.5%, whereas those between all of the *Acetobacter* and *Gluconacetobacter* species are above 94.0%. The Q-10 equipped *Gluconacetobacter* species formed a cluster closely related to the species of *Acetobacter* in the phylogenetic trees based on complete 16S rRNA sequences (Sievers et al., 1994a). Members of the genus *Acetobacter* have many characteristics in common with *Gluconacetobacter*. *G. europaeus*, *G. intermedius*, *G. oboediens*, *G. entanii*, and *A. pomorum* were isolated from vinegar and share the same ecological niches.

Gluconacetobacter can only be differentiated from *Acetobacter* by the determination of the ubiquinone type. The determination of the ubiquinone type is carried out by the method of reversed-phase paper chromatography (Yamada et al., 1969). Reversed-phase HPLC is used to determine ubiquinones quantitatively (Tamaoka et al., 1983; Franke et al., 1999).

Growth on mannitol agar and acid formation from mannitol occurred in both genera *Gluconacetobacter* and *Acetobacter*. Growth on and acid formation from carbon sources are not necessarily correlated features. Fewer than 10% of the *Acetobacter* strains produce acid from D-mannitol. On the other hand, D-mannitol supported growth for most strains of acetic acid bacteria.

Cultivation media *Gluconacetobacter* species, like *G. diazotrophicus*, *G. hansenii*, and *G. liquefaciens*, grow well on mannitol medium (MYP).[1] *Gluconacetobacter sacchari* strains grow well on GYC medium.[2] *G. xylinus* strains do not develop on MYP medium and should be cultivated on GY medium.[3] *G. europaeus* requires acetic acid for growth and was cultivated on modified AE medium (Entani et al., 1985).[4] *G. intermedius* grows well on MRS medium developed for lactobacilli (de Man et al., 1960), GY medium, or AE medium. *G. johannae* and *G. azotocaptans* were cultivated on GJA medium.[5]

**Editorial Note:* Yamada et al. (1997) proposed the elevation of the subgenus *Gluconoacetobacter* (Yamada and Kondo, 1984) to the generic level, based on partial base sequences of the 16S rRNA and the ubiquinone system. The name *Gluconoacetobacter* has been corrected to *Gluconacetobacter* in accordance with Rule 61 of the International Code of Nomenclature of Bacteria.

1. MYP medium (g/l distilled water): D-mannitol, 25.0; yeast extract, 5.0; peptone, 3.0; and agar, 12.0.

2. GYC medium (g/l distilled water): D-glucose, 100.0; yeast extract, 10.0; calcium carbonate, 20.0; and agar, 20.0.

3. GY medium (g/l distlled water): D-glucose, 100.0; yeast extract, 10.0; and agar, 12.0. (A concentrated glucose solution was autoclaved separately to avoid Maillard reactions.)

4. AE medium (per liter distilled water): yeast extract, 3.0 g; peptone, 4.0 g; D-glucose, 7.5 g; agar, 8.0 g; acetic acid, 30 ml (v/v); and ethanol (99.8%), 30 ml. The ethanol and acetic acid are added after sterilization of the basal medium.

5. GJA medium [medium 920 (per liter of distilled water)]: yeast extract, 2.7; D-glucose, 2.7; D-mannitol, 1.8; MES buffer (Sigma), 4.4; K_2HPO_4, 4.81; KH_2PO_4, 0.65; and agar, 15.0 (final pH 6.7).

Enrichment and Isolation Procedures

LGI medium is used for enrichment of *G. diazotrophicus*. For isolation of *G. diazotrophicus* from sugarcane roots and stems, acetic LGI agar plates (pH 4.5) supplemented with yeast extract (0.05 g/l) and cycloheximide (0.15 g/l) were used (Fuentes-Ramírez et al., 1993). Roots and stems were washed in sterile tap water, macerated in a blender, and for inoculation, dilutions in sugar solution (5% cane sugar in H_2O) were prepared. The acetic LGI medium consists of (quantities per liter): K_2HPO_4, 0.2 g; KH_2PO_4, 0.6 g; $MgSO_4{\cdot}7H_2O$, 0.2 g; $CaCl_2{\cdot}2H_2O$, 0.02 g; $Na_2MoO_4{\cdot}2H_2O$, 0.002 g; $FeCl_3{\cdot}6H_2O$, 0.01 g; bromothymol blue (0.5% solution in 0.2 N KOH), 5 ml; crystallized cane sugar, 100 g; agar, 8.0 g; final pH adjusted to 4.5 with acetic acid (Cavalcante and Döbereiner, 1988).

Maintenance Procedures

Strains of *Gluconacetobacter* can be maintained for 2–3 weeks at 4°C on agar media used for cultivation. *Gluconacetobacter* strains, with the exception of *G. europaeus*, can be frozen and kept at −75°C in the presence of 24% (v/v) glycerol. This maintenance procedure is also possible for *G. intermedius* grown in MRS broth. *Gluconacetobacter* survives lyophilization. Freeze-drying is possible under controlled conditions also for *G. europaeus*, e.g., the type strain of *G. europaeus* DSM 6160. Another reliable method is preservation of *Gluconacetobacter* strains under liquid nitrogen. For preservation of *Gluconacetobacter* isolates from vinegar, cells at the end of the logarithmic growth phase cultivated in modified AE broth were immediately centrifuged at 3000 × g at −10°C. They were resuspended and concentrated in ice-cold 20% malt extract and frozen in liquid nitrogen (Sokollek et al., 1998a).

Differentiation of the species of the genus *Gluconacetobacter*

The differentiation of the species of the genera *Gluconacetobacter*, *Acidomonas*, and *Asaia* is given in Table BXII.α.24.

List of species of the genus Gluconacetobacter

1. **Gluconacetobacter liquefaciens** (Asai 1935) Yamada, Hoshino and Ishikawa 1998b, 327[VP] (Effective publication: Yamada, Hoshino and Ishikawa 1997, 1250) (*Acetobacter liquefaciens* (Asai 1935) Gosselé, Swings, Kersters, Pauwels, and De Ley 1983c, 896; *Acetobacter aceti* subsp. *liquefaciens* De Ley and Frateur 1974, 277; *"Gluconobacter liquifaciens"* Asai 1935, 610.)
li.que.fa' ci.ens. L v. *liquefacio* to liquefy; L. part. adj. *liquefaciens* liquefying.

Colonial and cell morphology are as described for the genus. Motile by peritrichous flagella. 2-Keto-, 2,5-diketo-, and sometimes also 5-ketogluconic acid are synthesized from D-glucose. The majority of the strains produce γ-pyrones from D-glucose and D-fructose. Ketogenesis in *G. liquefaciens* occurs with glycerol, D-mannitol, and sorbitol. Acid is produced from ethanol, *n*-propanol, *n*-butanol, D-mannose, and D-glucose. Most strains are able to grow on *n*-propanol, ethanediol, glycerol, *meso*-erythritol, D-mannitol, D-galactose, D-fructose, D-glucose, Ca-D-gluconate, Ca-D,L-glycerate and Na-D,L-lactate. All strains are able to utilize ammonium as a sole source of nitrogen with ethanol as a carbon source, even without growth factors. Few strains do not require growth factors in the presence of D-mannitol. *G. liquefaciens* causes pink disease in pineapple fruits due to the production of 2,5-diketogluconic acid (Gosselé and Swings, 1986).

The mol% G + C of the DNA is: 62–65 (T_m).

Type strain: ATCC 14835, DSM 5603, IAM 1834, IFO 12388.

GenBank accession number (16S rRNA): X75617.

2. **Gluconacetobacter azotocaptans** Fuentes-Ramírez, Bustillos-Cristales, Tapia-Hernández, Jiménez-Salgado, Wang, Martínez-Romero and Caballero-Mellado 2001, 1312[VP]
a.zo.to.cap' tans. N.L. adj. *azotocaptans* nitrogen-catching.

G. azotocaptans was isolated from the rhizospheres of coffee plants. Cells are straight rods with rounded ends, approximately 1.6–2 × 0.5–0.6 μm, occurring singly or in pairs. Cells are motile by peritrichous flagella. Colonies on potato agar with sugarcane are beige or very light-brownish. Strains fix molecular nitrogen microaerophilically (Fuentes-Ramírez et al., 2001). Strains grow in 30% D-glucose or sucrose. No growth on D-mannitol, glycerol, and D-xylose. Strains grow on 0.5% ethanol but not with methanol. *G. azotocaptans* can be differentiated from *G. johannae* by RFLP of PCR-amplified 16S rDNA with *Rsa*I generating fragments of 504, 404, 246, 159, and 134 bp, respectively (Fuentes-Ramírez et al., 2001).

The mol% G + C of the DNA is: 64 (T_m).

Type strain: ATCC 700988, DSM 13594.

GenBank accession number (16S rRNA): AF192761.

3. **Gluconacetobacter diazotrophicus** (Gillis, Kersters, Hoste, Janssens, Kroppenstedt, Stephan, Teixeira, Döbereiner and De Ley 1989) Yamada, Hoshino and Ishikawa 1998b, 327[VP] (Effective publication: Yamada, Hoshino and Ishikawa 1997, 1250) (*Acetobacter diazotrophicus* Gillis, Kersters, Hoste, Janssens, Kroppenstedt, Stephan, Teixeira, Döbereiner and De Ley 1989, 362.)
di.a.zo.tro' phi.cus. M.L. masc. adj. *diazotrophicus* one that feeds on dinitrogen.

Straight rods with rounded ends. Motile by lateral or peritrichous flagella. Produces brown water-soluble pigments on D-glucose, yeast extract medium. Dark brown colonies are formed on potato agar supplemented with 10% sucrose. Forms 2-ketogluconic acid and 2,5-diketogluconic acid from glucose. The optimal growth pH is 5.5. High concentrations (10%) of sucrose are used for isolation of *G. diazotrophicus* strains and a medium composed of 2.5% mannitol, 0.5% yeast extract, and 0.3% peptone is suitable for cultivation.

Isolated from roots, stems, and leaves of sugarcane (Gillis et al., 1989), and coffee (Jímnez-Salgado et al., 1997) and, in addition, has been recovered from sweet potato, Cameroon grass (Caballero-Mellado et al., 1995), and mealy bugs, which act as a vector for carrying *G. diazotrophicus* to the leaf tissue of sugarcane (Ashbolt and Inkerman, 1990). *G. diazotrophicus* does not survive in the soil without the presence of host plants and is growing within a low pO_2 environment, which is necessary for the expression and

functioning of the nitrogenase (James and Olivares, 1997). The mechanisms of infection and colonization of sugarcane by *G. diazotrophicus* are described by James and Olivares (1997).

G. diazotrophicus is able to fix nitrogen in the presence of nitrates and at low pH values (Stephan et al., 1991; Burris, 1994) and seems best adapted to the sugarcane environment, since the nitrogenase activity is stimulated in mixed cultures (Cojho et al., 1993). Strains fix molecular nitrogen under microaerobic conditions. Sucrose concentration of 10% has a positive effect on nitrogenase activity protecting nitrogenase against inhibition by oxygen (Reis and Döbereiner, 1998). During N_2-fixation by *G. diazotrophicus*, activity of glucose dehydrogenase is enhanced and cytochrome a_1 (= cytochrome *ba*) is expressed as terminal oxidase (Flores-Encarnación et al., 1999). Most *G. diazotrophicus* strains produce levan as an exopolysaccharide that is synthesized by levansucrase (Hernández et al., 1995). The bacterium grows in the presence of 30% glucose and exhibits high rates of gluconic acid formation (Attwood et al., 1991). *G. diazotrophicus* grows well on sucrose, D-glucose, D-fructose, D-gluconate, and polyols like D-mannitol, D-sorbitol, and glycerol. The lack of growth on C4-dicarboxylates such as succinate, fumarate, and malate is due to the absence of a transport system for dicarboxylates in *G. diazotrophicus* (Alvarez and Martínez-Drets, 1995; Ureta et al., 1995). The lipopolysaccharide (LPS) of *G. diazotrophicus* was characterized by Fontaine et al. (1995) and contains rhamnose, mannose, and galactose as monosaccharide constituents in all investigated strains.

The mol% G + C of the DNA is: 61–63 (T_m).

Type strain: ATCC 49037, PAL 5, DSM 5601, LMG 7603.

GenBank accession number (16S rRNA): X75618.

4. **Gluconacetobacter entanii** Schüller, Hertel and Hammes 2000, 2019[VP]

en.ta′ni.i. L. gen. *entanii* of Entani, the name honors Etsuzo Entani, a Japanese microbiologist.

Cells are ellipsoidal to rod shaped, straight, or slightly curved, 0.8–1.2 × 1.3–1.6 µm, nonmotile, occurring singly, in chains, and mainly in pairs. Colonies are round, regular, umbonate, soft, glossy, and with a diameter of 1–2 mm on AE agar (Schüller et al., 2000).

G. entanii requires acetic acid in addition to ethanol and glucose for growth. Growth occurs only at total concentrations (sum of acetic acid and ethanol) exceeding 6.0%. At this concentration, *G. entanii* is not able to oxidize acetic acid further to CO_2 and H_2O. Oxidizes ethanol to acetic acid. Growth on 3% (v/v) ethanol in the presence of up to 11% acetic acid (v/v). Gluconate, glycerol, methanol, and lactate are not used as carbon source. The ability to utilize sorbitol and mannitol is strain dependent. No formation of ketogluconic acids from glucose. No formation of cellulose. Good growth on glucose, fructose, and sucrose in AE broth (4a/3e). AE broth (4a/3e) is composed of 0.5% glucose, 0.2% yeast extract, 0.3% peptone, 4% (w/v) acetic acid, and 3% ethanol (v/v) (Entani et al., 1985; Sievers et al., 1992; Sokollek and Hammes, 1997). *Gluconacetobacter entanii* is closely related to *G. hansenii* based on 16S rRNA sequence similarity. *G. entanii* can be distinguished from *G. hansenii* by its ability to grow on 3% (v/v) ethanol in the presence of 4–8% (w/v) acetic acid. *G. entanii* requires, in contrast to *G. europaeus*, ethanol as well as acetate and glucose for growth.

The mol% G + C of the DNA is: 58 (T_m).

Type strain: DSM 13536, LTH 4560.

GenBank accession number (16S rRNA): AJ251110.

5. **Gluconacetobacter europaeus** (Sievers, Sellmer and Teuber 1992) Yamada, Hoshino and Ishikawa 1998b, 327[VP] (Effective publication: Yamada, Hoshino and Ishikawa 1997, 1250) (*Acetobacter europaeus* Sievers, Sellmer and Teuber 1992, 656.)

eu.ro.pae′us. L. adj. masc. *europaeus* occurring in or coming from Europe.

Cells are rod shaped, straight, 0.7 × 2 µm, occurring singly or in pairs. Mobility and flagella not observed. Pale colonies, no pigments produced. Strains have an absolute requirement of acetic acid for growth. Growth occurs on AE medium in a relative humidity of 92–97%. *G. europaeus* growing on AE medium utilizes glucose and ethanol simultaneously. Cells die rapidly without an oxygen supply (Hitschmann and Stockinger, 1985). Catalase positive, oxidase negative. Acetate is oxidized to CO_2 and H_2O below an acetate concentration of 6%. Glucose is oxidized to 5-ketogluconate or 2-ketogluconate. Some strains produce cellulose/acetan.

Acetic acid bacteria produce hopanoids acting as membrane stabilizers (Rohmer et al., 1984; Ourisson et al., 1987). *G. europaeus* contains novel series of methylhopanoids with an additional methyl group at position C31 (Simonin et al., 1994).

Gluconacetobacter europaeus has been isolated from vinegar fermentations and is used in submerged cultures and trickling generators for industrial production of vinegar.

G. europaeus strains can be freeze-dried under controlled conditions and reactivated. Preservation of strains at −70°C in the presence of 25% glycerol and revival of these strains is still difficult.

The overall 23S rDNA sequence similarity values of *G. europaeus* type strain with the type strains of *G. intermedius* and *G. xylinus* are 99.2% and 98.9%, respectively.

The mol% G + C of the DNA is: 55–58 (T_m).

Type strain: ATCC 51845, DSM 6160.

GenBank accession number (16S rRNA): Z21936.

Additional Remarks: The accession number of the 23S rDNA of *G. europaeus* type strain is X89771 (Boesch et al., 1998).

6. **Gluconacetobacter hansenii** (Gosselé, Swings, Kersters, Pauwels and De Ley 1983c) Yamada, Hoshino and Ishikawa 1998b, 327[VP] (*Acetobacter hansenii* Gosselé, Swings, Kersters, Pauwels and De Ley 1983c, 896.)

han.se′ni.i. M.L. n. *hansenii* of E.C. Hansen, a Danish microbiologist, well known for his study on the acetic acid bacteria.

The cell morphology and colonial characteristics are as described for the genus. Ketogenic toward glycerol, D-mannitol, and sorbitol. Most strains produce 2-ketogluconic acid and 5-ketogluconic acid from D-glucose. Acid is produced from ethanol, *n*-propanol, *n*-butanol, D-mannose, and D-glucose. Strains of *G. hansenii* are unable to grow on ethanol, if ethanol is the sole carbon source and yeast extract is absent. Strains require growth factors.

The mol% G + C of the DNA is: 58–63 (T_m).

Type strain: ATCC 35959, DSM 5602, LMG 1527, NCIMB 8746.

GenBank accession number (16S rRNA): X75620.

7. **Gluconacetobacter intermedius** (Boesch, Trček, Sievers and Teuber 1998) Yamada 2000, 2226^VP (*Acetobacter intermedius* Boesch, Trček, Sievers and Teuber 1998, 1083.)
in.ter.me′ di.us. L. adj. masc. *intermedius* in the middle between.

Cells are rod shaped, straight, 0.7 × 2 µm, occurring singly or in pairs. Motility and flagella not observed. Pale colonies, no pigments produced. Catalase positive, oxidase negative. Acetate is oxidized to CO_2 and H_2O below an acetate concentration of 6%. *G. intermedius* strains grow with or without acetic acid. Growth occurs on AE medium in the presence of 3% (v/v) ethanol and up to 8% (v/v) acetic acid. Eleven of 13 strains of *G. intermedius* grow on GY medium and all strains show strong growth on MRS medium. No oxidation of glucose to 5-ketogluconate. Formation of dihydroxyacetone from glycerol. Most strains do not utilize sucrose as carbon source. Strains produce cellulose/acetan. *Gluconacetobacter intermedius* occurs in tea fungus beverages (Sievers et al., 1995b), spirit vinegar, and cider vinegar fermentations. The type strain TF2 (DSM 11804) was isolated from a commercially available tea fungus beverage (Kombucha) in Switzerland. Kombucha is a refreshing beverage obtained from fermentation of sugared tea with a symbiotic culture of *G. intermedius* and yeasts. The effects of Kombucha on human health are discussed by Dufresne and Farnworth (2000). *G. intermedius* produces a thick cellulose/acetan matrix under static conditions, which covered the surface of the beverage and keeps the cells in close contact with the atmosphere. The overall 23S rDNA sequence similarity values of *G. intermedius* type strain with the type strains of *G. europaeus* and *G. xylinus* are 99.2% and 99.0%, respectively.

An oligonucleotide probe based on the 23S rDNA of *G. europaeus* (23seu: 5′-AATGCGCCAAAAGCCGGAT-3′) developed for *G. europaeus* hybridizes with *G. europaeus* strains and with the following *G. xylinus* strains: LMG 25, ATCC 23768, and ATCC 10245. The probe does not hybridize with *G. intermedius* strains and is thus useful for the differentiation of *G. intermedius* from *G. europaeus* (Boesch et al., 1998).

The mol% G + C of the DNA is: 62 (T_m).

Type strain: TF2, DSM 11804.

GenBank accession number (16S rRNA): Y14694.

Additional Remarks: The accession number of the 23S rDNA sequence of the *G. intermedius* type strain is Y14680.

8. **Gluconacetobacter johannae** Fuentes-Ramírez, Bustillos-Cristales, Tapia-Hernández, Jiménez-Salgado, Wang, Martínez-Romero and Caballero-Mellado 2001, 1312^VP
jo.han′ nae. N.L. gen. n. *johannae* of Johanna, in honor of the Brazilian microbiologist, Johanna Döbereiner, who isolated *G. diazotrophicus* as the first nitrogen-fixing species of the genus *Gluconacetobacter.*

G. johannae was isolated from the rhizospheres of coffee plants. Cells are straight rods with rounded ends, approximately 1.5–1.9 × 0.5–0.6 µm, occurring singly, in pairs, or in short chains. Cells are motile by peritrichous flagella. Colonies on potato agar with sugarcane are brown. Strains fix molecular nitrogen microaerophilically (Fuentes-Ramírez et al., 2001). Strains grow in 30% D-glucose or sucrose. Slight to no growth on D-mannitol and glycerol. Strains grow on D-xylose as carbon source. Strains grow on 0.5% ethanol but not with methanol. *G. johannae* ATCC 700987 showed 45% DNA relatedness to the type strain of *G. azotocaptans*. *G. johannae* can be differentiated from *G. azotocaptans* by RFLP of PCR-amplified 16S rDNA with *Rsa*I generating fragments of 504, 405, 403, and 135 bp, respectively (Fuentes-Ramírez et al., 2001).

The mol% G + C of the DNA is: 58 (T_m).

Type strain: ATCC 700987, DSM 13595.

GenBank accession number (16S rRNA): AF111841.

9. **Gluconacetobacter oboediens** (Sokollek, Hertel, Hammes 1998b) Yamada 2000, 2226^VP (Sokollek, Hertel, Hammes 1998b, 939.)
ob.oe.di′ ens. L. adj. *oboediens* obedient.

G. oboediens DSM 11826 is phenotypically and genotypically similar to *G. intermedius* in respect to growth with and without acetic acid, and 16S rRNA sequence similarity is 100%. The type strains of *G. intermedius* and *G. oboediens* showed 76% DNA relatedness among each other (Sievers and Schumann, unpublished). Based on the DNA–DNA hybridization data and phenotypic similarities, it is obvious that *G. oboediens* is synonymous with *G. intermedius. G. oboediens* is able to grow on 3% (v/v) ethanol in the presence of up to 8% (w/w) acetic acid. No absolute requirement of acetic acid for growth. Growth in the presence of 30% (w/v) glucose with a strong formation of gluconic acid (≥130 g/l). Good growth on glucose, fructose, ribose, glycerol, and sucrose on yeast extract peptone agar. Cellulose is not formed.

Gluconacetobacter oboediens, type strain DSM 11826, was isolated from a submerged red wine vinegar fermentation at a factory in the southern part of Germany.

The mol% G + C of the DNA is: 60 (T_m).

Type strain: DSM 11826, LTH 2460.

GenBank accession number (16S rRNA): AJ001631.

10. **Gluconacetobacter sacchari** Franke, Fegan, Hayward, Leonard, Stackebrandt and Sly 1999, 1691^VP
sacch.ar′ i. M.L. gen. n. *sacchari* pertaining to the genus *Saccharum* , sugarcane, from which the organism was isolated.

Cells of *G. sacchari* are ellipsoidal to rod shaped, approximately 0.7–0.9 × 1.3–2.2 µm in size and occur singly, in pairs, or in short chains. Cells are motile by peritrichous flagella. An electron micrograph of the type strain DSM 12717 showing cellular morphology and flagellation is given in Fig. BXII.α.27 (Franke et al., 1999). *Gluconacetobacter sacchari* was isolated from the leaf sheath of sugarcane and from the pink sugarcane mealy bug *Saccharicoccus sacchari.* The occurrence of *G. sacchari* in mealy bug homogenates was detected by *in situ* hybridization with a Cy3-labeled specific primer targeting the 16S rRNA of *G. sacchari* (Franke et al., 2000).

G. sacchari strains grow in the presence of 0.01% malachite-green agar as does *G. liquefaciens.* To test the ability to grow in the presence of the dye malachite green, the agar plates containing (per liter of distilled water): 0.5 g yeast extract, 3.0 g vitamin-free Casamino acids, 1.0 g D-glucose, 1.0 g mannitol, 1.0 g calcium DL-lactate, 25 g agar, and 0.1 g malachite green (Gosselé et al., 1983a). *G. sacchari* strains grow in the presence of 30% D-glucose. Strains grow

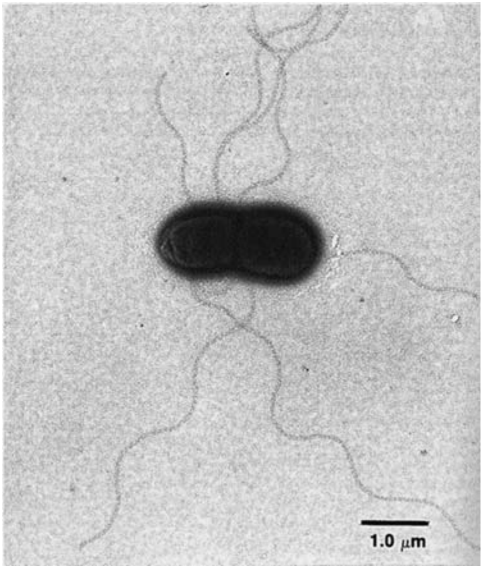

FIGURE BXII.α.27. Electron micrograph of *Gluconacetobacter sacchari* DSM 12717, showing rod-shaped to ellipsoidal cell form and peritrichous flagella. (Reprinted with permission from I.H. Franke et al., International Journal of Systematic and Evolutionary Microbiology *49:* 1681–1693, 1999, ©Society of General Microbiology, UK.)

on mannitol agar. Acid is produced from D-glucose, ethanol, and 1-propanol, but not from D-mannitol or sorbitol.

Strains of *G. sacchari* do not grow on the amino acids L-asparagine, L-glycine, L-glutamine, L-threonine, or L-tryptophan with D-mannitol as the carbon source[6] (Franke et al., 1999). *G. sacchari*, in contrast to *G. liquefaciens*, is not able to utilize these amino acids as the sole nitrogen source with D-mannitol as a carbon source.

Gluconacetobacter sacchari strains are closely related to *G. liquefaciens* by sharing 98.8–99.3% 16S rDNA sequence similarity. The DNA–DNA relatedness of the type strain of *G. sacchari* is 46% with *G. liquefaciens* (Franke et al., 1999). *G. sacchari* does not fix nitrogen in contrast to *G. diazotrophicus*, *G. azotocaptans*, and *G. johannae*.

6. The medium for testing the utilization of L-amino acids as sole nitrogen sources contains (per liter of 0.2 M Tris-maleate buffer, pH 5.4): D-mannitol, 30.0 g; L-amino acid, 1.0 g; salt solution A (per liter of distilled water: KH_2PO_4, 100 g and K_2HPO_4, 100 g), 5.0 ml; salt solution B (per liter of distilled water: $MgSO_4 \cdot 7H_2O$, 40.0 g; NaCl, 2.0 g; $FeSO_4 \cdot 7H_2O$, 0.2 g; and $MnSO_4 \cdot H_2O$, 1.5 g), 5.0 ml; D-biotin, calcium pantothenate, thiamine, folic acid, *p*-aminobenzoic acid, and vitamin B_{12}, 0.001 g each; pyridoxal-HCl, niacin and riboflavin, 0.0015 g each.

The mol% G + C of the DNA is: 62–67 T_m).
Type strain: DSM 12717, SRI 1794.
GenBank accession number (16S rRNA): AF127407.

11. **Gluconacetobacter xylinus** (Brown 1886) Yamada, Hoshino and Ishikawa 1998b, 327[VP] (Effective publication: Yamada, Hoshino and Ishikawa 1997, 1250) (*"Bacterium xylinum"* Brown 1886; *Acetobacter xylinus* (Brown 1886) Yamada 1984, 270; *Acetobacter aceti* subsp. *xylinus* (Brown 1886) De Ley and Frateur 1974, 277.)*
xy.li' nus. L. adj. *xylinus* woody, derived from; Gr. *xylon* wood.

Cells occurring singly, in pairs, in chains, or in small clusters. Peritrichously flagellated when motile. Synthesize cellulose and acetan. No growth on 3% ethanol in the presence of 5–8% acetic acid. *G. xylinus* strains grow well at D-glucose concentration of 100 g per liter medium. Acids are formed from ethanol, D-glucose, and D-xylose.

Acid formation from sucrose, D-galactose, and production of 5-ketogluconic acid from D-glucose is strain dependent. The type strain of *G. xylinus* does not produce acid from sucrose. The DNA from the type strain of *G. xylinus* showed 69–100% similarity to those from seven *G. xylinus* strains that form acid from sucrose (Tanaka et al., 2000b). *G. xylinus* BPR 2001 (*Acetobacter xylinus* subsp. *sucrofermentans*) differs from *G. xylinus* ATCC 23767 by growth on sucrose, by acid formation from sucrose and by oxidation of lactose (Toyosaki et al., 1995). 16S rRNA sequence similarity of *G. xylinus* ATCC 23767 with *G. xylinus* BPR 2001 (*Acetobacter xylinus sucrofermentans* JCM 9730) is 99.6%. Based on DNA–DNA relatedness, *G. xylinus* and *A. xylinus* subsp. *sucrofermentans* are genetically to homologous to maintain a subspecies under this species level (Tanaka et al., 2000b).

The overall 23S rDNA sequence similarity values of *G. xylinus* type strain with the type strains of *G. intermedius* and *G. europaeus* are 99.0% and 98.9%, respectively.

The mol% G + C of the DNA is: 59–63 (T_m).

Type strain: ATCC 23767, DSM 6513, IFO 15237, NCIMB 11664.

GenBank accession number (16S rRNA): X75619.

Additional Remarks: The accession number of the 23S rDNA of *G. xylinus* is X89812 (Boesch et al., 1998).

**Editorial Note:* The name *Acetobacter xylinum* was corrected to *Acetobacter xylinus* by Euzéby (1997) because the epithet *xylinus* as adjective to *Acetobacter* has to be masculine.

Genus IX. Gluconobacter *Asai 1935, 689*[AL]

MARTIN SIEVERS AND JEAN SWINGS

Glu.co.no.bac' ter. M.L. n. *acidum, gluconicum* gluconic acid; M.L. n. *bacter* masc. equivalent of Gr. neut. n. *bakterion* rod; M.L. masc. n. *Gluconacetobacter* gluconate rod.

Ellipsoidal to rod-shaped cells, 0.5–1.0 × 2.6–4.2 µm, occurring singly and/or in pairs, rarely in chains. The formation of enlarged, irregular cells may occur. Endospores are not formed. **Motile or nonmotile; if motile, the cells have 3–8 polar flagella**. Gram negative. Obligately aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Metabolism is never fermentative. Optimal temperature for growth is 25–30°C. Optimal pH for growth is 5.0–6.0; most strains will grow at pH 3.5. Catalase positive, oxidase negative. Negative for nitrate reduction, gelatin liquefaction, indole production, and H_2S formation. **Oxidize ethanol to acetic acid**. **Do not oxidize acetate or lactate to CO_2 and H_2O**. *Gluconobacter* strains generally

produce acid during growth on fructose, glucose, xylose, and maltose and tolerate up to 10% glucose. **Ketogenesis occurs from polyalcohols** (for example, dihydroxyacetone from glycerol). **All strains produce 2-ketogluconic acid from D-glucose**, and the majority of strains also form 5-ketogluconic acid. Formation of water-soluble brown pigment is correlated with the production of 2,5-diketogluconic acid and γ-pyrones from D-glucose. Most strains form acid from ethanol, D-mannitol, D-fructose, D-glucose, D-maltose, glycerol, and D-xylose. Few strains produce acid from lactose. The best carbon sources for growth are D-mannitol and D-glucose. **Possesses ubiquinone of the Q-10 type as major quinone**. The predominant fatty acid in *Gluconobacter* is the $C_{18:1\ \omega7}$ straight-chain unsaturated acid. **Isolated from sugar-rich environments such as fruits and flowers, honey bees, grapes and wine, palm sap, cocoa wine, cider, beer, and soft drinks**.

The mol% G + C of the DNA is: 52–64.

Type species: **Gluconobacter oxydans** (Henneberg 1897) De Ley 1961, 304 emend. Mason and Claus 1989, 181.

Further descriptive information

Metabolism *Gluconobacter* catabolizes D-glucose by the hexose monophosphate pathway. *Gluconobacter* is not able to overoxidize acetic acid to CO_2 and H_2O due to an incomplete tricarboxylic acid cycle, lacking succinate dehydrogenase (Greenfield and Claus, 1972). *Gluconobacter* strains prefer sugar-enriched environments in contrast to *Acetobacter* and *Gluconacetobacter* strains, which prefer alcohol-enriched environments (Asai, 1968).

Vitamin C production *Gluconobacter* species are used for oxidation of D-sorbitol into L-sorbose in the commercial production of vitamin C (ascorbic acid). Vitamin C is industrially produced by the Reichstein method: D-Glucose → D-Sorbitol → L-Sorbose → Diacetonesorbose → Diacetone-2-keto-L-gulonic acid → L-Ascorbic acid. The process begins with the nonbiological hydrogenation of D-glucose to produce D-sorbitol. The synthesis of L-sorbose from D-sorbitol is carried out biochemically by *Gluconobacter*. The L-sorbose is then converted nonbiologically to L-ascorbic acid. The PQQ-dependent sorbitol dehydrogenase from *G. oxydans* was characterized by Choi et al. (1995a).

Improved methods for vitamin C production that involve the biological formation of 2-keto-L-gulonic acid from D-sorbitol as an intermediate have been developed. The metabolic pathway for biosynthesis of 2-keto-L-gulonic acid from D-sorbitol by *Gluconobacter oxydans* includes L-sorbosone as an intermediate: D-Sorbitol → L-Sorbose → L-Sorbosone → 2-Keto-L-gulonic acid.The 2-keto-L-gulonic acid is then converted nonbiologically to vitamin C (Hoshino et al., 1990; Saito et al., 1997). Mutagenesis of *"Gluconobacter oxydans"* subsp. *melanogenes* IFO 3293 strain resulted in production of 60 g of 2-keto-L-gulonic acid per liter from 100 g D-sorbitol per liter (Sugisawa et al., 1990). Suppression of the formation of L-idonate from 2-keto-L-gulonic acid is a prerequisite for an improved 2-keto-L-gulonic acid production in *Gluconobacter*. Overexpression of the L-sorbose dehydrogenase and L-sorbosone dehydrogenase genes in *G. oxydans* resulted in an improved 2-keto-L-gulonic acid production of the recombinant strain (up to 230%) compared to that of the wild-type strain (Saito et al., 1997). Production of 2-keto-L-gulonic acid from L-sorbose via L-sorbosone is catalyzed in *G. oxydans* IFO 3293 by a membrane-bound L-sorbose dehydrogenase and a L-sorbosone dehydrogenase located in the cytoplasm. Cloning of the gene coding for the membrane-bound L-sorbosone dehydrogenase from *Gluconacetobacter liquefaciens* IFO 12258 and expression of this gene in *G. oxydans* IFO 3293 revealed a recombinant strain that could carry out the formation of 2-keto-L-gulonic acid by membrane-bound dehydrogenases (Shinjoh et al., 1995). *Ketogulonigenium vulgare* DSM 4025 (former classified as *G. oxydans* DSM 4025) oxidizes L-sorbose to 2-keto-L-gulonic acid (Urbance et al., 2001) and produces vitamin C from L-gulono-γ-lactone. The enzyme L-gulono-γ-lactone dehydrogenase catalyzes this oxidation reaction, has a molecular weight of 110 kDa, and is composed of three subunits (Sugisawa et al., 1995).

Glucose dehydrogenase *Gluconobacter* strains are not known to have any pathogenic effect toward humans or animals but are capable of causing a bacterial rot of apples and pears, which is accompanied by various shades of browning. The bacteria enter the apples through wounds in the cuticula and apple tissue. Strains of *G. oxydans* cause pink disease of pineapple, which is characterized by the formation of pink to deep brown discolorations after heating (e.g., during canning) of the diseased fruit. Glucose dehydrogenase (GDH) is responsible for this fruit discoloration (Cha et al., 1997). GDH catalyzes the oxidation of D-glucose to D-gluconate at the outer surface of the cytoplasmic membrane. D-Gluconate is oxidized by the activity of the D-gluconate-dehydrogenase to 2-ketogluconic acid, which is further converted to 2,5-diketogluconate catalyzed by the 2,5-diketogluconate dehydrogenase (Qazi et al., 1991; Matsushita et al., 1994). 2,5-Diketogluconate may react with natural compounds in the juice to become chromogenic upon heating (Cha et al., 1997). 2,5-Diketogluconate has been also detected in *Gluconacetobacter liquefaciens* strains (Gosselé et al., 1980). Gluconic acid production in *G. oxydans* is mainly the result of the membrane-bound pyrroloquinoline quinone (PQQ)-dependent glucose dehydrogenase, because the activity of the quinoprotein is 30-fold higher than the activity of the cytoplasmic NADP-dependent GDH (Pronk et al., 1989). The PQQ-dependent GDH from *G. oxydans* consists of 808 amino acids encoded from a 2424-bp DNA sequence. A one-point mutation at nucleotide 2359 has replaced the histidine at position 787 with asparagine in the protein of a *G. oxydans* strain. This single amino acid substitution changes the substrate specificity of the quinoprotein GDH, resulting in the conversion of maltose to maltobionic acid in addition to the glucose oxidation (Cleton-Jansen et al., 1991).

Intact cells of *G. oxydans* with glucose oxidation activity in the late exponential phase of 13 μmol of glucose/g dry weight per min were used for construction of a biosensor for determination of glucose. The sensitivity of the glucose sensor was 50 nA/mM glucose and the range of the calibration curve was 0–0.8 mM of glucose concentrations (Švitel et al., 1998).

Gluconobacter strains flourish on sugars and are found in sugary niches such as flowers and fruits. *Gluconobacter* is a typical spoiler of soft drinks causing off-flavors in, e.g., orange juice. *Gluconobacter* strains are also found associated with palm trees, the sap of which is fermented to palm wine. *Gluconobacter oxydans* strains have been isolated from grapes and detected as cider- and beer-spoiling organisms (Swings, 1992).

Plasmids and phages Strains of *G. oxydans* typically cannot utilize lactose as carbon source. The lactose transposon Tn951 was conjugally introduced from *E. coli* (RP1::Tn951) to *G. oxydans*. The heterologous expression level of Tn951-encoded β-galactosidase in a *G. oxydans* strain was less than 5% of the fully induced *E. coli* activity (Condon et al., 1991). Transposon Tn5 was introduced in *G. oxydans* ATCC 9937 by conjugation using plasmid

pSUP 2021. Tn5 transposition occurred on the plasmid pVJ1 resulting in a mutant of this strain deficient in glucose dehydrogenase activity (Gupta et al., 1997). The shuttle vector pGE1 (mob, Km ^{r}), which can replicate both in *G. oxydans* and *E. coli*, has been used for cloning the L-sorbosone dehydrogenase gene of *Gluconacetobacter liquefaciens* IFO 12258 in *G. oxydans* IFO 3293 to improve the production of 2-keto-L-gulonic acid in the vitamin C manufacturing process (Shinjoh and Hoshino, 1995).

The *G. oxydans* plasmid pGO128 was cloned in pACYC177 and its complete nucleotide sequence was determined (AJ428837). Plasmid pGO128 from *G. oxydans* DSM 3504 is composed of 4340 bp. The analysis of the nucleotide sequence revealed three open reading frames, located on the same strand. ORF1 encodes for a resolvase. The protein encoded by ORF2 is 38% homologous to a virulence-associated protein vapE from the plant pathogen bacterium *Xylella fastidiosa*.

Phage A-1 (Schocher et al., 1979; Jucker and Ettlinger, 1981; Robakis et al., 1985a) and phages GW6210 and JW2040 (Robakis et al., 1985b) from *G. oxydans* have been isolated and characterized. Phage A-1 caused abnormalities in the microbial process of the oxidation of D-sorbitol to L-sorbose by *G. oxydans* (Schocher et al., 1979).

Enrichment and Isolation Procedures

Enrichment of *Gluconobacter* strains present in flowers, fruits, grapes, bees, beer, palm wine, and soft drinks can be achieved using the following medium (g per liter of distilled water): D-glucose, 100.0; yeast extract, 5.0; peptone, 3.0; acetic acid, 1.0; cycloheximide 0.1. After incubation at 30°C for 3–5 d in flasks with shaking, those cultures showing growth are streaked onto plates of a $CaCO_3$-containing medium, where the colonies dissolve the $CaCO_3$ (Carr and Passmore, 1979). The medium for the chalk-ethanol test is composed of (per liter of distilled water): glucose, 0.5 g; yeast extract, 5.0 g; peptone, 3.0 g; calcium carbonate, 15.0 g; agar, 12.0 g; and ethanol (99.8%), 15 ml (sterile-filtered and added after sterilization of the basal medium). The overoxidation of acetic acid by *Acetobacter*, *Gluconacetobacter*, and *Acidomonas* strains results in a reprecipitation of $CaCO_3$. Colonies that dissolve the $CaCO_3$ without reprecipitation of the $CaCO_3$ are isolated, further purified on GYC medium[1], and characterized for identification and distinction from *Frateuria*.

Maintenance Procedures

Stock cultures of *Gluconobacter* should be grown on GYC medium, MYP medium,[2] or DSYP medium[3] at 28–30°C. The cultures can be maintained for short-term storage in a refrigerator (4–5°C) for 3–4 weeks. For long-term preservation, *Gluconobacter* can be frozen and kept at −75°C in the presence of 24% (v/v) glycerol. *Gluconobacter* strains can be stored as lyophilized cultures.

Differentiation of the genus *Gluconobacter* from other genera

See Table BXII.α.10 in the chapter on the family *Acetobacteraceae* for differences of *Gluconobacter* from the other genera of acetic acid bacteria. The medium of Carr and Passmore (1979) provides rapid differentiation of *Gluconobacter* from *Acetobacter*. The genus *Frateuria* (*Frateuria* groups in the *Gammaproteobacteria*) most closely resembles the polarly-flagellated *Gluconobacter* but, in contrast to *Gluconobacter*, is able to oxidize lactate to CO_2/H_2O and does not produce 5-ketogluconic acid. Further information for differentiation of *Gluconobacter* from related genera is given under the section of the family *Acetobacteraceae*.

Taxonomic Comments

Within the genus *Gluconobacter*, the species *G. oxydans*, *G. frateurii*, *G. cerinus*, and *G. asaii* were genetically characterized based on 16S rRNA gene sequences (Sievers et al., 1995a) and DNA–DNA hybridization data (Micales et al., 1985; Tanaka et al., 1999). *G. asaii*, *G. frateurii*, and *G. cerinus* showed lower mol% G + C contents of DNA than *G. oxydans*. Phylogenetic trees reflecting the distant and close relationships of *Gluconobacter* based on the results of maximum likelihood analyses are shown in Figs. BXII.α.16 and BXII.α.17 in *Acetobacteraceae*. The overall 16S rRNA gene sequence similarities within the members of the genus *Gluconobacter* are 97.8% to 98.8%, corresponding to 14 to 32 base differences. All four species of *Gluconobacter* form a coherent, closely related cluster that is separated from the other genera of the family *Acetobacteraceae* (Sievers et al., 1994a, 1995a). The ubiquinone composition in *G. oxydans* ATCC 19357 is 3% of Q-9 and 97% of Q-10, in *G. cerinus* IFO 3267, and in *G. asaii* IFO 3276: 4% of Q-9 and 96% of Q-10, respectively, and in *G. frateurii* IFO 3264: 7% Q-9 and 93% Q-10 (Tanaka et al., 1999).

Based on DNA–DNA hybridization data, *G. cerinus* IFO 3262, 3263, 3269 and *G. asaii* IFO 3265 were identified as *G. frateurii* (Tanaka et al., 1999). *G. asaii* IFO 3265 is phenotypically similar to *G. frateurii* (Mason and Claus, 1989). Due to the high values of DNA relatedness (84–96%) between the type strains of *Gluconobacter cerinus* and *Gluconobacter asaii*, *G. asaii* is considered a junior subjective synonym of *G. cerinus* (Yamada et al., 1999; Katsura et al., 2002).

Differentiation of the species of the genus *Gluconobacter*

G. oxydans, *G. frateurii*, *G. cerinus*, and *G. asaii* are differentiated phenotypically by the requirement for nicotinic acid, growth on D-ribitol and L-arabitol (Mason and Claus, 1989), and the formation of acid from D-arabitol, D-ribitol, and L-arabitol (Tanaka et al., 1999) (Table BXII.α.25). Three transfers into nicotinate-deficient media are necessary to demonstrate nicotinate dependence (Mason and Claus, 1989). The nicotinate-deficient medium is composed of 1% vitamin-free Casamino acids (Difco) and 1% mannitol adjusted to pH 6.0, plus a vitamin solution to achieve the final concentrations of 0.00015% pyridoxal hydrochloride, 0.00015% riboflavin, 0.0001% biotin, 0.0001% thiamine, 0.0001% pantothenic acid, and 0.0001% *para*-aminobenzoic acid.

Differential characteristics of the species of the genus *Gluconobacter* are given in Table BXII.α.25.

1. GYC medium (g per liter of distilled water): D-glucose, 100.0; yeast extract, 5.0; peptone 3.0; $CaCO_3$, 12.0; agar, 12.0.

2. MYP medium (g per liter of distilled water): D-mannitol, 25.0; yeast extract, 5.0; peptone, 3.0; and agar, 12.0.

3. DSYP medium (g per liter of distilled water): D-sorbitol, 50.0; yeast extract, 5.0; peptone 3.0; and agar 12.0.

TABLE BXII.α.25. Differentiation of *Gluconobacter* species[a]

Characteristic	*G. oxydans*	*G. asaii*	*G. cerinus*	*G. frateurii*
Growth without nicotinate[b]	−	+	+	+
Growth on D-ribitol[b]	−	−	+[c]	+
Growth on L-arabitol[b]	−	−	+[c]	+
Acid formation from:[d]				
D-Arabitol	−	+	+	+
D-Ribitol	−	−	−	+
L-Arabitol	−	−	−	+

[a]Symbols: see standard definitions.

[b]Data from Mason and Claus (1989) and Yamada and Akita (1984a).

[c]Negative strains are present.

[d]Data from Tanaka et al. (1999). The medium (8 ml) for testing of acid formation contained (g per liter of distilled water): pentitol (D-arabitol, D-ribitol, or L-arabitol), 5.0; peptone, 5.0; yeast extract, 3.0; bromocresol purple, 0.02. Acid formation was judged by change of color from purple to yellow (Tanaka et al., 1999). Formation of acid by the use of this medium was determined by the authors with the type strains of the *Gluconobacter* species and some isolates.

List of species of the genus Gluconobacter

1. **Gluconobacter oxydans** (Henneberg 1897) De Ley 1961, 304[AL] emend. Mason and Claus 1989, 181.
ox'y. dans. M.L. part. adj. *oxydans* acid-giving, oxidizing.

All strains produce 2-ketogluconic acid, 5-ketogluconic acid, and 2,5-diketogluconic acid from D-glucose and dihydroxyacetone from glycerol. *G. oxydans* strains grow to an OD_{620} nm of less than 1.0 after 24 h of incubation and three passages (24 h of incubation each) in media lacking nicotinate. All strains grow to an OD_{620} nm of 0.5 or less in medium containing ribitol or arabitol as the primary carbon source (Mason and Claus, 1989). All strains produce acid from ethanol, *n*-propanol, D-glucose, D-arabinose, D-fructose, D-ribose, D-mannose, D-sorbitol, and D-mannitol, and tolerate up to 10% D-glucose. Carbon sources for growth are D-mannitol, glycerol, or D-sorbitol. Batch cultures of *G. oxydans* have shown that glucose is the preferred substrate of this species rather than lactate (Poget et al., 1994). The type strain of *G. oxydans*, ATCC 19357, does not form acid from D-arabitol, ribitol, L-arabitol, and sucrose (Tanaka et al., 1999).

G. oxydans is not further divided into subspecies, based on cluster analysis of protein profiles from *Gluconobacter* strains (Gosselé et al., 1983a).

The genome sizes of four *G. oxydans* strains were estimated to be between 2240 and 3787 kb by pulsed-field gel electrophoresis upon *Xba*I digestion of their genomes (Verma et al., 1997).

The mol% G + C of the DNA is: 56–64 (T_m).
Type strain: ATCC 19357, IFO 14819, DSM 7145.
GenBank accession number (16S rRNA): X73820.

2. **Gluconobacter asaii** Mason and Claus 1989, 183[VP]
a.sa'i.i. M.L. n. *asaii* of Toshinobu Asai, Japanese microbiologist, who described the genus *Gluconobacter*.

All strains produce acid from ethanol, D-glucose, D-xylose, maltose, and tolerate up to 10% D-glucose. *G. asaii* strains grow to an OD_{620} nm of 1.0 or more after 24 h of incubation and three passages (24 h of incubation each) in media lacking nicotinate. All strains fail to grow beyond an OD_{620} of 0.5 after 24 h when either ribitol or arabitol is used as the primary carbon source. *G. asaii* strain IFO 3297a is characterized by its unique ability to cause alkalinization of polyol media during growth on mannitol, ribitol, or arabitol. The polyol medium is composed of (g per liter of distilled water): vitamin-free Casamino acids (Difco), 3.0; yeast extract, 5.0; and polyol (mannitol, ribitol, or arabitol), 5.0 (Mason and Claus, 1989). The type strain for *G. asaii* (IFO 3276) does not form acid from ribitol, L-arabitol, and sucrose. Since *G. asaii* IFO 3276 showed species-level similarity of 88% by DNA–DNA hybridization with *G. cerinus* IFO 3267 (Tanaka et al., 1999); *G. asaii* IFO 3276 does not represent the species *Gluconobacter asaii* as type strain.

The mol% G + C of the DNA is: 52–55 (T_m).
Type strain: ATCC 49206, IFO 3276, DSM 7148.
GenBank accession number (16S rRNA): AB063287.

3. **Gluconobacter cerinus** Yamada and Akita 1984b, 503[VP] (Effective publication: Yamada and Akita 1984a, 124.)
ce.ri' nus. L. adj. *cerinus* wax-colored.

Cells are polarly flagellated when motile. Colonies are glossy and smooth. Produces 2-ketogluconate and 5-ketogluconate from glucose. 2,5-Diketogluconate is not produced from D-glucose. Produces dihydroxyacetone from glycerol. Growth occurs on ribitol, xylitol, and L-arabitol. Requires pantothenic acid but not nicotinate for growth. All strains produce acid from ethanol, D-glucose, and D-fructose.

By comparison of electrophoretic patterns from enzymes, the differentiation of *G. cerinus* and *G. oxydans* strains as two separate groups was shown (Yamada and Akita, 1984a).

G. cerinus and *G. frateurii* are phenotypically similar in respect to growth on ribitol and L-arabitol (Yamada and Akita, 1984a; Mason and Claus, 1989). The type strain for *G. cerinus* IFO 3267, in contrast to *G. frateurii* IFO 3264, does not form acid from ribitol and L-arabitol. Weak formation of acid from sucrose is observed by *G. cerinus* IFO 3267 (Tanaka et al., 1999). The type strains of *G. cerinus* and *G. frateurii* have a DNA–DNA similarity value of 23% (Micales et al., 1985) and a 16S rRNA gene sequence similarity value of 98.8%, corresponding to 15 nucleotide differences (Sievers et al., 1995a). The two colony types (glossy and smooth) of the type strain *G. cerinus* IFO 3267 have identical 16S rRNA gene sequences.

The mol% G + C of the DNA is: 54–58 (T_m).
Type strain: ATCC 19441, IFO 3267, DSM 9533.
GenBank accession number (16S rRNA): AB063286.

4. **Gluconobacter frateurii** Mason and Claus 1989, 182[VP]
fra.teur'i.i. M.L. n. *frateurii* of Joseph Frateur (1903–1974), Belgian microbiologist, who is well known for his study of acetic acid bacteria.

All strains produce acid from ethanol, glucose, xylose, maltose, sorbitol, mannitol, lactose, ribitol, and *myo*-inositol, and tolerate up to 15% D-glucose. *G. frateurii* strains grow to an OD_{620} nm of 1.0 or more after 24 h of incubation and three passages (24 h of incubation each) in media lacking nicotinate (except strain IFO 3272). All strains grow to an OD_{620} nm of 1.0 or more after 24 h when either ribitol or arabitol is used as the primary carbon source (Mason and Claus, 1989). The type strain *G. frateurii* IFO 3264 forms acid from D-arabitol, ribitol, L-arabitol, and sucrose (Tanaka et al., 1999).

The mol% G + C of the DNA is: 53–55 (T_m).

Type strain: ATCC 49207, IFO 3264, DSM 7146.

GenBank accession number (16S rRNA): X82290.

Genus X. **Paracraurococcus** *Saitoh, Suzuki and Nishimura 1998, 1045*[VP]

CHRISTOPHER RATHGEBER AND VLADIMIR V. YURKOV

Pa.ra.cra.u.ro.coc'cus. Gr. prep. *para* like, along side of; Gr. adj. *crauros* fragile; Gr. n. *coccus* berry; M.L. masc. n. *Paracraurococcus* coccus like *Craurococcus*.

Gram-negative, nonmotile cocci, 0.8–1.5 μm in diameter. Cell division occurs by binary fission. Cells grow heterotrophically under aerobic conditions giving rise to red colonies on solid media. **Obligately aerobic, containing bacteriochlorophyll (bchl) *a* organized into reaction center and light-harvesting complexes, as well as carotenoid pigments. No growth occurs anaerobically under illuminated conditions.** Facultatively photoheterotrophic. The habitat is soil.

Type species: **Paracraurococcus ruber** Saitoh, Suzuki and Nishimura 1998, 1046.

FURTHER DESCRIPTIVE INFORMATION

P. ruber is currently the only known representative of the genus *Paracraurococcus*. Phylogenetically this species belongs to the *Alphaproteobacteria*, most closely related to the genera *Craurococcus*, *Roseococcus*, *Rhodopila*, and *Acidiphilium*.

P. ruber forms small (<1mm diameter), irregular, red-to-dark-red colonies on agar media (Fig. BXII.α.28A). Circular, convex, and smooth colonies may appear; these colonies have physiological properties equivalent to strains forming irregular colonies.

Cells of *P. ruber* grown in NPG (Saitoh and Nishimura, 1996) medium adjusted to pH 6.8 appear as cocci. The cells range in size from 0.8 to 1.5 μm in diameter, appear singly or in pairs, and often form aggregates. Cells are nonmotile, spore production has not been observed. *P. ruber* accumulates poly-β-hydroxybutyrate granules when grown under regular culture conditions. Cell division is by way of binary fission (Fig. BXII.α.28B).

Divalent cations appear to be required to maintain proper cell structure in liquid media. Cells lyse when suspended in aqueous solution, however, lysis can be prevented by the addition of divalent cations such as Ca^{2+} or Mg^{2+}. Additions of NaCl, KCl, and sucrose are not sufficient to prevent lysis. The addition of divalent cations to culture media is not required for growth, but has been shown to promote growth in all strains. When cells are grown on solid media, addition of divalent cations is not required and does not affect growth rate.

Intact cells of *P. ruber* show absorption spectrum peaks at 802 nm and 856 nm, corresponding to Bchl *a* organized into reaction center and light-harvesting complexes, respectively. Crude pigment extracts in methanol show absorption spectrum peaks confirming the presence of carotenoid pigments (362 and 492nm) and Bchl *a* (770 nm). Bchl *a* levels have been estimated at 0.3 nmol/g dry cell weight, with slightly higher levels found in strains forming circular, smooth colonies. Cells grown under illuminated conditions have been shown to contain lower levels of Bchl *a*, as compared to cells grown in the dark, indicating that illumination suppresses the synthesis of Bchl *a* in these strains (Saitoh and Nishimura, 1996). Strong inhibition of Bchl *a* synthesis by light has been detected in many aerobic phototrophic bacteria (Yurkov and Beatty, 1998a). Absorption difference spectra (illuminated minus unilluminated) of membrane fractions indicate a photochemically active photosynthetic apparatus, similar to those

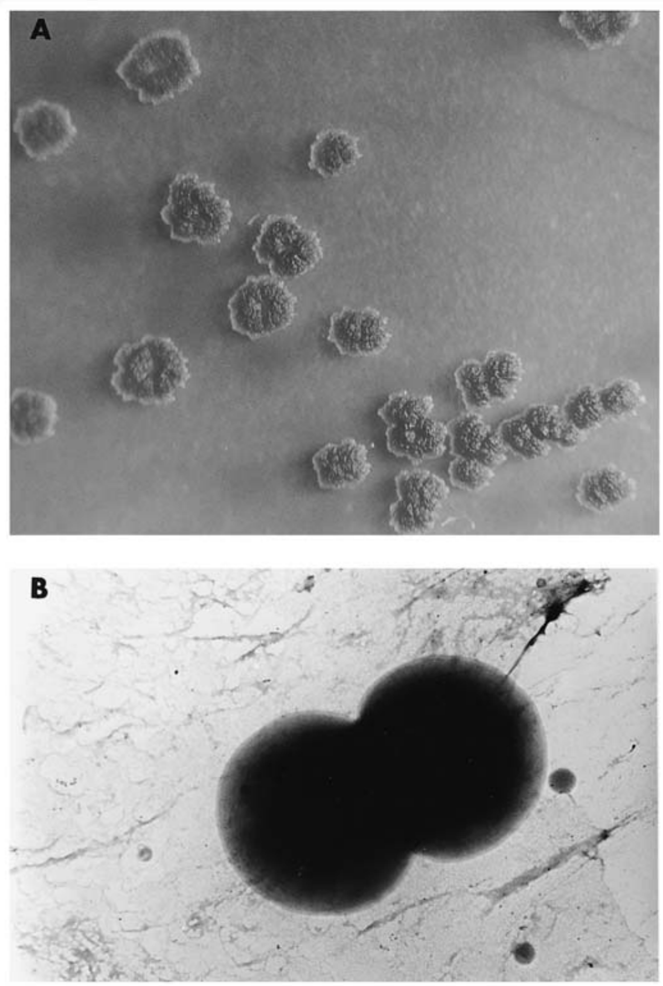

FIGURE BXII.α.28. *Paracraurococcus ruber.* (*A*) Photograph showing red, irregular colonies grown on agar plates. (*B*) Electron microscopic photograph showing division by binary fission. (Courtesy of Y. Nishimura.)

found in other aerobic, as well as typical anaerobic phototrophic bacteria (Saitoh and Nishimura, 1996). *P. ruber* cells contain large amounts of carotenoic acids and smaller amounts of spirilloxanthin.

The cellular fatty acid composition of *P. ruber* consists of octadecanoic acid as well as smaller amounts of octadecadienoic acid, 2-hydroxyoctadecenoic acid, 3-hydroxytetradecanoic acid, and 3-hydroxyoctadecanoic acid. Ubiquinone is the only quinone detected. The major quinone is Q-10 and the quinones Q-7, Q-8, and Q-9 occur in smaller quantities. The cellular lipid profile consists of phospholipids of phosphatidylethanolamine, bisphosphatidylglycerol, and phosphatidylglycerol (Saitoh and Nishimura, 1996).

P. ruber grows heterotrophically under aerobic conditions, and does not grow anaerobically under either illuminated or unilluminated conditions. However light intensities of about 2000 lux stimulate growth under aerobic conditions. Organic substrates utilized are D-xylose, fumarate, L-glutamate, glycerol, D-fructose, D-galactose, D-glucose, D-arabinose, L-rhamnose, D-ribose, D-fucose, DL-lactate, malonate, pyruvate, gluconate, and L-malate. Acids are produced oxidatively from sugars. Hydrolyzes Tween 20, 40, and 60. Tween 80 and gelatin are not hydrolyzed.

NaCl is not required for growth and cells do not grow above 0.4% NaCl. Susceptible to chloramphenicol, streptomycin, and tetracycline, and resistant to penicillin and polymixin B.

Mesophilic, with growth occurring between 16°C and 42°C, with an optimum growth temperature between 30°C and 34°C. The pH range is between 5.5 and 8.1, with optimum growth occurring at pH 6.6–6.8. Nicotinic acid and pantothenate are required as growth factors.

Enrichment and Isolation Procedures

Two strains of *P. ruber* were isolated from soil samples taken from a playground in Yamasaki Noila, of Osakajo Park in Chuoh Ward, Osaka, on a 100-fold dilution of nutrient agar medium supplemented with 1.5% agar.

Maintenance Procedures

Strains can be maintained on a NPG medium (Saitoh and Nishimura, 1996) adjusted to pH 6.8. Long-term storage procedures have not been described.

Differentiation of the genus *Paracraurococcus* from other genera

Paracraurococcus can be differentiated from other genera based on several characteristics. The presence of Bchl *a* organized into reaction center and light-harvesting complexes can be shown by absorption spectrum peaks at 802 and 856 nm, respectively. Light-harvesting complex I, absorbing at 856 nm, is very rarely found among photosynthetic bacteria. The only known species that contains similar light-harvesting complexes is *Roseococcus thiosulfatophilus* (Yurkov and Beatty, 1998a). The presence of Bchl *a* and the inability to grow under illuminated, anaerobic conditions distinguishes *Paracraurococcus* from members of the purple nonsulfur bacteria and places it among the obligately aerobic phototrophic bacteria.

Paracraurococcus can be differentiated from other genera of aerobic phototrophs based on color, red-to-dark-red colonies, as well as its unusual requirement for divalent cations to maintain cell structure in suspension.

On a phylogenetic tree, *Paracraurococcus* forms a separate line of descent with the closely related genus *Craurococcus*. However, *Paracraurococcus* can be distinguished from *Craurococcus* based on differences in absorption spectrum characteristics. *Paracraurococcus* shows absorption spectrum peaks at 802 and 856 nm, whereas *Craurococcus* shows absorption spectrum peaks at 800 and 872 nm, indicating a difference in the structural organization of the light-harvesting complex I between the two genera (see Table BXII.α.23 in Genus *Craurococcus*).

Taxonomic Comments

16S rRNA gene sequence analysis shows that *Paracraurococcus* forms a separate line of descent, along with *Craurococcus*, within the *Alphaproteobacteria*. This line falls within a cluster formed by the genera *Roseococcus*, *Rhodopila*, and *Acidiphilium* (Saitoh et al., 1998).

List of species of the genus Paracraurococcus

1. **Paracraurococcus ruber** Saitoh, Suzuki and Nishimura 1998, 1046[VP]

ru.ber. L. adj. *ruber* red-colored, red bacterium.

Gram-negative cocci, 0.8–1.5 µm in diameter, nonmotile, divide by means of binary fission. Cells contain Bchl *a* organized into reaction center and light-harvesting complexes, giving rise to absorption spectrum peaks at 802 and 856 nm, respectively, as well as spirilloxanthin and carotenoic acids. Facultative photoheterotrophs, incapable of anaerobic growth even under illuminated conditions. Aerobic growth is stimulated by light intensities of 2000 lux. Best growth substrates include D-xylose, fumarate and L-glutamate. Glycerol, D-fructose, D-galactose, D-glucose, D-arabinose, L-rhamnose, D-ribose, D-fucose, DL-lactate, malonate, pyruvate, gluconate, and L-malate also serve as the sole carbon source for heterotrophic growth. Incapable of growth on D-mannitol, sorbitol, methanol, ethanol, 1,2-propanediol, kerosene, acetate, butyrate, citrate, formate, glycolate, propionate, succinate, phthalate, *p*-hydroxybenzoate, and benzoate. Hydrolyze Tween 20, 40, and 60, but do not hydrolyze Tween 80. Produce catalase, oxidase, and urease. Reduce nitrate to nitrite. Denitrification not observed. Slight hydrolysis of starch. Do not hydrolyze esculin or gelatin. Do not produce phosphatase, deoxyribonuclease, or indole, but do produce H_2S. Voges–Proskauer test and methyl-red test are negative. Accumulate poly-β-hydroxybutyrate granules.

Optimal growth occurs at pH 6.6–6.8 and 30–34°C. Incapable of growth in NaCl concentrations higher than 0.4%. Require divalent cations to maintain cell structure in suspension. Sensitive to chloramphenicol, streptomycin, and tetracycline. Resistant to penicillin and polymixin B. Nicotinic acid and pantothenate are required as growth factors. Habitat: soil from a playground located in Yamazaki, Noda, of Osakajo Park in Chuoh Ward, Osaka, Japan.

The mol% G + C of the DNA is: 70.3–71.0 (HPLC).

Type strain: NS89, CIP 105708, JCM 9931.

GenBank accession number (16S rRNA): D85827.

Genus XI. **Rhodopila** *Imhoff, Trüper and Pfennig 1984, 341*[VP]

MICHAEL T. MADIGAN AND JOHANNES F. IMHOFF

Rho.do.pi' la. Gr. n. *rhodon* the rose; M.L. fem. n. *pila* a ball or sphere; M.L. fem. n. *Rhodopila* red sphere.

Cells are spherical to ovoid, motile by means of polar flagella, and divide by binary fission (Fig. BXII.α.29). **Gram negative, belonging to the *Alphaproteobacteria*.** Internal photosynthetic membranes are of the vesicular type. **Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids. Major fatty acids are $C_{18:1}$ (~75%) and $C_{16:0}$. Ubiquinones, menaquinones, and rhodoquinones with 9 and 10 isoprene units are present.**

Growth occurs preferably photoheterotrophically under anoxic conditions in the light. Cells may be sensitive to oxygen but **grow under microoxic conditions in the dark.** Growth factors are required. Acidophilic freshwater bacteria that live in warm sulfur springs.

The mol% G + C of the DNA is: 66.3.

Type species: **Rhodopila globiformis** (Pfennig 1974) Imhoff, Trüper and Pfennig 1984, 341 (*Rhodopseudomonas globiformis* Pfennig 1974, 205.)

FURTHER DESCRIPTIVE INFORMATION

Rhodopila globiformis is the only known species of this genus and is characterized by a number of peculiar physiological properties. It is an acidophilic bacterium, capable of growth at the lowest pH known for phototrophic purple nonsulfur bacteria (PNSB) (Pfennig, 1969a, 1974). Different pH optima for *Rhodopila globiformis* have been noted during growth with mannitol (pH 4.8–5.0) and fumarate (pH 5.6) as carbon sources (Pfennig, 1974). Defining characteristics are given in Table BXII.α.26; carbon sources and electron donors used are given in Table BXII.α.27. The genus is compared to other phototrophic members of the *Rhodospirillales* in Tables 1 and 2 of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria" (Volume 2, Part A, pp. 121–123). The relationships of these bacteria based on 16S rDNA analysis are shown in Fig. 1 (p. 124) of that chapter.

Rhodopila globiformis is a photoheterotroph, unable to use most of the carbon substrates used by other phototrophic purple nonsulfur bacteria. Ammonia is assimilated via the glutamine synthetase/glutamate synthase reaction (NADH-dependent). Glutamate dehydrogenase is not present, but low activities of an alanine dehydrogenase were found (Madigan and Cox, 1982).

Growth with sulfate as sole sulfur source is possible at low concentrations, but at more than 1 mM sulfate, growth is inhibited. The inhibitory effects of higher sulfate concentrations are thought to be due to misregulation of the enzymes involved (Hensel and Trüper, 1976; Imhoff et al., 1981) and can be overcome by supplementation with a suitable reduced sulfur source. All enzymes necessary for sulfate assimilation are present. Sulfate is reduced via adenosine-5′-phosphosulfate (Imhoff, 1982). Good sulfur sources are cysteine and thiosulfate. Some of the latter is assimilated, but most of it is oxidized to tetrathionate (Then and Trüper, 1981). Sulfite and sulfide are growth-inhibitory even at low concentrations.

Rhodopila globiformis has unique aliphatic ketocarotenoids as major components (Schmidt and Liaaen-Jensen, 1973; Schmidt, 1978) and small amounts of asymmetrical gamma-carotene and neurosporene (S. Takaichi, personal communication). *Rhodopila globiformis* also contains unusual polar lipids (Imhoff et al., 1982), a "small type" cytochrome c_2 (Dickerson, 1980b), and is among the few species of the PNSB that have readily detectable amounts of a high potential iron-sulfur protein (HiPIP).

The type strain of *Rhodopila globiformis* was isolated from a weak red layer present in an acidic sulfur spring along the Gibbon River, Yellowstone National Park (USA). There are several warm springs in this area which are located on the east side of the Grand Loop Road in Yellowstone, about 100 m northeast of Beryl Spring. The springs are warm (~40°C), contain large amounts of S^0 (presumably from the oxidation of sulfide), and can be

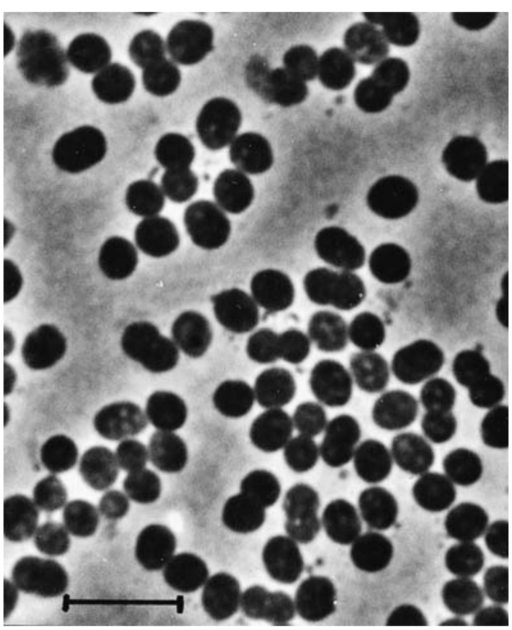

FIGURE BXII.α.29. Phase-contrast photomicrograph of cells of *Rhodopila globiformis* strain DSM 161[T]. Bar = 5 μm. (Courtesty of N. Pfennig.)

TABLE BXII.α.26. Characteristics of *Rhodopila globiformis*[a]

Characteristic	*Rhodopila globiformis*
Cell diameter (μm)	1.6–1.8
Internal membrane system	Vesicles
Motility	+
Color	Purple-red
Bacteriochlorophyll	*a*
Growth factors	Biotin, *p*-aminobenzoic acid
Aerobic growth	(+)
Oxidation of sulfide	−
Salt requirement	None
Optimal temperature (°C)	30–35
Optimal pH	4.8–5.0
Habitat	Fresh water
Mol% G + C of the DNA[c]	66.3
Cytochrome *c* size	Small
Major quinones	Q-9/10, MK-9/10, RQ-9/10
Major fatty acids:	
$C_{14:0}$	5.8
$C_{16:0}$	9.3
$C_{16:1}$	4.7
$C_{18:0}$	1
$C_{18:1}$	74.4

[a]Symbols: +, positive in most strains; −, negative in most strains; (+), weak growth or microaerobic growth only; nd, not determined; Q–9/10, ubiquinones 9 and 10; MK-9/10, menaquinones 9 and 10; RQ-9/10, rhodoquinones 9 and 10.

TABLE BXII.α.27. Carbon sources and electron donors used by *Rhodopila globiformis*[a]

Source/donor	*Rhodopila globiformis*
Carbon sources:	
Acetate	−
Arginine	−
Aspartate	−
Benzoate	−
Butyrate	−
Caproate	−
Caprylate	−
Citrate	−
Ethanol	+
Formate	−
Fructose	+
Fumarate	+
Glucose	+
Glutamate	−
Glycerol	−
Glycolate	−
Lactate	−
Malate	+
Mannitol	+
Methanol	−
Pelargonate	−
Propionate	−
Pyruvate	+
Succinate	+
Tartrate	+
Valerate	−
Electron donors:	
Hydrogen	nd
Sulfide	nd
Sulfur	−
Thiosulfate	−

[a]Symbols: Symbols: +, positive in most strains; −, negative in most strains; +/−, variable in different strains; nd, not determined.

very acidic. Measurements in a series of such springs showed pH values as low as 2.7, with most of them in the range of pH 3–4 (M.T. Madigan, unpublished results). Other locations in Yellowstone where *Rhodopila globiformis* has been observed include warm sulfur springs on the periphery of Nymph Lake; an isolate of *R. globiformis* (strain NL) that matches the type strain in most phenotypic properties was isolated from such a spring (M.T. Madigan, unpublished results). *R. globiformis* coexists in these springs with the extremely acidophilic red alga *Cyanidium caldarum* (Brock, 1978), which supports evidence of the true acidophilic nature of *R. globiformis*.

Enrichment and Isolation Procedures

If samples from suitable natural habitats are available, *Rhodopila globiformis* can be selectively enriched in media with gluconate (or ethanol) as carbon source, thiosulfate as sulfur source, and ammonia or N_2 as nitrogen source at acidic pH (4.8–5.0). Isolation can be achieved by standard procedures for phototrophic purple bacteria under strictly anoxic conditions (Imhoff, 1988; Imhoff and Trüper, 1992). Agar shake cultures established using samples of suspected blooms of *R. globiformis* yield cherry-red colonies within one week at 35°C and 1000 lux incandescent illumination. A suitable medium for *R. globiformis* (after Pfennig, 1974) is given in the footnote below.[1]

1. The medium contains (per liter): KH_2PO_4, 0.5 g; NH_4Cl, 0.4 g; $MgSO_4 \cdot 7H_2O$, 0.4 g; NaCl, 0.4 g; $CaCl_2 \cdot 2H_2O$, 0.05 g; $Na_2S_2O_3 \cdot 5H_2O$, 0.2 g; ferrous citrate, 0.005 g; mannitol, 1.5 g; gluconate, 0.5 g; biotin, 100 µg; *p*-aminobenzoic acid, 200 µg; and trace element solution 6, 10 ml. The initial pH is adjusted to 5.0.

Maintenance Procedures

Cultures of *R. globiformis* are well preserved in liquid nitrogen or at −80°C in a mechanical freezer. Mid-exponential phase cell suspensions should be mixed with glycerol or DMSO to yield final concentrations of 10% and 5%, respectively, and kept at 0°C for 15 min and then frozen immediately.

Differentiation of the genus *Rhodopila* from other genera

The genus *Rhodopila* is represented by a single species. *Rhodopila globiformis* differs from all other anoxygenic phototrophic *Alphaproteobacteria* in its outstanding physiological and chemotaxonomic properties and phylogenetic position based on 16S rDNA sequence analysis. First and foremost, acidophily (Pfennig, 1974) and unique carotenoid composition (Schmidt, 1978) characterize *Rhodopila globiformis*. Furthermore, cytochrome c_2 structure (Dickerson, 1980b), quinone and polar lipid composition (Imhoff and Bias-Imhoff, 1995), sulfate assimilation via adenosine-5′-phosphosulfate (Imhoff, 1982), presence of a high potential iron-sulfur protein (HiPIP), and 16S rDNA sequence are characteristics that differentiate *Rhodopila* from other phototrophic *Alphaproteobacteria*. Comparative 16S rDNA sequence analysis of *R. globiformis* shows a clear relationship to both phototrophic and chemotrophic species. A particularly close relationship exists to the acidophilic chemotrophic bacteria including *Acidiphilium* species (Fig. 1 p. 124 in the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A; see also Fig. 1 p. 136 in the introductory chapter "Aerobic Bacteriochlorophyll-Containing Bacteria", Volume 2, Part A). This suggests that the acidophilic lifestyle of *R. globiformis* is a fundamental physiological property rooted in its phylogenetic ties to other acidophilic bacteria. The close relationship to *Acidiphilium* species is of particular interest, because these bacteria contain an extraordinary bacteriochlorophyll *a* with Zn instead of Mg as the chelated metal ion (Wakao et al., 1993, 1996; see Genus *Acidiphilium*).

Taxonomic Comments

Several outstanding characteristics of *Rhodopila globiformis* warrant its treatment as a separate genus (Imhoff et al., 1984). This species was originally described as *Rhodopseudomonas globiformis* (Pfennig, 1974) and later reclassified based on unique physiological, chemotaxonomic, and phylogenetic characteristics (Imhoff et al., 1984).

List of species of the genus Rhodopila

1. **Rhodopila globiformis** (Pfennig 1974) Imhoff, Trüper and Pfennig 1984, 341[VP] (*Rhodopseudomonas globiformis* Pfennig 1974, 205.)
glo.bi.for′ mis. L. n. *globus* sphere; L. n. *forma* shape; M.L. n. *globiformis* of spherical shape.

Cells are spherical to ovoid, diplococcus-shaped before cell division, under optimal growth conditions 1.6–1.8 μm in diameter (depending on the culture conditions diameter ranges from 1.0 to 2.5 μm), and motile by means of polar flagella. Internal photosynthetic membranes are of the vesicular type. Color of cultures grown anaerobically in the light is intensely purple-red; microaerobically grown cells are pink. Absorption spectra of living cells show maxima at 378, 594, 813, and 862 nm and a shoulder at 890 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and as major components unusual aliphatic ketocarotenoids.

Cells grow preferably photoheterotrophically under anoxic conditions in the light, but also chemotrophically under microoxic conditions in the dark. Best growth is obtained with gluconate, mannitol, fructose, or ethanol as carbon source. Glucose, tartrate, fumarate, succinate, malate, pyruvate, and yeast extract at low concentration are also assimilated. No growth occurs with fatty acids, lactate, citrate, glycerol, mannose, sorbitol, amino acids, and benzoate as carbon source. Besides ammonia, which is the best nitrogen source, N_2, glutamate, glutamine, aspartate, arginine, urea, asparagine, and alanine are used. Peptone and yeast extract are utilized at low concentrations (0.05%) but are growth-inhibitory at higher concentrations. Nitrate is not assimilated. Thiosulfate, cysteine, or low concentrations of sulfate are the best sulfur sources. Sulfate is growth inhibitory at concentrations above 1 mM. Methionine and tetrathionate can also be used, but sulfide and sulfite inhibit growth even at low concentrations. Biotin and *p*-aminobenzoic acid are required as growth factors.

Acidophilic freshwater bacterium with optimal growth at 30–35°C (no growth at and above 40°C) and at pH 4.8–5.0 with mannitol as carbon source (pH range: 4.2–6.5).

The mol% G + C of the DNA is: 66.3 (Bd).

Type strain: Pfennig 7950, ATCC 35887, DSM 161.

GenBank accession number (16S rRNA): D86513.

Genus XII. **Roseococcus** *Yurkov, Stackebrandt, Holmes, Fuerst, Hugenholtz, Golecki, Gad'on, Gorlenko, Kompantseva and Drews 1994c, 430[VP]*

Vladimir V. Yurkov

Ro′se.o.coc′cus. M.L. adj. *roseus* rose, pink; Gr. n. *coccus* sphere or spheroidal shape; M.L. masc. n. *Roseococcus* pink spherical bacterium.

Cells are Gram negative, **coccoidal, pink** and motile by means of polar flagella. Divide by binary fission. **Bacteriochlorophyll *a* and carotenoid pigments** are present. **Obligately aerobic, chemoorganotrophic** (respiratory metabolism) and **facultatively photoheterotrophic**. **No growth occurs under anaerobic conditions in the light.** May use thiosulfate as an additional energy source. Methanol is not utilized. NaCl not required for growth.

The mol% G + C of the DNA is: 70.4.

Type species: **Roseococcus thiosulfatophilus** Yurkov, Stackebrandt, Holmes, Fuerst, Hugenholtz, Golecki, Gad' on, Gorlenko, Kompantseva and Drews 1994c, 432.

Further descriptive information

The genus *Roseococcus* is phylogenetically related to members of the *Alphaproteobacteria*; this class also includes other aerobic anoxygenic phototrophic bacteria as well as purple nonsulfur photosynthetic and several nonphotosynthetic species. *Roseococcus* is moderately related to *Rhodopila globiformis*, *Thiobacillus acidophilus*, and species of the genus *Acidiphilium* (levels of 16S rDNA sequence homology, >90%) (Yurkov et al., 1994c).

Only one species of the genus is currently isolated and described, *Roseococcus thiosulfatophilus*, represented by pink-red coccoidal cells of 0.9–1.3 × 1.3–1.6 μm in size (Fig. BXII.α.30) and motile by means of a single polar flagellum. The pink-red color of this species is due mainly to two polar red pigments, C_{30} carotene-dioate (4,4′-diapocarotene-4,4′-dioate) and the respective diglucosyl ester (di[β-D-glucopyranosyl]-4,4′-diapocarotene-4,4′-dioate). Together they contribute 95% of the total carotenoid content (Yurkov et al., 1993). Such highly polar C_{30} carotenoid glycosides have never before been observed in other phototrophic bacteria, although the same carotenoid and its diglycosylated form have previously been postulated to exist in *Methylobacterium rhodinum* (formerly *Pseudomonas rhodos*) (Yurkov et al., 1993).

Absorption spectra of the intact cells of *R. thiosulfatophilus* yielded several peaks: at 482, 510, 538, 800, and 859 nm (Yurkov and Gorlenko, 1991). Absorption peaks at 482, 510, and 538 nm are due to the presence of two highly polar red carotenoids described above. Absorption peaks in the infra-red spectrum region indicate the incorporation of bacteriochlorophyll *a* into the reaction center (minor peak at 800 nm) and an unusual type of light-harvesting complex (major peak at 859 nm). Subsequent purification of light-harvesting complexes from these bacteria by detergent treatment of membranes and sucrose density gradient centrifugation revealed the existence of a new *R. thiosulfatophilus* light-harvesting complex I with an absorption peak at 856 nm. The reaction center of *R. thiosulfatophilus* possesses a tightly bound cytochrome *c* (of 44 kDa) that serves as the immediate

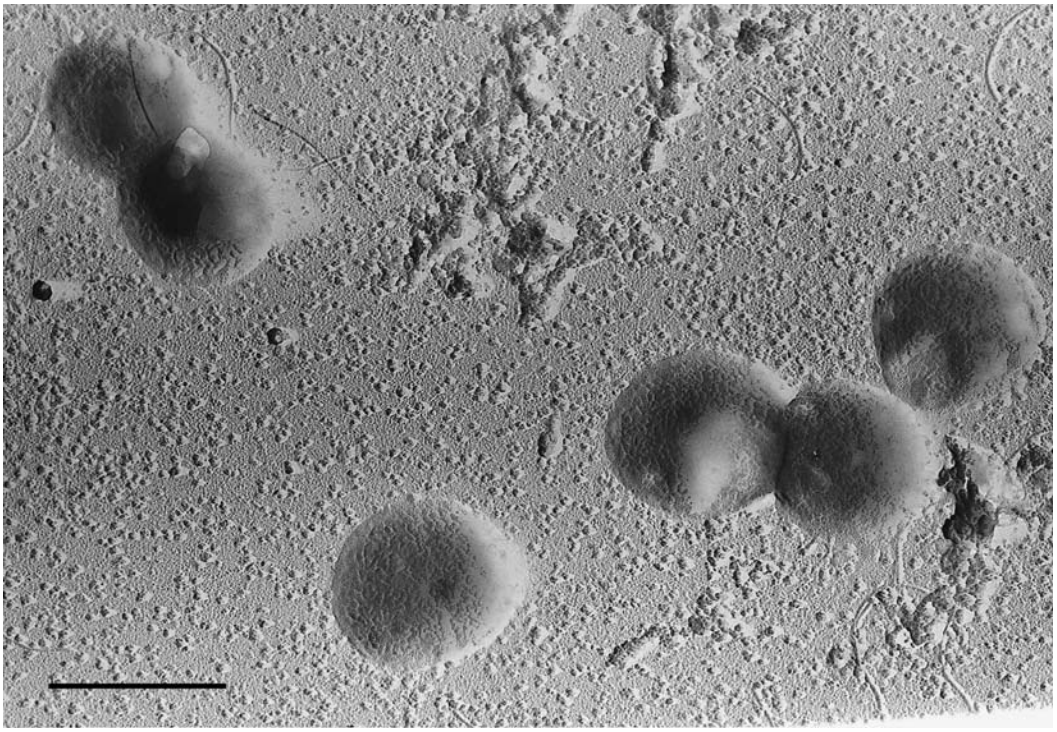

FIGURE BXII.α.30. Coccal cells of *Roseococcus thiosulfatophilus*. Scanning electron micrograph of carbon shadowed cells. Bar = 1.0 μm. (Courtesy of V. Yurkov.)

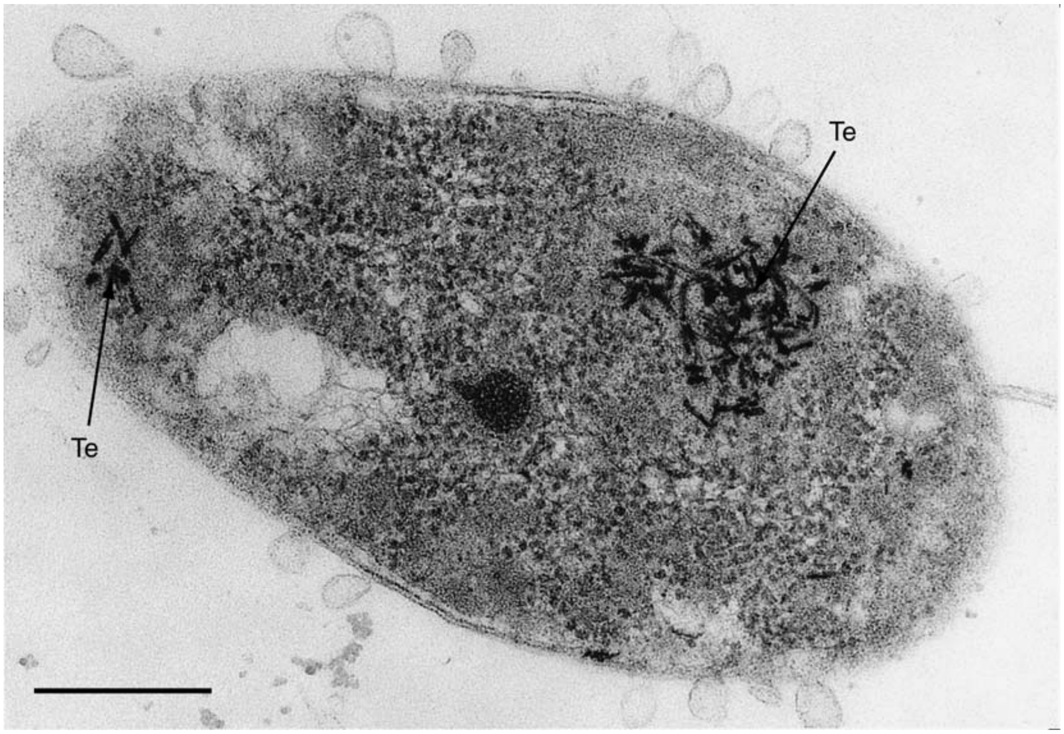
electron donor to the photooxidized reaction center. The photosynthetic apparatus of *R. thiosulfatophilus* was shown to be functional in terms of a cyclic electron transfer under aerobic conditions. It is not functional anaerobically (Yurkov et al., 1995, 1998a).

Most of the *R. thiosulfatophilus* carotenoids are not bound to the bacteriochlorophyll-protein complexes of the photosynthetic apparatus but to the envelope fraction (cytoplasmic membrane and cell wall) (Yurkov et al., 1993). The excess of carotenoids in the membranes does not contribute to the light-harvesting function of the light-harvesting complexes (Yurkov et al., 1994a).

R. thiosulfatophilus is highly resistant to the toxic heavy metal oxide tellurite (Yurkov et al., 1996). However, the resistance of *R. thiosulfatophilus* to tellurite is not always correlated to its reduction to tellurium. High-level resistance without tellurite reduction was observed for *R. thiosulfatophilus* grown with L-glutamine, succinate, malate, tartrate, or acetate as the organic carbon sources. Tellurite reduction with intracellular deposition of small tellurium crystals in *R. thiosulfatophilus* was shown in rich organic medium (Fig. BXII.α.31). These results are similar to that observed for *Erythromicrobium ezovicum*, implying that tellurite reduction is not essential to confer tellurite resistance and some other important mechanisms could play a role in the resistance character (Yurkov et al., 1996).

Enrichment and Isolation Procedures

R. thiosulfatophilus was isolated in pure culture from a cyanobacterial mat developed in an alkaline sulfide high temperature spring situated in the Bol' shaya River valley. Isolation procedures are similar to that described for the genus *Erythromicrobium* (see the chapter on the *Erythromicrobium*).



Maintenance Procedures

Maintenance of *R. thiosulfatophilus* in liquid culture, on agar plates and long-term preservation are the same as described for the genus *Erythromicrobium*.

Differentiation of the genus *Roseococcus* from other genera

The genus *Roseococcus* has many specific features that differentiate this genus from other genera of aerobic anoxygenic phototrophic bacteria: very high mol% G + C DNA content (70.4) and low DNA homology determined by DNA–DNA hybridization, morphological peculiarities (cell shape and color), carotenoid composition, photosynthetic apparatus components, ability to oxidize thiosulfate to sulfate, and resist high concentrations of toxic tellurite in a special manner (See above).

Roseococcus thiosulfatophilus shares high 16S rDNA sequence similarity with the purple nonsulfur bacterium *Rhodopila globiformis*, which is the closest phylogenetic relative (Yurkov et al., 1994c). Both *Roseococcus thiosulfatophilus* and *R. globiformis* contain bacteriochlorophyll *a* and are able to oxidize thiosulfate. Both these microorganisms also form pink colonies and their mol% G + C contents are high (66.3 and 70.4). There are, however, considerable differences in the growth conditions which they prefer; *Rhodopila globiformis* prefers to grow anaerobically under photoheterotrophic conditions, while *Roseococcus thiosulfatophilus* is obligately aerobic. The antenna systems of these two organisms are also different. *Rhodopila globiformis* seems to have two light-harvesting complexes (with absorption peaks at 813, 862, and 890 nm), whereas *Roseococcus thiosulfatophilus* has only one (with an absorption peak at 856 nm).

FIGUREBXII.α.31. *Roseococcus thiosulfatophilus*, electron microscopy of ultrathin sections. Intracellular localization of tellurium (*Te; indicated by arrows*) as a product of tellurite reduction. Bar = 0.25 μm. (Courtesy of V. Yurkov.)

Taxonomic Comments

The genus *Roseococcus* was created by Yurkov and Gorlenko in 1991 for bacterial strains isolated from a sulfide high temperature spring, based on their morphological, physiological, and DNA–DNA hybridization analyses (Yurkov and Gorlenko, 1991). A valid description of this genus was supplemented by additional results on the photosynthetic apparatus organization, carotenoid composition, and phylogeny (Yurkov et al., 1994c).

List of species of the genus Roseococcus

1. **Roseococcus thiosulfatophilus** Yurkov, Stackebrandt, Holmes, Fuerst, Hugenholtz, Golecki, Gad' on, Gorlenko, Kompantseva and Drews 1994c, 432[VP]
thi' o.sul.fa.to' phi.lus. M.L. adj. *thiosulfatophilus* thiosulfate liking.

Gram-negative, pink cocci that are 0.9–1.3 × 1.3–1.6 μm and are motile by means of single polar flagellum. Cells contain bacteriochlorophyll *a* and carotenoids. Membranes isolated from cells grown semiaerobically in the dark have absorption maxima at 478, 501, and 505 nm (carotenoids) and at 800 and 855 nm (bacteriochlorophyll). The major carotenoid is C_{30} carotene-dioate. Aerobic, chemoorganotrophic, and facultatively photoheterotrophic.

Growth occurs on yeast extract and when succinate, acetate, pyruvate, citrate, lactate, malate, or glutamate are used as sole carbon source; weak growth occurs with glucose, maltose, and glycerol. Fructose, sucrose, ribose, arabinose, butyrate, formate, fumarate, propionate, benzoate, tartrate, methanol, ethanol, mannitol, and glycolate are not used. Gelatin, starch, and Tween-80 are not hydrolyzed.

The cells can oxidize thiosulfate to sulfate in the presence of organic compounds. Ribulose diphosphate carboxylase activity is not detected. The cells are susceptible to tetracycline, streptomycin, polymyxin-B, erythromycin, amikacin, kanamycin, neomycin, aureomycin, vancomycin, chloramphenicol, and fusidic acid, but resistant to gentamicin, lincomycin, nystatin, bacitracin, and penicillin. Oxidase and catalase positive.

Resistant to the heavy metal oxide tellurite. Reduction of tellurite results in the accumulation of elemental tellurium inside the cells. Tellurite resistance and reduction depend on supplemented organic carbon source. The storage material consists of polysaccharides, poly-β-hydroxybutyrate, and polyphosphate.

Habitat: freshwater cyanobacterial mat of a thermal alkaline sulfide spring (54°C; pH 9.3; 7.4 mg/l sulfide; 1.6 mg/l oxygen).

The mol% G + C of the DNA is: 70.4 (T_m).

Type strain: Strain RB3, ATCC 700004, DSM 8511.

GenBank accession number (16S rRNA): X72908.

Genus XIII. **Roseomonas** *Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1998, 627*[VP] *(Effective publication: Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1993, 3282)*

ROBBIN S. WEYANT AND ANNE M. WHITNEY

Ro.se.o.mo′nas. M.L. adj. *roseus* rosy, rose-colored, or pink; Gr. n. *monas* a unit; M.L. n. *Roseomonas* a pink-pigmented bacterium.

Plump cocci, coccobacilli, or short rods. Arranged singly and less frequently in pairs or short chains. Gram negative. **Aerobic.** Growth occurs on trypticase soy agar with and without 5% sheep blood, heart infusion agar with and without 5% rabbit blood, chocolate agar, and buffered charcoal yeast extract (BCYE) agar. Most strains grow on MacConkey agar. Growth occurs at 25°C, 30°C, 35°C, and for most strains, 42°C. Optimal growth temperature is 35°C. No growth in media containing greater than 6% NaCl. Pinpoint colonies appear after 48–72 h incubation on BCYE agar. Colonies are raised, entire, glistening, and often mucoid. **Pale pink growth pigment is produced. Catalase and urease positive.** Oxidase variable. Motility variable. Indole is not produced. Associated with human infections, usually as a secondary or opportunistic pathogen. Interrelatedness of species by DNA–DNA hybridization is 7–53%.

The mol% G + C of the DNA is: 65–71.

Type species: **Roseomonas gilardii** Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1998, 627 (Effective publication: Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1993, 3282.)

FURTHER DESCRIPTIVE INFORMATION

Phylogenetic treatment The genus *Roseomonas* contains three named species and three currently unnamed genomospecies: *R. gilardii*, *R. cervicalis*, *R. fauriae*, and *Roseomonas* genomospecies 4, 5, and 6. Fig. BXII.α.32 illustrates the phylogenetic relatedness among the species of *Roseomonas* based on 16S rDNA sequence similarity. As currently defined, *Roseomonas* is a dichotomous genus with one cluster of species, including *R. gilardii*, *R. cervicalis*, and *Roseomonas* genomospecies 4 and 5 in the family *Acetobacteraceae* and another cluster, including *R. fauriae* and *Roseomonas* genomospecies 6 in the family *Rhodospirillaceae*. Both *Roseomonas* clusters are in the *Alphaproteobacteria*.

Cell and flagellum morphology *Roseomonas* cells can be visualized using the Gram stain and other common staining techniques. Gram-stained preparations of 48-hour cultures show weakly staining Gram-negative plump coccoid rods, occasionally appearing in pairs or short chains. Cells of *R. fauriae* and *Roseomonas* genomospecies 6 have a more rod-like appearance than cells of the other species. Motility varies between species and between strains within species. Motile strains are found in all species except *Roseomonas* genomospecies 5. When present, motility is provided by a single polar flagellum per cell (Weyant et al., 1996).

Cellular fatty acid (CFA) composition *Roseomonas* species produce two characteristic CFA profiles that correlate with the dichotomy of the genus. The profile produced by *R. gilardii*, *R. cervicalis*, and *Roseomonas* genomospecies 4 and 5 is characterized by large amounts (43–53%) of *cis*-11-octadecenoic, δ-*cis*-11,12-methyleneoctadecanoic (10–25%), 2-hydroxyoctadecenoic (2–5%), and 2-hydroxy-δ-*cis*-11,12-methyleneoctadecanoic (3–11%) acids. The profile produced by *R. fauriae* and *Roseomonas* genomospecies 6 is characterized by very large amounts (63–90%) of *cis*-11-octadecenoic and small amounts of 3-hydroxytetradecanoic (2–6%), *cis*-9-hexadecenoic (3–12%), *cis*-9,12-octadecadienoic, *cis*-9-octadecenoic, and octadecanoic acids (Wallace et al., 1990; Weyant et al., 1996).

Colonial and cultural characteristics Growth is achieved in aerobic conditions on most nonselective media, including trypticase soy agar with and without 5% sheep blood, heart infusion agar with and without 5% rabbit blood, chocolate agar, nutrient agar, Sabouraud dextrose agar, and buffered charcoal yeast extract (BCYE) agar. Most strains also grow on MacConkey and Thayer–Martin media. When cultured under optimal conditions, pinpoint colonies are observed after 48 hours of incubation at 35°C. Colonies are typically shiny, raised, entire, and often mucoid. Young colonies have a pale pink color that darkens with age.

Genetics The organization of the genus *Roseomonas* was determined in a DNA–DNA hybridization-based study of 42 strains by Rihs et al. (1993). Using the guidelines of the *ad hoc* committee on reconciliation of approaches to bacterial systematics (Wayne et al., 1987), six genomospecies, three named and three currently unnamed, were identified. The DNA mol% G + C contents of the six genomospecies range from 65.0 for *Roseomonas* genomospecies 6 to 70.4 for *R. cervicalis*. Lewis et al. (1997) have applied molecular subtyping approaches, including pulsed-field gel electrophoresis of chromosomal digests (PFGE) and random amplified polymorphic DNA (RAPD) analysis, to *R. gilardii* clinical isolates. RAPD analysis was reported to be more discriminatory than PFGE and less susceptible to interference by mucoid extracellular material produced by the isolates (Lewis et al., 1997).

Antibiotic sensitivity A significant proportion of the current *Roseomonas* literature contains information related to antibiotic susceptibility of *R. gilardii* strains (Gilardi and Faur, 1984; Korvick et al., 1989; Rihs et al., 1993; Lewis et al., 1997; Sandoe et al.,1997). Antibiotics to which all *R. gilardii* strains are susceptible include the aminoglycosides (gentamicin, amikacin, and tobramycin), tetracycline, and imipenem. One strain tested by Sandoe et al. (1997) was sensitive to netilmicin. All *R. gilardii* strains are resistant to piperacillin and erythromycin. The majority of strains tested were resistant to first- and second-generation cephalosporins. Susceptibility to third-generation cephalosporins varied within and between studies. The eight strains studied by Lewis et al. (1997) and two strains studied by Korvick et al. (1989) were susceptible to ceftriaxone, but only 1 of 23 strains studied by Rihs et al. (1993) was susceptible to this antibiotic. Likewise, the two strains studied by Korvick et al. (1989) were susceptible to cefotaxime but only 1 of 23 strains studied by Rihs et al. (1993) was susceptible. All strains studied were resistant to ceftazidime. Quinolone susceptibility also varied between studies. All eight strains studied by Lewis et al. (1997) and the strain studied by Sandoe et al. (1997) were susceptible to ciprofloxacin, but only 15 of 23 strains studied by Rihs et al. (1993) were susceptible. The study by Rihs et al. (1993) also included norfloxacin, to which 19 of 23 strains tested were susceptible. Susceptibility to sulfamethoxazole/trimethoprim and to penicillins (including natural, extended spectrum, and combinations with β-lactamase inhibitors) was variable in all studies that included more than

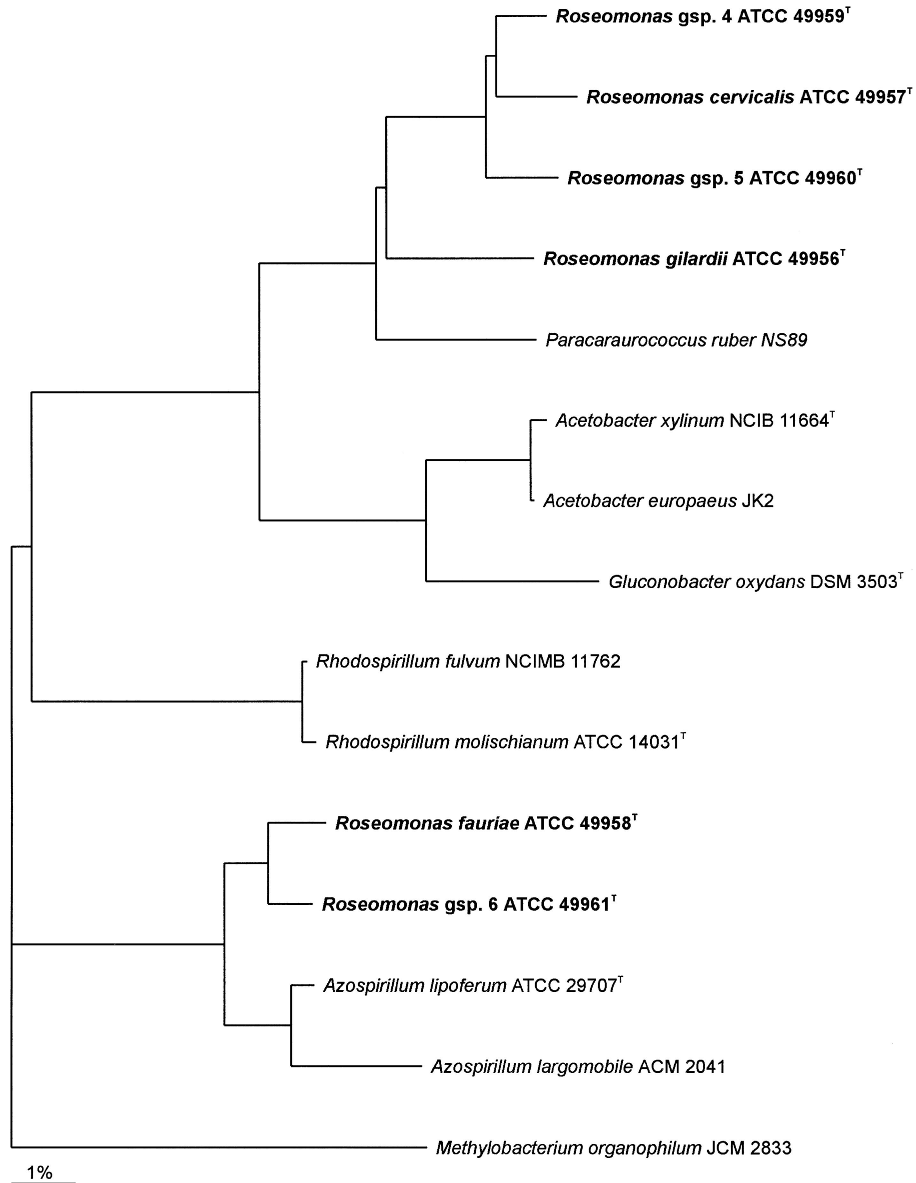

FIGURE BXII.α.32. Phylogenetic tree based on 16S rDNA sequence homologies between the type strains of *Roseomonas* species and type or reference strains of closely related taxa. *Acetobacter xylinum* and *Acetobacter europaeus* have been proposed as *Gluconacetobacter xylinus* and *Gluconacetobacter europaeus* (Yamada et al., 1997, 1998b); *Rhodospirillum fulvum* and *Rhodospirillum molischianum* have been proposed as *Phaeospirillum fulvum* and *Phaeospirillum molischianum* (Imhoff et al., 1998).

one strain. Two strains tested by Korvick et al. (1989) were sensitive to chloramphenicol but resistant to clindamicin, vancomycin, and rifampin.

Rihs et al. (1993) also provided *in vitro* antibiotic susceptibility profiles for strains of the other *Roseomonas* species. All strains tested were sensitive to aminoglycosides, quinolones, tetracycline, imipenem, and penicillins in combination with β-lactamase inhibitors. Most strains were resistant to natural and extended spectrum penicillins, aztreonam, nitrofurantoin, and cephalosporins. Variable results were obtained for the sulfonamides.

Pathogenicity *Roseomonas* species have been associated with human infections, usually as secondary or opportunistic pathogens. There is currently no evidence that indicates *Roseomonas* species cause disease in plants or animals other than humans. Most *Roseomonas* infections have been reported in patients with significant underlying disease and, in many cases, *Roseomonas* strains were isolated in mixed culture. In a series of 35 cases reviewed by Struthers et al. (1996), *Roseomonas* strains were most commonly isolated from middle-aged women with one of several underlying conditions, including cancer and diabetes; blood was the most common source of isolation; and only 75% of strains were isolated in pure culture. Similar findings were reported by Lewis et al. (1997), who reviewed a series of eight cases of *R. gilardii* infection. All eight patients had underlying conditions, including ovarian cancer, AIDS, multiple myeloma, non-Hodg-

kin's lymphoma, and breast cancer. *R. gilardii* was isolated from blood cultures of seven patients; all of whom had central venous catheters and four of whom had polymicrobic infections. Based on the cases reported in the literature, *R. gilardii* is more likely to be associated with human infections than are the other *Roseomonas* species.

Ecology The ecology of *Roseomonas* has not been studied directly, with the great majority of known strains having been isolated from human clinical specimens. There are some suggestions in the literature that these organisms may reside in potable water. Of 42 *Roseomonas* strains studied by Rihs et al. (1993), three *R. gilardii* strains were isolated from potable water. Wallace et al. (1990) reported the source of 2 of the 156 strains that they studied to be a saline contaminant and ice. Another possible ecological niche for these organisms is human skin or mucosal surfaces. The type strain of *R. cervicalis* was isolated from a human cervix culture and *Roseomonas* genomospecies 5 has been isolated as a commensal from young adults attending a sexually transmitted diseases clinic (Rihs et al., 1993; Struthers et al., 1996).

Enrichment and Isolation Procedures

Roseomonas species grow on most commonly used bacteriological media, including trypticase soy agar with and without 5% sheep blood, heart infusion agar with and without 5% rabbit blood, Sabouraud dextrose agar, nutrient agar, buffered charcoal yeast extract agar, and chocolate agar. Selective media that may be used to enrich for these organisms include Thayer–Martin agar and MacConkey agar, although a few MacConkey-negative strains have been described (Odugbemi et al., 1988; Weyant et al., 1996). Growth is inhibited in media containing more than 6% NaCl. Optimal growth temperature is 35°C and aerobic atmospheric conditions are satisfactory.

Maintenance Procedures

Strains can be maintained for short periods (up to 3 months) as cultures in motility deeps. Motility medium deeps in screw cap tubes are inoculated with a sterile inoculation needle by stabbing fresh growth approximately 5 cm into the agar with a single stroke. The tubes are incubated for 1–2 d at 35°C with the screw cap opened slightly to allow for air exchange. After growth is observed in the tube, the cap is tightened to prevent desiccation and the tube is stored at room temperature. Successful long-term storage can be achieved by suspending fresh growth in defibrinated rabbit blood and freezing in liquid nitrogen (Weyant et al., 1996).

Procedures for Testing Special Characters

The oxidation–fermentation (OF) medium of King (Weyant et al., 1996) is more sensitive than the Hugh–Leifson formulation (Hugh and Leifson, 1953) in detecting acid production from carbohydrates with *Roseomonas* strains (Rihs et al., 1993). Long-wave absorbance of UV light is a relatively simple procedure for differentiating *Roseomonas* from *Methylobacterium* strains. Colonies grown on BCYE agar are exposed to a long wave UV lamp (365 nm) at a distance of approximately 5 inches (15 cm) in a dark room. *Methylobacterium* colonies will appear dark due to the absorbance of the light, whereas *Roseomonas* species will be easily visible due to the reflection of the light (Rihs et al., 1993). Interlab variability for the oxidase test with *R. gilardii* strains has been reported (Rihs et al., 1993). When tested by the Kovacs method (Kovács, 1956), some strains may test negative at 10 seconds but will produce a weak reaction after 30 seconds.

Differentiation of the genus *Roseomonas* from other genera

Roseomonas shares many phenotypic characteristics with *Methylobacterium*, a genus of aerobic, pink-pigmented, oxidative, Gram-negative rods. *Methylobacterium* strains have also been isolated from human clinical specimens (Weyant et al., 1996). Characteristics useful in differentiating these two genera are given in Table BXII.α.28. *Roseomonas* strains fail to produce acid from methanol, assimilate acetamide, and absorb long-wave (365 nm) UV light (Rihs et al., 1993). Most *Roseomonas* strains grow on MacConkey agar, although detectable growth may require 3–7 d of incubation. Esculin hydrolysis and motility are useful in differentiating strains of some *Roseomonas* species from *Methylobacterium*. Strains of *R. fauriae* and *Roseomonas* genomospecies 6 are esculin-positive, and strains of *Roseomonas* genomospecies 5 are nonmotile, which differentiate them from *Methylobacterium* strains.

Taxonomic Comments

Strains subsequently shown to be *Roseomonas* were first described in a study of pink-pigmented clinical isolates by Gilardi and Faur. They designated their strains as an "unnamed pink-pigmented taxon" that could be differentiated phenotypically from *Methylobacterium* (Gilardi and Faur, 1984). This term was used by Odugbemi et al. and Korvick, et al. to describe additional isolates from human blood cultures (Odugbemi et al., 1988; Korvick et al., 1989). In 1990 Wallace, et al. published an extensive phenotypic and cellular fatty acid analysis of 156 pink-pigmented strains submitted to the U.S. Centers for Disease Control and Prevention for identification. Included within the study group were the strains described by Odugbemi et al. and by Gilardi and Faur. Four phenotypic groups (Pink Coccoid Groups I, II, III, and IV) that were differentiated by esculin hydrolysis, oxidation of D-xylose and D-mannitol, and cellular fatty acid profiles were described (Wallace et al., 1990). In 1993, Rhis et al., published a polyphasic classification study of 42 strains, including the strains from Gilardi and Faur, Odugbemi et al., Korvick et al., and representatives of all four Pink Coccoid Groups from Wallace et al. Using DNA–DNA hybridization, in conjunction with morphological, biochemical, and antibiotic susceptibility profile analysis, the genus containing six new species (*Roseomonas gilardii*, *R. cervicalis*, *R. fauriae*, and *Roseomonas* genomospecies 4, 5, and 6) was described (Rihs et al., 1993). Recently obtained 16S rDNA sequence information now suggests phylogenetic dichotomy within the genus *Roseomonas* (Fig. BXII.α.32). The type species, *R. gi-*

lardii, along with *R. cervicalis* and *Roseomonas* genomospecies 4 and 5 are mostly closely related to taxa in the family *Acetobacteraceae*. *R. fauriae* and *Roseomonas* genomospecies 6, however, are more closely related to taxa in the family *Rhodospirillaceae*. Cellular morphology (more rod-like for *R. fauriae* and *Roseomonas* genomospecies 6), CFA profile analysis, and intraspecies DNA–DNA hybridization findings also suggest a dichotomy between the species clustered around *R. gilardii* and those clustered around *R. fauriae* (Rihs et al., 1993; Weyant et al., 1996).

Differentiation of the species of the genus *Roseomonas*

Biochemical tests useful in the differentiation of *Roseomonas* species are given in Table BXII.α.29. *R. fauriae* and *Roseomonas* genomospecies 6 are the only *Roseomonas* species that contain strains which test positive for esculin hydrolysis. The ability to produce acid from L-arabinose, D-galactose, and D-xylose differentiates *R. fauriae* from *Roseomonas* genomospecies 6. Acidification of D-mannose differentiates *Roseomonas* genomospecies 4 from the other esculin-negative species. Motility and glycerol oxidation are useful in differentiating between *R. gilardii*, *R. cervicalis*, and *Roseomonas* genomospecies 5. All *Roseomonas* genomospecies 5 strains studied thus far have been negative for either citrate alkalinization or acid production from glycerol, which differentiates this species from *R. gilardii* (Rihs et al., 1993).

List of species of the genus Roseomonas

1. **Roseomonas gilardii** Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1998, 627[VP] (Effective publication: Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1993, 3282.)
gi.lar′ di.i. M.L. gen. n. *gilardii* named after Gerald L. Gilardi, who first described these organisms in 1978.

The morphological and cultural characteristics are as described for the genus. Other characteristics of this species are given in Table BXII.α.30.

This species has been associated with opportunistic infections of humans, including bacteremia. Although a few strains have been isolated from potable water, the natural reservoir of this species is unknown.

The mol% G + C of the DNA is: 67.6–71.2 (T_m).

Type strain: 5424, ATCC 49956, CIP 104026.

2. **Roseomonas cervicalis** Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1998, 627[VP] (Effective publication: Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1993, 3282.)
cer.vi.ca′ lis. M.L. adj. *cervicalis* from the cervix.

The morphological and cultural characteristics are as described for the genus. Other characteristics of this species are given in Table BXII.α.30.

This species has been associated with urogenital and eye infections of humans.

The mol% G + C of the DNA is: 70.4 (T_m).

Type strain: E7107, ATCC 49957, CIP 104027.

3. **Roseomonas fauriae** Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1998, 627[VP] (Effective publication: Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1993, 3282.)
faur′ i.a.e. M.L. n. *fauriae* named after Yvonne Faur, who first described *Roseomonas* isolates in 1978.

The morphological and cultural characteristics are as described for the genus. Other characteristics of this species are given in Table BXII.α.30.

This species has been associated with bacteremia and wound infections of humans.

The mol% G + C of the DNA is: 68 (T_m).

Type strain: C610, ATCC 49958, CIP 104028.

Other Organisms

1. *Roseomonas* genomospecies 4 Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1993, 3282.

The morphological and cultural characteristics are as described for the genus. Other characteristics of this species are given in Table BXII.α.30.

This genomospecies has been isolated from human wound, ear, and cervix specimens.

The mol% G + C of the DNA is: 67.8 (T_m).

Deposited strain: E7832, ATCC 49959.

2. *Roseomonas* genomospecies 5 Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1993, 3282.

The morphological and cultural characteristics are as described for the genus. Other characteristics of this species are given in Table BXII.α.30.

This genomospecies has been isolated from human blood, bone tissue, and breast tissue.

The mol% G + C of the DNA is: 65 (T_m).

Deposited strain: F4700, ATCC 49960.

3. *Roseomonas* genomospecies 6 Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1993, 3282.

The morphological and cultural characteristics are as described for the genus. Other characteristics of this species are given in Table BXII.α.30.

This genomospecies has been isolated from human wound material.

The mol% G + C of the DNA is: 65.4 (T_m).

Deposited strain: F4626, ATCC 49961.

Genus XIV. **Stella** *Vasilyeva 1985, 520*[VP]

LEANA V. VASILYEVA

Stel'la. M.L. fem. n. *Stella* star, to denote star-shaped morphology of cells.

Cells are flat, **six-pronged stars**, **radially symmetrical**, and 0.7–3.0 µm. Occur singly or in pairs. Some strains possess **gas vesicles**. Spores are not formed. **Gram negative**. Aerobic. Reproduction is by **symmetrical cell division**.

Chemoorganotrophic, using a variety of amino acids or organic acids. Aerobic and oxidative. **Oligocarbophilic**.

Occur in soil, freshwaters, and artificial ecosystems where complete decomposition of organic matter is underway; typical representative of the microflora of dispersal systems.

The mol% G + C of the DNA is: 69.3–73.5 (T_m).

Type species: **Stella humosa** Vasilyeva 1985, 520.

FURTHER DESCRIPTIVE INFORMATION

Flat, star-shaped bacteria were first observed by Nikitin and colleagues (Nikitin et al., 1966) and shortly thereafter by Staley (Staley, 1968). Since that time, these prosthecobacteria have been discussed in a number of publications (Vasilyeva, 1970, 1972b, 1980, 1984, 1986; Vasilyeva et al., 1974; Hirsch et al., 1977; Stanley et al., 1979; Hirsch and Schlesner, 1981; Staley et al., 1981; Terekhova et al., 1981; Schlesner, 1983; Reimer and Schlesner, 1989).

The characteristic morphology of *Stella* species is that of a flat, six-pointed star ("Star of David"). There are also intermediate forms among the flat prosthecobacteria, such as the flat triangles observed in organisms assigned to the genus *Labrys* (Vasilyeva and Semenov, 1984), and the genus *Angulomicrobium* (Vasilyeva et al., 1979).

The reproduction of star-shaped bacteria is quite similar in all strains studied. Cell division proceeds by cross-wall formation along a line where the cell has the smallest diameter and between opposite pairs of prongs. Both daughter cells retain three prongs each from the mother cell and then form three new additional prongs (Vasilyeva, 1972b). The cell cytoplasm appears to be similar to that of other Gram-negative bacteria, and so far, no obvious intracellular membrane component that might account for the prong structures that occur on the flat cells of the organism has been observed. Poly-β-hydroxybutyrate storage granules are apparent within some cells. Morphology of the star-shaped forms can vary with changes in concentration of nutrient in the broth, as well as within different strains.

The phylogenetic position of the genus *Stella* indicates that the star-shaped organism belongs to the *Alphaproteobacteria* (Fischer et al., 1985; Stackebrandt et al., 1988a, b; Stackebrandt, et al., 1988a).

Strains of the genus *Stella* are able to utilize a variety of organic acids or amino acids as substrates. The majority of strains utilize pyruvate, citrate, α-ketoglutarate, succinate, malate, acetate, and glutamate. Some strains additionally utilize lysine, glutamine, cysteine, cystine, L-alanine, asparagine, aspartate, and gluconate, and only one or a few strains utilize fumarate, butyrate, valerate, D-alanine, arginine, proline, threonine, or histidine. None of the strains utilizes propionate, benzoate, urea, ethanol, methanol, monomethylamine, leucine, isoleucine, methionine, valine, tryptophan, phenylalanine, glycine, or oxyproline. Complex carbohydrate or protein polymers, cellulose, starch, and gelatin are not catabolized. In addition to the compounds listed, star-shaped bacteria require 0.01% yeast extract or Casamino acids in the growth medium. A mixture containing 0.1% L-glutamic acid and various B vitamins can be substituted for the yeast extract. Star-shaped bacteria are obligately aerobic, and their metabolism is oxidative (Vasilyeva et al., 1974).

The strains of *Stella* were obtained from a variety of soil, aquatic, and animal fecal materials (Hirsch and Schlesner, 1981; Vasilyeva, 1985; Schlesner, 1992).

From ecological observations performed with direct microscopic techniques and enrichment broth cultures, it is apparent that these organisms are found in habitats where active degradation of organic substances is occurring. Thus, these prosthecobacteria are typical representatives of the aerobic oligotrophic microflora of dispersal (Zavarzin, 1970), now designated as dissipotrophs (Vasilyeva and Zavarzin, 1995), which are defined as an ecological group of bacteria that utilize low molecular weight compounds formed by other microorganisms during hydrolysis of particulate organic matter.

ENRICHMENT AND ISOLATION PROCEDURES

The most successful method for recovery of *Stella* species involves the use of enrichment cultures containing prosthecobacteria growing in association with aerobic cellulose-decomposing bacteria on Hutchinson medium. The unique morphology of these star-shaped bacteria is usually obvious under phase-contrast microscopy. Colonies on agar plates are usually mixed, and a long series of subculturing and reisolation of single colonies is required for selection of pure cultures.

Pure cultures of organisms can be maintained either in dilute meat-peptone media (1:5), such as nutrient broth with beef extract and peptone added and solidified with 2% (w/v) agar, or in media described by Staley (1989). This defined medium supplemented with 0.01% yeast extract can be used for determination of carbon source utilization.

MAINTENANCE PROCEDURES

Strains can be maintained on slants in the refrigerator for at least 6 months. Lyophilization can be used for long-term preservation.

DIFFERENTIATION OF THE GENUS *STELLA* FROM OTHER GENERA

The cluster of star-shaped bacteria appears to represent a clear and distinct group within the collection of budding and/or appendaged bacteria. The mode of cell division, occurring as a cross-wall separating two equal daughter cells with a profile of two three-pronged flat crowns, provides a major means to separate organisms in the genus *Stella* from other prosthecobacteria, such as *Hyphomicrobium*, *Hyphomonas*, *Pedomicrobium*, *Rhodomicrobium*, *Ancalomicrobium*, *Ancalochloris*, *Prosthecomicrobium*, and *Prosthecochloris.* The flat cellular morphology of *Stella* is shared with the genus *Labrys*, but the latter multiplies by budding. DNA–DNA homology between *Stella* species and *Labrys* is quite low.

DIFFERENTIATION OF THE SPECIES OF THE GENUS *STELLA*

The two species, *S. humosa* and *S. vacuolata*, of the genus *Stella* are differentiated by the presence or absence of gas vesicles, which correlates with a number of other characters, such as substrate utilization and a slightly different mol% G + C content

of their DNA. All vacuolate strains had DNA–DNA homologies in the range of 74–100%; however, some nonvacuolated strains had DNA–DNA homologies in the range of 60–72% while others had homologies as low as 3%, indicating that stellas are heterogeneous. Two additional species, "*S. aquatica*" and "*S. pusilla*", were described by Schlesner (Schlesner, 1983); differentiating characters, however, remain unclear.

List of species of the genus Stella

1. **Stella humosa** Vasilyeva 1985, 520[VP]
hu.mo′sa. M.L. fem. adj. *humosa* soil, earth.

Cells are flat, six-pronged stars 0.7–3.0 µm in diameter and occur singly or in pairs (Fig. BXII.α.33). No clusters or other aggregates are formed. Gram negative with typical three-layered cell envelope. Nonmotile. Multiplication by symmetrical cell division. Aerobic. Poly-β-hydroxybutyrate granules are formed as the reserve substance.

Colonies are grayish white, circular, compact, and up to 2.5 mm in diameter after incubation for 14 d at 28°C.

Chemoorganotrophic, utilizing as sole energy source a limited number of organic acids of the tricarboxylic acid cycle and amino acids for respiration. Carbohydrates are not fermented or utilized. Yeast extract is required by all strains but may be replaced by glutamic acid and B vitamins in some strains. No hydrolytic activity. Polysaccharides and proteins not degraded. Oligocarbophilic.

Optimal temperature for growth is 28–30°C. Optimal pH is neutral for the type strain and is slightly alkaline for others. Growth of some strains is stimulated by the addition of up to 1% NaCl. Catalase and oxidase positive.

Sensitive to neomycin (0.5–1.0 µg/ml); moderately sensitive to penicillin (8 µg/ml for type strain) and monomycin (2–10 µg/ml) as well as to most other antibacterial antibiotics (Terekhova et al., 1981).

Plasmids have so far not been detected.

The mol% G + C of the DNA is: 69.3–72.9 (T_m).

Type strain: AUCM B-1137, ATCC 43930, DSM 5900.

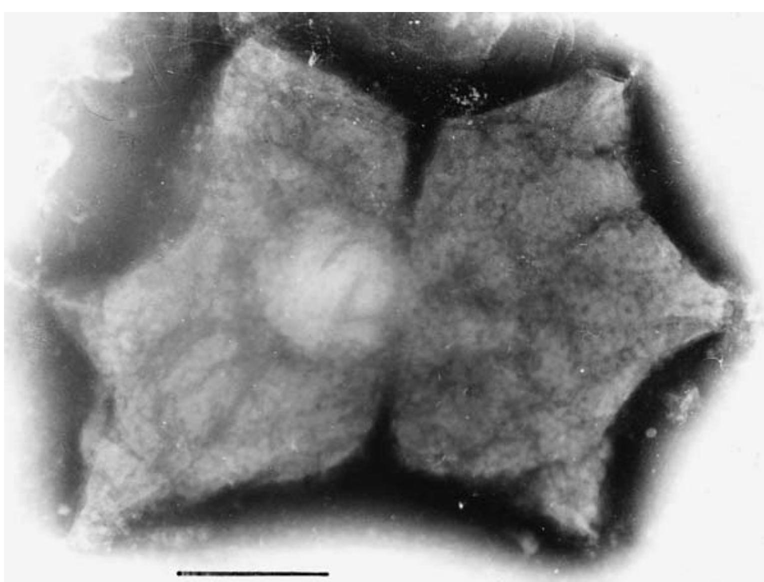
2. **Stella vacuolata** Vasilyeva 1985, 521[VP]
va′cu.o.la.ta. L. adj. *vacuus* empty, void; L. adj. *latus* broad, wide; M.L. adj. *vacuolata* large areas in cytoplasm that appear empty due to gas vesicle formation.

Cells are flat, six-pronged stars 1.9–2.5 µm in diameter. Occur singly or in pairs. Clusters or aggregates are not formed. Gram negative, nonmotile. Multiplication by symmetrical division into two initially three-pronged daughter cells. Distinctive morphological feature is the presence of gas vesicles throughout cell cytoplasm (Fig. BXII.α.34). Cells exhibit considerable buoyancy.

Colonies on agar prepared with dilute meat-peptone media (1:5) are milky white, circular and viscous and may reach 2.5 mm in diameter.

Growth in liquid broth: A pellicle is formed and sediment occurs on the bottom of tube. Growth is inhibited by shaking cultures and by 1% NaCl.

Chemoorganotrophic, aerobic. Selected amino acids and organic acids of the tricarboxylic acid cycle are utilized as energy sources. Yeast extract is required for growth, although Casamino acids or L-glutamic acid and a B vitamin mixture can substitute for yeast extract. Carbohydrates are



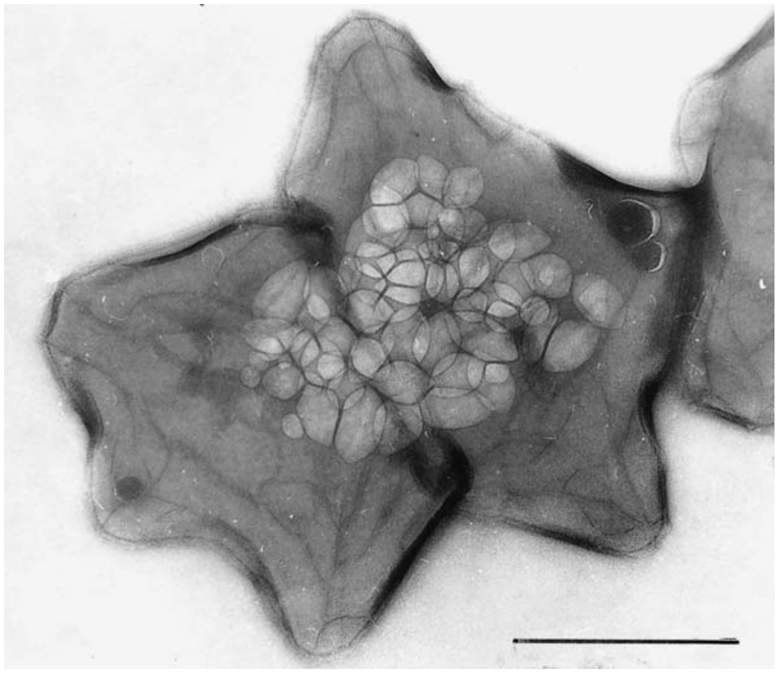


FIGURE BXII.α.33. *Stella humosa* type strain AUCMB-1137. Phosphotungstic acid-negative stain. Bar = 0.5 µm. (Reprinted with permission from E.N. Mischustin, Izvestiya Akademii Nauk SSSR. Seriya Biologicheskaya *5:* 730, 1980, ©Izdatel′stvo Nauka, Moscow, Russia.)

FIGUREBXII.α.34. *Stella vacuolata* Bright areas in cytoplasm are gas vesicles. Uranylacetate-negative stain. Bar = 1.0 μm.

not utilized but do not inhibit growth. Do not possess the ability to utilize polymers.

Optimal temperature for growth: 28°C. Optimal pH for growth: neutral or slightly alkaline. Plasmids were not detected.

Habitat: isolated from horse manure and sewage sludge from a piggery.

The mol% G + C of the DNA is: 70–73.5 (T_m).

Type strain: AUCM B-1552, ATCC 43931, DSM 5901.

Genus XV. **Zavarzinia** *Meyer, Stackebrandt and Auling 1994, 182*[VP] *(Effective publication: Meyer, Stackebrandt and Auling 1993, 393)*

THE EDITORIAL BOARD

Za.var.zi′ ni.a. M.L. n. *Zavarzinia* named for Georgi Alexandrovich Zavarzin, the Russian microbiologist who with his co-workers made the first thorough investigation of mesophilic, Gram-negative carboxidotrophic strains.

The genus description is the same as the description for *Zavarzinia compransoris.*

The mol% G + C of the DNA is: 66.1.

Type species: **Zavarzinia compransoris** (ex Nozhevnikova and Zavarzin 1974) Meyer, Stackebrandt and Auling 1994, 182 (Effective publication: Meyer, Stackebrandt and Auling 1993, 393.)

List of species of the genus Zavarzinia

1. **Zavarzinia compransoris** (ex Nozhevnikova and Zavarzin 1974) Meyer, Stackebrandt and Auling 1994, 182[VP] (Effective publication: Meyer, Stackebrandt and Auling 1993, 393.)

com.pran′ so.ris. L. *compransoris* of a dinner companion.

Gram-negative, curved rod. Motile by means of a polar flagellum, 6–8.5 μm in length. Colonies are thin and translucent. Cells swarm on wet agar surfaces. Catalase positive. Thiamine required for growth. *"Pseudomonas gazotropha"* provides thiamine in mixed cultures. Utilizes organic acids (except citrate) and amino acids as sole carbon and energy sources. No growth on sugars. Under aerobic conditions, utilizes ammonia, nitrate, nitrite, hydroxylamine, and urea as nitrogen sources. Heterotrophic denitrification occurs with pyruvate as the electron donor and forming N_2O. Chemolithoautotrophic growth with CO, with a doubling time of 18 h, and incorporation of 4% of the CO oxidized into cell carbon. Possesses cytochromes *a*, *b*, and *c*, but not b_{563}.

The mol% G + C of the DNA is: 66.1.

Type strain: ATCC 51430, DSM 1231, LMG 5821, LMG 8357, Z-1155.

Order II. **Rickettsiales** Gieszczykiewicz 1939, 25^AL emend. Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2156

J. STEPHEN DUMLER AND DAVID H. WALKER

Rick.ett.si.a′ les. M.L. fem. n. *Rickettsia* type genus of the order; *-ales* ending to denote order; M.L. fem. pl. n. *Rickettsiales* the *Rickettsia* order

Rod-shaped, coccoid or irregularly shaped bacteria with typical Gram-negative cell walls and no flagella. Multiply only inside host cells. Can be cultivated in living tissues such as those of embryonated chicken eggs and metazoan cell cultures. All are regarded as parasitic or mutualistic. The bacteria are parasitic forms associated with host cells of the mononuclear phagocyte system, the hematopoietic system, or the vascular endothelium of vertebrates; with various organs and tissues of helminths; or with tissues of arthropods, which may act as vectors or primary hosts. May cause disease in man or in other vertebrate or invertebrate hosts. Mutualistic forms in insects and helminths may be required for development and reproduction of the host under some circumstances.

The mol% G + C of the DNA is: 28–56.

Type genus: **Rickettsia** da Rocha-Lima 1916, 567.

TAXONOMIC COMMENTS

In the ninth edition of *Bergey's Manual of Determinative Bacteriology*, Section 9, the order *Rickettsiales* was divided into three families, *Rickettsiaceae*, *Bartonellaceae*, and *Anaplasmataceae*. The recent removal of the family *Bartonellaceae* as well as some genera and species in the family *Anaplasmataceae* from the order also removes all species that could be propagated extracellularly—either on artificial media or on the surface of host cells. In addition, modern molecular classification methods and the recognition of shared biological and morphological features have allowed a reclassification of some *Rickettsiaceae* genera and species into the family *Anaplasmataceae*. These methods have also allowed the removal of some genera and species from *Rickettsiaceae* and *Anaplasmataceae* as well as the removal of the tribe structure of the family *Rickettsiaceae*. Currently, the order contains only the families *Rickettsiaceae* and *Anaplasmataceae*.

Family I. **Rickettsiaceae** Pinkerton 1936, 186^AL emend. Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2156

XUE-JIE YU AND DAVID H. WALKER

Rick.ett.si.a′ ce.ae. M.L. fem. n. *Rickettsia* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Rickettsiaceae* the *Rickettsia* family.

Mainly **diplococcus-shaped, but can also be rod shaped or coccoid**. Gram negative. **Obligately intracellular. Intimately associated with arthropod hosts.** No flagella or endospores occur. No member of the family has yet been cultivated in cell-free media. Some species can be parasitic in man and other vertebrates, causing diseases (e.g., typhus and related illnesses in man) that are transmitted by arthropods (lice, fleas, ticks and mites). Some are confined to the invertebrate host as pathogens or symbionts.

The mol% G + C of the DNA is: 29–33.

Type genus: **Rickettsia** da Rocha-Lima 1916, 567.

TAXONOMIC COMMENTS

Historically, the designation "rickettsia" has been used indiscriminately for many small rods that could not be cultivated and were not otherwise identified. Most frequently, but not always, these organisms were seen in association with arthropods. The last edition of the *Manual of Systematic Bacteriology* (1st edition, 1984) reflects the considerable progress that has been made in establishing a more precise definition of the family *Rickettsiaceae* and in eliminating species that do not fit the definition. The process continues with this edition. In the last edition, the family *Rickettsiaceae* included three tribes: *Rickettsieae*, *Ehrlichieae*, and *Wolbachieae*. In this edition, the tribes are eliminated. The tribe *Rickettsieae* contained three genera: *Rickettsia*, *Rochalimaea*, and *Coxiella*. The genus *Rickettsia* is retained in the family *Rickettsiaceae*. Neither *Rochalimaea* nor *Coxiella* are genotypically related to *Rickettsia* except for a superficial phenotypic similarity between *Rickettsia* and *Coxiella*. *Rochalimaea* has been combined with *Bartonella* and removed from the family *Rickettsiaceae* (Brenner et al., 1993). *Coxiella* has been removed from the family *Rickettsiaceae* and placed in the order *"Legionellales"*. Organisms in tribes *Ehrlichieae* and *Wolbachieae* have been removed from the family *Rickettsiaceae* and combined into the family *Anaplasmataceae*. *Rickettsia tsutsugamushi* was placed in a new genus *Orientia* as *Orientia tsutsugamushi* (Tamura et al., 1995). At present the family *Rickettsiaceae* consists of two genera: *Rickettsia* and *Orientia*. All organisms in the family are phylogenetically related (Fig. BXII.α.35).

Genus I. **Rickettsia** *da Rocha-Lima 1916, 567^AL*

XUE-JIE YU AND DAVID H. WALKER

Rick.ett′ si.a. M.L. fem. n. *Rickettsia* named after Howard Taylor Ricketts, who first associated organisms of this description with spotted fever and typhus and who died of typhus contracted in the course of his studies.

Short, often paired rods, 0.3–0.5 × 0.8–2.0 µm. The rickettsial envelope has a typical Gram-negative structure with a bilayer inner membrane, a peptidoglycan layer, and a bilayer outer membrane. The cells are often surrounded by a protein microcapsular layer and slime layer. Rickettsiae retain basic fuchsin when stained by the method of Giménez (1964). The organisms are

FIGURE BXII.α.35. The length of each pair of branches represents the distance between sequence pairs. The numbers on the branch indicate the bootstrap values.

obligately intracellular and reside free in the cytoplasm of the eucaryotic host cell, where they divide by **binary fission**. Rickettsiae of the spotted fever group (SFG) may also reside in the nucleus of the eucaryotic host cells. **Rickettsiae are closely associated with arthropods** (ticks, mites, fleas, lice, and other insects) **for their maintenance in nature**. Their natural cycle usually involves both a vertebrate and an invertebrate host. For some, the arthropod host is both a reservoir and a vector. **Transovarian transmission** of the agent from the infected female to the next generation is the essential mechanism for the maintenance of many species (Burgdorfer, 1988). Rickettsial cells are usually unstable when separated from host components, except for highly stable forms found in the feces of arthropod hosts; stability can be enhanced by certain proteins, sucrose, and reagents that tend to maintain the integrity of outer membranes, osmolarity, and ATP level. Rickettsiae are best preserved by rapid freezing and storage below −50°C. The cells are rapidly inactivated at 56°C. Rickettsiae derive energy from the metabolism of glutamate via the citric acid cycle, but do not utilize glucose. They transport and metabolize phosphorylated compounds but do not synthesize or degrade nucleoside monophosphates. **Rickettsiae are etiological agents of typhus and spotted fevers in humans.** There are 21 recognized species.

The mol% G + C of the DNA is: 29–33.

Type species: **Rickettsia prowazekii** da Rocha-Lima 1916, 567 (Nom. Cons. Opin. 19, Jud. Comm. 1958, 158.)

FURTHER DESCRIPTIVE INFORMATION

Phylogeny In the 1st edition of *Bergey's Manual of Systematic Bacteriology*, the organisms in the genus *Rickettsia* were divided into the typhus group (TG) and the spotted fever group (SFG). *R. prowazekii*, *R. typhi*, and *R. canadensis* were included in the TG; these species stimulate antibodies that react more strongly with *Proteus vulgaris* OX19 antigen than OX2 antigen and share LPS antigens. The other rickettsiae were included in the SFG; they stimulate antibodies that react more strongly with antibody specific for *Proteus vulgaris* OX2 antigen and share their own LPS antigens.

In the present edition, *Rickettsia* species are divided into three groups based on phylogeny (Fig. BXII.α.35), as follows. The TG includes *R. prowazekii* and *R. typhi*. The SFG includes *R. aeschlimannii*, *R. africae*, *R. akari*, *R. australis*, *R. conorii*, *R. felis*, *R. helvetica*, *R. honei*, *R. japonica*, *R. massiliae*, *R. montanensis*, *R. parkeri*, *R. peacockii*, *R. rhipicephali*, *R. rickettsii*, *R. sibirica*, and *R. slovaca* (Bouyer et al., 2001). The third group, the ancestral group, includes *R. bellii*, *R. canadensis*, and the AB male-killing bacterium;

this group represents early divergent lineages within the genus (Stothard et al., 1994).

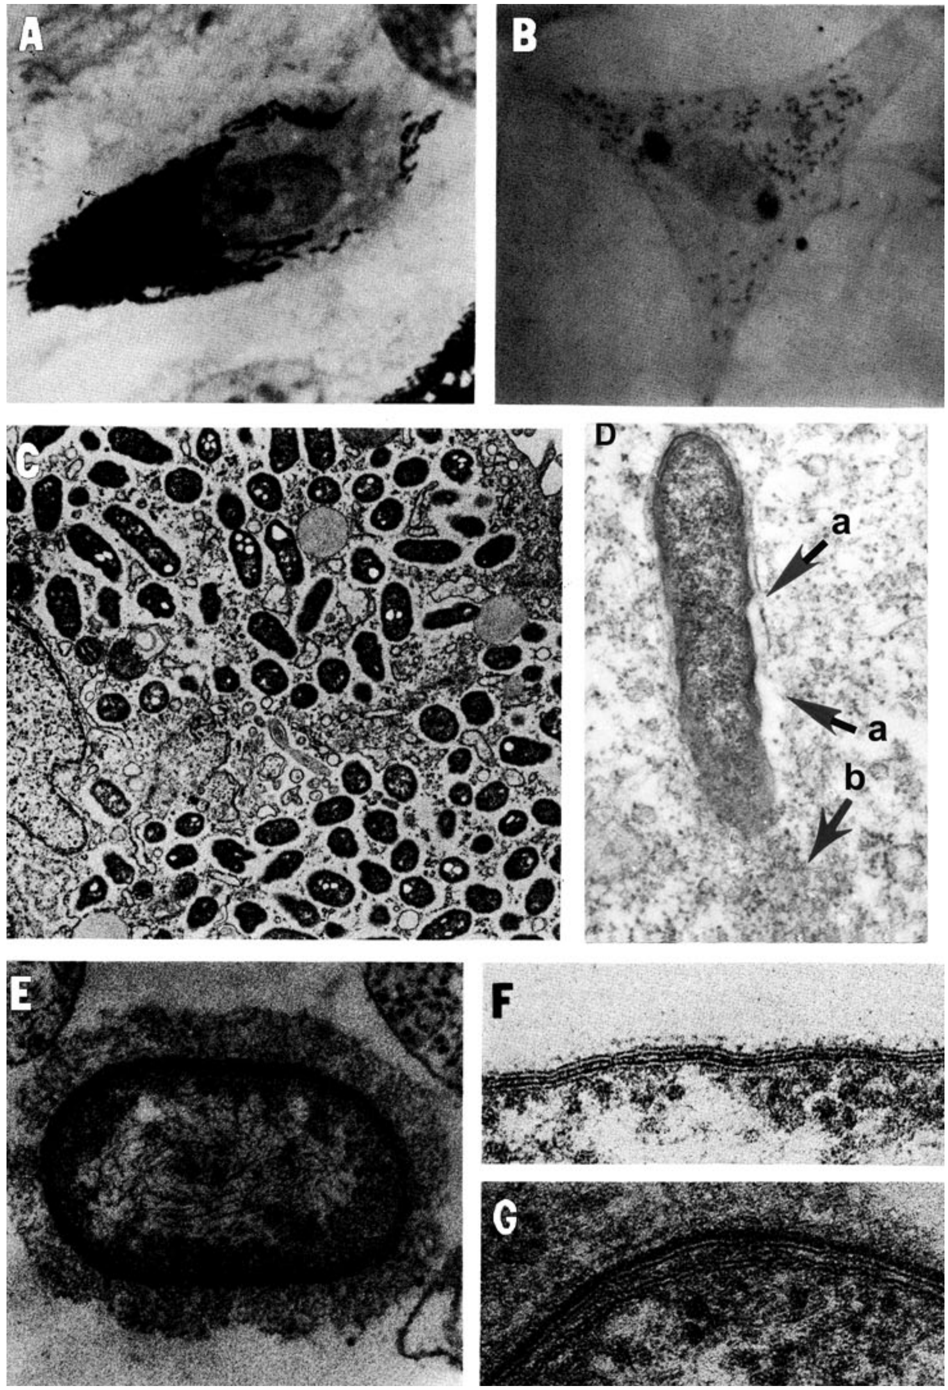
The numbers of named SFG species have increased markedly since the last edition owing to the improvement of isolation approaches and molecular methods for identification. However, there is no consensus concerning the criteria used to define a species of *Rickettsia*. The 16S rRNA gene sequences show 97.2–99.9% similarity among the SFG rickettsiae. The 16S rRNA gene sequences are ≥99.7% similar among the following *Rickettsia* species: *R. africae*, *R. conorii*, *R. massiliae*, *R. parkeri*, *R. sibirica*, *R. slovaca*, and *R. rickettsii*. Thus, many designated species of SFG rickettsiae actually might be clones or strains of a single species according to the standards used for classifying other bacteria. In this chapter, we have compiled information about all *Rickettsia* species that were either included in the Approved Lists of Bacterial Names validly published after January 1980 regardless of where they stand in phylogeny. Rickettsiae need to be classified in the future by an authorized committee according to defined criteria.

Cell structure Although rickettsiae are relatively small bacteria, they closely resemble other Gram-negative bacteria. In smears from yolk sac, tissue, or cell culture, rickettsiae are best visualized by the Giménez (1964) stain. By this procedure, rickettsiae stain bright red with basic fuchsin, while the background is decolorized and stains a pale greenish blue with the malachite green counterstain (Fig. BXII.α.36A and B).

The rickettsial cell wall contains peptidoglycan, which consists of glutamic acid, alanine, and diaminopimelic acid in a molar ratio of 1.0:2.3:1.0. The small amount of lysine found in the peptidoglycan preparation suggests that a peptidoglycan-linked lipoprotein(s) might be present (Pang and Winkler, 1994).

In ultrathin sections viewed by electron microscopy, rickettsiae are surrounded by a typical Gram-negative envelope (Fig. BXII.α.36E–G). The rickettsial cytoplasm contains ribosomes and strands of DNA. Organisms of the genus *Rickettsia* are typically surrounded in the host cell by an electron-lucent zone that has been proposed to represent a slime layer, which is stabilized by the presence of antibodies (Fig. BXII.α.36E). During the course of infection, rickettsial morphology can change: older cells can become smaller and more electron dense. In *R. prowazekii*, cells may stop dividing after prolonged cultivation and become 3–4 μm long. They also may contain translucent vacuole-like structures, which in some cases appear to occupy as much as 25% of the cytoplasm (Wisseman and Waddell, 1975; Silverman et al., 1980). Intracytoplasmic crystalline structures may also be formed, presumably by a DNA-binding protein homologous to the Dps protein of *E. coli* (Frenkiel-Krispin and Minsky, 2002; personal communication, Dr. Vsevolod Popov). SFG rickettsiae usually do not form vacuoles and crystalline structures.

Cultivation Rickettsiae must be cultivated in tissue culture or yolk sac of developing chicken embryos (Cox, 1941). L929 and Vero cells are used most frequently, but a great variety of other cells has been used, including chicken embryo fibroblasts, golden hamster BHK-21 cells, HEL cells, monocytes and polymorphonuclear leukocytes.



In irradiated chicken embryo cells at 34°C, *R. prowazekii* multiplies with a generation time of about 9 h until a very high rickettsial density is reached (Fig. BXII.α.36C). If the inoculum is derived from rickettsiae harvested past their logarithmic growth phase, exponential growth is preceded by a lag phase. The nucleus is not invaded. The rickettsiae are released by the disruption of massively infected cells (Wisseman and Waddell, 1975). Growth in other cell types is qualitatively comparable.

Plaques have been produced on a variety of cell monolayers by procedures similar to, but somewhat more difficult than, those used in virology, since monolayers must be maintained for 5–11 days and the introduction of antibiotics must be carefully avoided (Wike and Burgdorfer, 1972). Plaques appear early and are usually larger for most SFG rickettsiae than with TG rickettsiae. SFG rickettsiae form plaques after 5–8 days with a diameter of 2–3 mm. TG rickettsiae form smaller plaques (1 mm) between 8–10 days. TG rickettsiae produce visible plaques on primary chick embryo fibroblasts and on low-passage mouse embryo fibroblasts but do not form reproducible plaques on continuous cell culture lines. TG rickettsiae may produce visible plaques on continuous cell lines if modified procedures are used. One procedure involves a primary overlay with a medium at pH 6.8, which is followed 2–3 days later with a secondary overlay at neutral pH that contains 1 μg of emetine per ml and 20 μg of NaF per ml. Another procedure involves overlay with a medium containing 50 ng of dextran sulfate per ml (Policastro et al., 1996).

Nutrition and metabolism The nutritional requirements of the rickettsiae, as distinct from those of their host cells, are not known. Rickettsiae grow in heavily irradiated cells (Weiss and Dressler, 1958) that have lost the ability to divide, and they grow in the presence of a low level of cycloheximide that inhibits host protein synthesis. Under these conditions, rickettsiae incorporate exogenous amino acids and adenine, but not thymidine (Weiss et al., 1972). Thus, rickettsial growth occurs independently of host cell protein synthesis, host cell division, and DNA or RNA synthesis. Rickettsiae require a CO_2-enriched atmosphere to grow in chicken embryo cells when an organic buffer is substituted for sodium bicarbonate.

Evolutionarily, rickettsiae are thought to be derived from a free-living bacterial ancestor by the following sequence of events. A free-living aerobic bacterium entered and established an intracellular parasitic relationship with the pre-eucaryote (i.e., an ancestral eucaryote lacking organelles). This made it possible for many chemical substrates to be readily obtained by the bacterium from the host and used without further metabolic modification by the bacterium. The genes of the bacterium involved in metabolic pathways such as glycolysis, fermentation and biosynthesis of small molecules were then redundant with the host cell genes. These redundant genes then had the freedom to mutate, and the mutations might result either in genes with new functions or in pseudogenes. Pseudogenes eventually would be deleted from the genome to make the bacterium more efficient in its use of energy. Gene reduction eventually resulted in a small genome in intracellular bacteria. The loss of genes essential to a free-living mode made the bacterium further dependent on the host cell to supply the substrates, and eventually it lost its ability to live outside the host cell.

Much evidence can be adduced for the above scheme. For instance, no genes required for *de novo* synthesis of nucleotides have been found in the genome of *R. prowazekii*. However, the *R. prowazekii* genome encodes all of the enzymes required for the interconversion of nucleoside monophosphates into all of the other required nucleotides (Andersson et al., 1998). Thus, rickettsiae depend on the monophosphate compounds of the host cell for their nutrition, but they can also utilize their di- and triphosphates. AMP is neither synthesized nor degraded, a situation that seems to be true of the other nucleoside monophosphates as well (Williams and Peterson, 1976). Rickettsiae possibly acquire most amino acids from host cells directly, because only the genes associated with biosynthesis of lysine and serine are found in the genome of *R. prowazekii*. *R. prowazekii*

FIGUREBXII.α.36. Interaction with host cells and fine structure of rickettsiae. (*A* and *B*) Giménez stained preparations. (*C-G*) Transmission electron micrographs of ultrathin sections stained with uranyl acetate and lead citrate. *A*, Human F-1000 fibroblast infected with the Breinl strain of *Rickettsia prowazekii.* A large mass of rickettsiae comprises the entire left portion of the cell with some perinuclear organisms evident. No nuclear involvement is apparent (× 1200). *B*, Secondary chicken embryo fibroblast infected with the Sheila Smith strain of *Rickettsia rickettsii.* Note the sparse, diffusely distributed cytoplasmic organisms and the two distinct compact masses of the organisms within the nuclear region (× 1200). *C*, *R. prowazekii*-infected secondary chicken embryo fibroblast late in infection, showing large numbers of free cytoplasmic rickettsiae without vacuolar membrane, most of which contain vacuole-like structures characteristic of typhus organisms in the stationary phase of growth (× 13,600). *D R. rickettsii* (Sheila Smith strain) in a human endothelial cell (HUVEC) 15 minutes after infection is in the process of escaping from the phagosome. Breaks in the phagosomal membrane (a), and formation of an F-actin tail (b) are apparent (× 31,350). *E*, *R. prowazekii* (Breinl strain) released from an infected host cell and treated with specific human immune serum to demonstrate the slime layer on the surface of the organism (× 67,000). *F*, Cell envelope of *R. prowazekii* including microcapsular layer. The envelope of *R. rickettsii* is morphologically similar (× 196,000). *G*, Cell envelope of *Orientia tsutsugamushi.* Note the thickened outer leaflet of the envelope compared with that of *R. prowazekii* (*above*) (× 171,000). requires host cell proline. Maximal rickettsial growth occurs only in host cells with an intracellular proline pool of 1.0 mM or greater (Austin and Winkler, 1988a). *R. prowazekii* also requires host cell serine or glycine for growth (Austin et al., 1987). Interconversion of serine and glycine is catalyzed by a rickettsial serine hydroxymethyltransferase. Rickettsiae have a membrane-bound ATP/ADP translocase that mediates exchange of ATP and ADP. Rickettsiae exchange extracellular ATP for intracellular ADP without a change in the total adenylate pool. The concentration of phosphate acts as a regulatory signal for the rate of ADP-ATP exchange. The influx of ATP is greatly favored over ADP under conditions of low phosphate in the host cell cytoplasm. Upon transport into the cell, ATP is hydrolyzed by ATPase to generate a membrane potential in the absence of electron transport. Unlike *Chlamydia* cells, which depend totally on the host cell for energy, rickettsiae also synthesize their own ATP (see below). Thus, we do not know to what extent rickettsiae depend on the host cell for ATP. The fact that both *R. prowazekii* and *R. conorii* have five copies of an ATP/ADP translocase gene indicates that a large amount of ATP may be required by rickettsiae from

host cells. The general notion is that rickettsiae acquire host cell ATP early in the infectious cycle via the ATP/ADP translocase and that rickettsiae may synthesize their own ATP to compensate for the depletion of cytosolic ATP late in the infection. The ATP/ADP translocase gene was possibly acquired from the host cell, because it is found only in rickettsiae and chlamydiae (Wolf et al., 1999)

Genes encoding all enzymes of the tricarboxylic acid (TCA) cycle are present in *R. prowazekii.* The primary source of energy is oxidation of glutamate (Bovarnick and Snyder, 1949). Glutamine and pyruvate are also utilized, but to a lesser extent (Weiss, 1973). Glutamine is converted to glutamate by a deamidase. The amino group of the glutamate is transferred to oxaloacetate with the formation of aspartate and α-ketoglutarate by a reversible glutamate-oxaloacetate transaminase. In addition, glutamate is also converted to NH_3 and α-ketoglutarate by a NAD(P)-dependent glutamate dehydrogenase (Weiss, 1973). Glutamate oxidation drives electron transport coupled to oxidative phosphorylation as well as active transport of at least two amino acids, lysine and proline. In *R. prowazekii* the incorporation of P_i into ATP accompanying glutamate oxidation is catalyzed by a membrane-bound ATPase and is sensitive to dicyclohexylcarbodiimide, cyanide, arsenite, and 2,4-dinitrophenol.

Glucose and glucose-6-phosphate are not utilized by rickettsiae. *R. prowazekii* transports uridine 5'-diphosphoglucose (UDPG) but not glucose. *R. prowazekii* takes up glucose phosphates to a much lesser extent than UDPG. *R. prowazekii* does not have hexokinase and phosphoglucomutase, enzymes required for the metabolism of glucose and glucose-6-phosphate (Winkler and Daugherty, 1986). The inability to use glucose as a substrate indicates that rickettsiae may use UDPG as precursors for synthesis of the slime layer, peptidoglycan, and LPS. Rickettsiae must also obtain glycolytic intermediates and products such as acetyl coenzyme A, which are required in the citrate synthase reaction of the TCA cycle. The genes encoding three components (E1–E3) of the pyruvate dehydrogenase complex are found in *R. prowazekii*, indicating that this organism may utilize cytosolic pyruvate. Rickettsiae may use host cell pyruvate by the same mechanism as mitochondria. Pyruvate is imported into mitochondria directly from the cytoplasm, and subsequent conversion into acetyl coenzyme A and CO_2 is catalyzed by pyruvate dehydrogenase. In *R. prowazekii*, pyruvate dehydrogenase activity is dependent on coenzyme A, NAD, and thiamine pyrophosphate and is inhibited by NADH, but not adenylates.

Antigenic structure The major antigens of *Rickettsia* are lipopolysaccharide, lipoprotein, outer membrane proteins, and heat shock proteins. The Weil-Felix reaction has been used as a presumptive diagnostic test for rickettsial diseases. It is based on the cross-reaction of antibodies to rickettsial antigens from primary rickettsial infections with the somatic antigens of three strains: *Proteus vulgaris* strains OX19 and OX2, and *Proteus mirabilis* strain OXK. The rickettsial antigens do not elicit an anamnestic antibody response to these *Proteus* antigens in recrudescent typhus. The antibodies of Japanese spotted fever patients are reactive with the LPS of OX2 as well as OX19. Thus, the cross-reactive antigens between *Rickettsia* and *Proteus* are most likely present in the LPS. The O-polysaccharides of the LPS of typhus rickettsiae are composed of glucose, glucosamine, quinovosamine, and phosphorylated hexosamine, which are also found in the O-polysaccharide of the LPS from *P. vulgaris* OX19 used in the Weil-Felix test. These findings suggest that these O-polysaccharides may represent the antigens common to LPSs from TG rickettsiae and *P. vulgaris* OX19 (Amano et al., 1998). The antibodies of scrub typhus patients recognize the antigens of OXK only (Amano et al., 1996).

A 17-kDa protein is a genus-common protein of rickettsiae that has been identified in all *Rickettsia* species examined (Anderson, 1990). The sequences of the gene encoding the 17-kDa protein gene are conserved among rickettsial species, indicating the importance of it to the survival of the rickettsiae. The protein is predicted to be a lipoprotein, and part of the protein is surface exposed. Thus, it has been speculated that the 17-kDa protein may play a scaffolding and protective role in the rickettsiae (Anderson, 1990).

All rickettsiae have a 135-kDa outer membrane protein B (OmpB) that has been identified as an S-layer protein of rickettsiae (Ching et al., 1990). OmpB is the most abundant rickettsial surface protein, and it contains species-, group- and genus-specific epitopes (Anacker et al., 1987).

SFG rickettsiae have an additional outer membrane protein, OmpA. *R. felis* and *R. peacockii* have an OmpA that is truncated by the presence of premature stop codons. OmpA contains a hydrophilic region of tandem repeat units, which consists of over 40% of the amino acid sequences (Anderson et al., 1990). The repeat units are not identical and thus are divided into three types, with type I composed of 75 amino acids, type II of 72 amino acids, and type III of 85 amino acids. The type II repeats are less conserved and are further divided into two subtypes (IIa and IIb) (Anderson et al., 1990). The *ompA* sequences up-stream and down-stream of the repeat region are conserved among SFG rickettsial species. Although the sequences of the repeats are conserved among *R. rickettsii*, *R. conorii* and *R. akari*, the number and the order of arrangement of repeat units vary among SFG rickettsiae (Gilmore, 1993). However, the third type of repeat unit found in *R. australis* differs greatly from other SFG rickettsial repeat units. *R. australis* has only type III repeat units, which have only 21% identity to the type I repeat of *R. rickettsii* (Stenos and Walker, 2000). The antigenic diversity of SFG rickettsiae is determined in large part by the number, order, and type of repeat units.

Both OmpA and OmpB have been demonstrated to stimulate protective immunity against rickettsial challenge of vaccinated animals (Sumner et al., 1995; Dasch et al., 1999).

A striking feature of rickettsiae is that all the identified rickettsial outer membrane proteins belong to the autotransporter family. These proteins include OmpA, OmpB, and four ORFs encoding the hypothetical proteins Sca1 (Accession RP018), Sca2 (RP081), Sca3 (RP451), and Sca5 (RP704) (Andersson et al., 1998). Unlike other transport systems, autotransporter proteins are transported across the cytoplasmic or inner membrane and the outer membrane without the assistance of accessory proteins. An autotransporter protein consists of three functional domains: the amino-terminal leader sequence, the secreted mature (α) protein and a carboxy-terminal (β) domain. The signal peptide inserts itself into the inner membrane, directing the export of the precursor molecule by action of the general secretion pathway into the periplasm. The precursor is cleaved by the signal peptidase to release the mature polypeptide into the periplasm. Once in the periplasm, the β-domain of the protein is inserted into the outer membrane to form a β-barrel pore, and the passenger domain is translocated to the cell surface through the pore. The precursor of OmpB is a 168 kDa-protein that is post-translationally processed to the 135-kDa mature OmpB by cleavage of a 32-kDa β-peptide (Hackstadt et al., 1992).

The amino acid sequences of the β-peptides of all five rickettsial autotransporters are highly homologous and share ho-

mology with autotransporters from distantly related bacteria (Henderson et al., 1998). The diversity among the passenger domains that are coupled with the conserved β-domain suggests that the autotransporters are either derived originally from a single gene or resulted from recombination of unrelated proteins with the β-domains (Henderson et al., 1998). Sca 1 and Sca 2 consist of only the β-domain without the passenger peptide. Thus, Sca 1 and Sca 2 may be involved in the transport of other rickettsial proteins. Most of the autotransporter proteins are adhesins or proteases of bacteria, indicating that OmpA, OmpB, Sca3, and Sca5 might be important rickettsial virulence factors.

Drug and antibiotic susceptibility Rickettsiae are naturally resistant to most classes of antimicrobial agents. Contemporary methods determine rickettsial susceptibility to antimicrobial drugs in cell culture. Even the most effective antimicrobial activities against *Rickettsia* are bacteriostatic rather than bactericidal. The antimicrobial drugs that are most effective, i.e., that have the lowest minimal inhibitory concentrations, belong to the following classes: tetracyclines, chloramphenicol, rifampin, fluoroquinolones (pefloxacin, ofloxacin, ciprofloxacin) and some, but not all, macrolides (josamycin, azithromycin, clarithromycin). Doxycycline is the drug of choice in most clinical settings, except for patients who are pregnant or hypersensitive to tetracyclines (Raoult et al., 1990; Walker and Sexton, 1999). There has been long empiric experience with the use of chloramphenicol for the successful treatment of rickettsioses, but the outcome is less satisfactory for Rocky Mountain spotted fever than treatment with doxycycline (Holman et al., 2001). Josamycin has been shown to be an effective treatment of boutonneuse fever during pregnancy. Ciprofloxacin, ofloxacin, pefloxacin, clarithromycin, and azithromycin have been reported to ameliorate the course of boutonneuse fever (Bella et al., 1990; Cascio et al., 2001). The results of treatment with rifampin have been less conclusive, and *R. massiliae*, *R. aeschlimannii*, *R. montanensis*, and *R. rhipicephali* are relatively resistant to rifampin. *Rickettsia prowazekii* is susceptible to erythromycin *in vitro*; however, rapid selection of antimicrobial resistant mutants occurs. *Rickettsia* species are resistant to aminoglycosides and to penicillin and other β-lactam antimicrobial agents.

Sulfonamides are not only ineffective, they actually exacerbate rickettsial infections. In contrast, an analog of sulfonamide, *p*-aminobenzoic acid, is rickettsiostatic and was used successfully to treat Rocky Mountain spotted fever in the 1940s prior to the availability of broad spectrum antibiotics.

Pathogenicity A number of *Rickettsia* species cause severe disease in humans. Before the advent of the broad-spectrum antibiotics, epidemic typhus and Rocky Mountain spotted fever—caused by *R. prowazekii* and *R. rickettsii*, respectively—had a very high case fatality rate. Epidemic typhus has changed the course of history on many occasions (Zinsser, 1935). Rocky Mountain spotted fever and epidemic typhus have exacted a heavy toll on their early investigators.

Other named rickettsiae and their diseases include *R. typhi* (murine typhus), *R. conorii* (boutonneuse fever, Mediterranean spotted fever, Astrakhan fever, Israeli spotted fever), *R. sibirica* (North Asian tick typhus), *R. australis* (Queensland tick typhus), *R. akari* (rickettsialpox), *R. japonica* (Japanese spotted fever), *R. africae* (African tick bite fever), *R. honei* (Flinders Island spotted fever), and *R. felis* (flea-borne spotted fever).

Rickettsiae are inoculated into the skin in the saliva during feeding by an infected tick, mite, or flea or by scratching of rickettsia-laden feces deposited by an infected louse or flea. Rickettsiae are distributed throughout the body via the bloodstream where they enter their principal target, endothelial cells.

In the interaction of rickettsiae with host cells, the entry process involves three steps: attachment, internalization and escape from the phagosome. Rickettsiae adhere to the host cell by means of a rickettsial adhesin and a host cell receptor. Experimental evidence indicates that a ligand and receptor interaction mediate rickettsial attachment. Adsorption of *R. prowazekii* to L-cells and human endothelial cells can be saturated and is dependent on time and multiplicity of infection (Walker and Winkler, 1978; Walker, 1984). Pure *R. prowazekii* is more efficient than a crude suspension in entry into chicken embryo cells (Wisseman et al., 1976). The difference is due to competition between rickettsial receptors on host cell membrane fragments and on intact host cells. The receptors on host cells have yet to be identified, although experimental evidence suggests the host receptor for rickettsiae contains cholesterol as a binding moiety. *R. prowazekii* binds to the cholesterol-containing fraction of chloroform-methanol extracts of erythrocyte membranes (Ramm and Winkler, 1976). Digitonin and amphotericin B, which bind to cholesterol, inhibit the adsorption of *R. prowazekii* to erythrocyte ghosts and reduce plaque formation by *R. rickettsii* in chicken embryo cell monolayers (Walker et al., 1983). However, there is no effect of these agents on the interaction of *R. prowazekii* and L929 cells (Austin and Winkler, 1988b).

OmpA has been implicated as an adhesin of *R. rickettsii* because monoclonal antibodies to OmpA block *R. rickettsii* attachment (Li and Walker, 1998). There is evidence that both OmpA and OmpB are adhesins of *R. japonica* (Uchiyama, 1999).

Rickettsiae enter the host cell via induced phagocytosis that requires undefined rickettsial activity and host cell cytoskeletal rearrangements. Adsorption and internalization require metabolically competent rickettsiae and active participation of the host cell. Inactivation of *R. prowazekii* results in decreased adsorption to L929 cells and endothelial cells (Walker, 1984). *R. prowazekii* adheres to, but is unable to enter, cells treated with a cytoskeletal actin polymerization inhibitor such as cytochalasin B (Walker and Winkler, 1978). Owing to rickettsial infection of nonphagocytic cells, the internalization process is usually called invasion.

Once phagocytosed by the host cell, rickettsiae rapidly escape from the phagosome prior to its fusion with a lysosome (Fig. BXII.α.36D). A rickettsial enzyme is hypothesized to lyse the phagosome membrane to release rickettsiae. The enzyme is most likely a phospholipase because the incubation of *R. prowazekii* with erythrocytes results in hemolysis and formation of free fatty acids and lysophosphatides (Winkler and Miller, 1981; Walker et al., 2001). The phospholipase is of rickettsial origin rather than host cell origin (Winkler, 1990). The nature of the rickettsial phospholipase has not been determined directly. Although phospholipase A2 (PLA2) has been suggested as the rickettsial enzyme that lyses the phagosomal membrane, rickettsial genome sequencing has not revealed a gene encoding a PLA2. A rickettsial protein (Accession RP534) has a calcium-independent PLA2 motif (Yu et al., 2000b), which is homologous to the gene for a cytotoxin (ExoU) of *Pseudomonas aeruginosa* (Vallis et al., 1999). Within the cytosol, rickettsiae acquire nutrients, ATP, amino acids, and nucleic acid precursors from the host by active transport mechanisms and replicate slowly (Winkler, 1990).

SFG rickettsiae stimulate actin-based mobility, resulting in intercellular spread. TG rickettsiae accumulate to massive quantities intracellularly until the cell bursts, releasing the rickettsiae. Observations in cell culture systems suggest that the mechanisms

of intracellular movement and destruction of the host cell differ among SFG and TG rickettsiae (Silverman and Wisseman, 1979; Silverman et al., 1980). TG rickettsiae are released from host cells by lysis of the cells. After infection with *R. prowazekii* or *R. typhi*, the rickettsiae continue to multiply until the cell is packed with organisms and then bursts. Cell death possibly results from apoptosis or from membranolytic activity that previously has been hypothesized to be phospholipase A2 (Winkler and Miller, 1982; Walker et al., 1984; Winkler and Daugherty, 1989; Silverman et al., 1992; Manor et al., 1994; Winkler et al., 1994; Ojcius et al., 1995). Before lysis, TG rickettsia-infected host cells have a normal ultrastructural appearance. SFG rickettsiae seldom accumulate in large numbers and do not burst the host cells. They escape from the cell by stimulating polymerization of host cell-derived F-actin tails (Fig. BXII.α.37), which propel them through the cytoplasm and into filopodia, from the tip of which they emerge (Schaechter et al., 1957; Teysseire et al., 1992; Heinzen et al., 1993, 1999). The rickettsial protein responsible for the actin-based movement of SFG rickettsiae has yet to be identified. The genome sequence of *R. conorii* has not revealed a rickettsial protein homologous to ActA or Ics, the proteins responsible for actin polymerization by *Listeria monocytogenes* and *Shigella flexneri*, respectively; however, a hypothetical protein of 520 residues (RC0909) exhibits an overall organization similar to that of ActA. Both proteins are highly charged at the N-terminus and have a central proline-rich region. RC0909 has a weak similarity to the WASP (Wiskott-Aldrich Syndrome Protein) homology domain 2, which regulates the formation of the actin filaments (Ogata et al., 2001).

Rickettsia rickettsii stimulates the production of reactive oxygen species by infected endothelial cells, resulting in oxidative stress and lipid peroxidation-mediated injury to host cell membranes (Walker et al., 1983, 1984; Silverman and Santucci, 1988; 1990; Eremeeva et al., 2001; Walker et al., 2001). *R. rickettsii* also directly stimulates activation of transcription factor NF-κB by a proteosome-independent mechanism. The consequences include inhibition of endothelial cell apoptosis as well as proinflammatory effects (Sporn et al., 1997; Sahni et al., 1998). The key pathophysiologic effect of disseminated rickettsial infection of endothelium is increased vascular permeability—a life-threatening event in the brain and lungs in Rocky Mountain spotted fever and epidemic typhus and in a smaller proportion of patients with boutonneuse fever and murine typhus. A hallmark of most rickettsioses is a rash that represents multiple focal networks of rickettsia-infected microvascular endothelium in the skin. Except in Rocky Mountain spotted fever and epidemic and murine typhus, another characteristic visible sign of rickettsiosis is an eschar—the site of cutaneous necrosis where the tick or mite inoculated the rickettsiae.

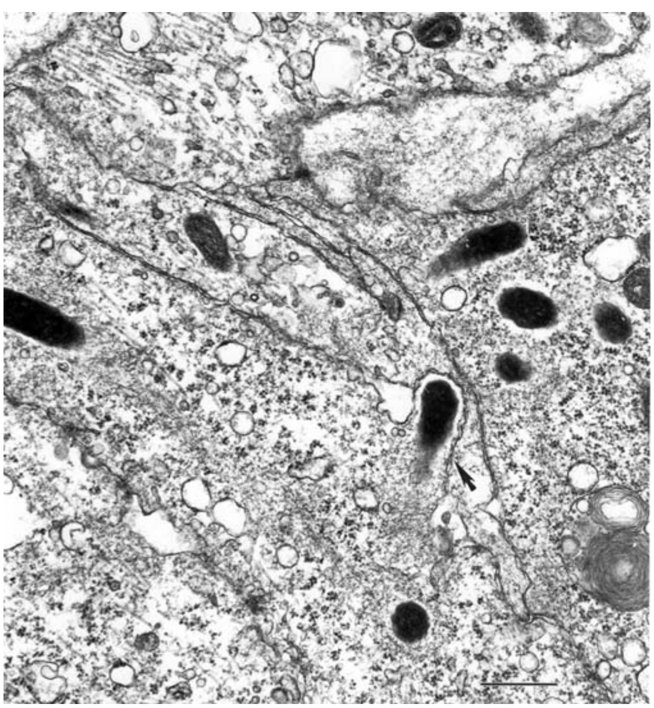

FIGURE BXII.α.37. Electron photomicrograph of *Rickettsia conorii*-infected Vero cells. A rickettsial cell with an actin tail protrudes into an adjacent cell (*arrowhead*). Bar represents 1 μm. Photomicrograph courtesy of Vsevolod Popov.

Antirickettsial immune mechanisms are dominated by T-lymphocyte-mediated cellular immunity. Cytokines, particularly gamma interferon and tumor necrosis factor-α, secreted by T-lymphocytes, macrophages, and natural killer cells, activate infected endothelial cells and other cells to kill intracellular rickettsiae by nitric oxide-dependent mechanisms and other mechanisms. Cytotoxic CD8 T-lymphocytes are critical effectors of the clearance of rickettsiae. Antibodies directed against OmpA and OmpB, but not lipopolysaccharide, also contribute to protective immunity. The potential pathologic effects of cytokines and cytotoxic T-lymphocyte activity have not been determined.

Ecology A consistent characteristic of *Rickettsia* species is their residence in an arthropod host as at least a part of their ecological niche. Transovarian maintenance from one generation of tick, mite, or flea to the next via infected ova that hatch into infected larvae is a factor in the maintenance in nature of all SFG rickettsiae (e.g., *R. akari*, *R. australis*, *R. conorii*, *R. felis*, *R. honei*, *R. peacockii*, *R. rickettsii*, and *R. sibirica*) as well as *R. typhi*. For some *Rickettsia* species, such as *R. peacockii*, transovarian transmission appears to be the only mechanism of survival (Niebylski et al., 1996, 1997b). For others, such as *R. rickettsii*, the organism exerts a pathologic effect on the tick that would eventually result in extinction of the rickettsia (Niebylski et al., 1999). Thus, it appears that its virulence comprises an additional survival strategy, the ability to invade and grow in a vertebrate host (e.g., cotton rats) to a sufficient level and duration of rickettsemia to establish infection in uninfected feeding larval and nymphal ticks, with the subsequent transovarian maintenance of the rickettsiae. In this way the death of infected ticks that is brought about by the pathogenic effects of their rickettsial infection is balanced by replacement by new infected tick lines. Ticks infected with highly virulent rickettsiae (e.g., *R. rickettsii*) are infected by fewer rickettsiae than ticks infected with rickettsiae of no apparent pathogenicity (e.g., *R. montanensis*). For *R. typhi*, transovarian maintenance is less important than horizontal spread via rickettsemic *Rattus*.

In the human-body louse (*Pediculus humanus corporis*) cycle of *R. prowazekii*, the lice do not transmit the rickettsiae vertically to the next generation. Indeed, *R. prowazekii* kills 100% of infected *P. humanus corporis* lice. However, the likely natural cycle of *R. prowazekii* in the flying squirrel (*Glaucomys volans*) involves its own flea (*Orchopeas howardii*) and louse (*Neohematopinus sciuropteri*) without severe pathologic effects on the vertebrate and invertebrate hosts (Bozeman et al., 1975, 1981). Epidemics of louse-borne typhus depend upon the establishment of latent human infection with *R. prowazekii*. Years later, recrudescence of the infection occurs, accompanied by rickettsemia. Human body lice

acquire the rickettsiae by feeding upon the patient's infected blood and then move to nonimmune persons. It is postulated that this human-louse cycle was first established in North America after accidental human infection originating from contact with infected flying squirrel ectoparasites in the pre-Columbian era. Human body lice were present in the New World at that time.

Knowledge of rickettsial ecology is preponderantly based on investigations of medical epidemiology and hematophagous arthropods. The discovery of rickettsial strains closely related to *R. bellii* in herbivorous insects and in association with plant pathology (papaya bunchy top disease) indicates that our view of the diversity and evolutionary origin of *Rickettsia* is likely overly anthropocentric.

Enrichment and Isolation Procedures

Isolation of rickettsiae from ecologic survey specimens or from clinical material requires strict adherence to safety precautions. A biological safety level 3 facility and an approved safety cabinet in which negative air pressure is maintained are recommended.

Rickettsiae are most commonly isolated in cell culture, although historically the isolation of rickettsiae employed inoculation of adult male guinea pigs or embryonated chicken eggs (Walker, 1996). Vero, L-929, HEL, and MRC5 are cell lines commonly used for isolation of rickettsiae. Heparin-anticoagulated plasma or buffy coat ideally is collected before the patient is given antirickettsial treatment. Isolation of rickettsiae is enhanced by centrifugation of the inoculum onto monolayers in shell vials (La Scola and Raoult, 1996a). Rickettsiae are detected by examining monolayers stained by Giemsa, Giménez, or immunofluorescence methods with 82% of positive samples identified after 48 hours incubation. Rickettsiae are susceptible to some classes of antibiotics. Thus, the culture media ideally should not contain antibiotics although penicillin, streptomycin, and sulfonamides have been used to suppress the growth of bacteria from contaminated specimens.

If the samples are contaminated with bacteria or if cell culture is not available, rickettsiae can be also isolated using animals. The guinea pig is the animal of choice for rickettsiae of the typhus and spotted fever groups. Burgdorfer et al. (1975) found the meadow vole (*Microtus pennsylvanicus*) to be particularly susceptible and valuable for the isolation of spotted fever rickettsiae. The mouse is the animal of choice for *R. australis* and *R. akari*. Rickettsial species vary considerably in virulence for the guinea pig and mouse (Table BXII.α.31). Spleen and other organs are collected from guinea pigs during the 2nd and 3rd day of fever or from moribund mice and are passed into cell culture or embryonated eggs. When a rickettsial species of low virulence, such as *R. montanensis* is expected, the spleen is passed on the 10th–12th day after injection, even in the absence of fever or other signs of illness.

Chicken embryos are generally used for the production of stocks of rickettsiae isolated in laboratory animals. Embryonated eggs can also be used for primary isolation if the inoculum is free from adventitious agents (blood or ticks whose exterior surfaces have been decontaminated by immersion in Merthiolate and by repeated washing). Chicken embryos must be obtained from flocks maintained on a rigorous antibiotic-free diet. Yolk sac inoculation during the 5th–7th d of embryo development is the only satisfactory route for propagation of rickettsiae in eggs (Cox, 1941). The optimal conditions for cultivation and harvest vary with the rickettsial group (Table BXII.α.31).

Rickettsiae have also been isolated from the hemolymph of ticks by the shell vial centrifugation-enhanced method of cell culture. A drop of hemolymph is obtained by amputating the distal portion of one or more legs and is inoculated into a shell vial containing a L929 cell monolayer. The vials are centrifuged at 700 × g for 1 h to increase rickettsial attachment and entry into the cells.

Purification of rickettsiae is accomplished by the separation of rickettsiae from host cell components by differential centrifugation or density gradient centrifugation.

Release of rickettsiae from host cells is achieved as follows. If rickettsiae are grown in yolk sacs, the yolk sacs should be ground using a tissue homogenizer and diluted in 10 volumes of sucrose phosphate glutamate (SPG) buffer (0.22 M sucrose, 0.01 M potassium phosphate and 0.005 M potassium glutamate [pH 7.0]) (Bovarnick et al., 1950). If cell culture is used to propagate rickettsiae, the cells should be harvested in SPG buffer and sonicated for 10-sec periods several times on ice until most of cells are broken.

To remove large particles of debris, the rickettsial suspension is centrifuged at 200 × g for 10 min. The supernatant is then centrifuged at 10,000 × g for 20 min to pellet the rickettsiae. The aqueous phase (and fat layer if yolk sacs are involved) is discarded, and the pellet is resuspended in SPG buffer in an appropriate volume for the Renografin centrifugation.

Renografin is the common gradient material used for purification of rickettsiae by density gradient centrifugation (Weiss et al., 1975). The gradient can be either linear or discontinuous. A linear gradient is made using two concentrations of Renografin, 32% and 42%, by a gradient mixer. A discontinuous gradient consists of Renografin concentrations of 32, 36, and 42%. A discontinuous gradient may be made by adding the solutions in ascending or descending order. If the solution is added in ascending order, the 42% solution is added to the bottom of the centrifuge, then the 36% solution is added slowly on top of the 42% solution using a pipette or a syringe along the edge of the tube. The tip of the pipette or the syringe should just touch the surface of the 42% solution to avoid disturbing the solution. Finally, the 32% solution is added on top of the 36% solution by same method. If the solution is added in descending order, the 32% solution is added into the bottom of the centrifuge tube, then the 36% solution is added slowly by inserting the tip of the pipette or syringe to the bottom of the tube. Finally, the 42% solution is added slowly by inserting the tip of the pipette or syringe to the bottom of the tube. A rickettsial suspension prepared by differential centrifugation is added on top of the Renografin solution. Five ml of rickettsial suspension may be added to a 30 ml Renografin gradient column. The rickettsiae are centrifuged at 87,275 × g for 60 min. Two bands (the heavy and light bands) are usually visible at the interfaces between the 32% and 36% Renografin layers and between the 36% and 42% Renografin layers. The bands are collected by aspiration using a pipette or a syringe inserted into the middle of a band or by puncture of the centrifuge tube beneath the band. The suspension is diluted using SPG to two volumes minimum and mixed well by inverting the tube. The suspension is centrifuged at 11,400 × g for 20 min. The pellet contains the purified rickettsiae, which are then suspended in SPG buffer for storage.

The organisms in the heavy band are defective in their infective and metabolic activities, as compared to organisms from the light band. The greater density of heavy-banding organisms is due to their lack of an intact permeability barrier to Renografin. The proportion of heavy-banding organisms in a rickett-

[e]*R. peacockii* has an *ompA* pseudogene.

sial suspension is influenced by the growth phase when they are harvested from infected yolk sacs, as well as by the conditions and media to which they subsequently are exposed (Hanson et al., 1981).

Maintenance Procedures

Rickettsial stocks are usually prepared from infected cell culture or yolk sacs. Infected cells should be harvested before all the cells have detached from the flask. Portions of the infected cells are stored as stock. Infected yolk sacs are ground and diluted to 10 volumes in SPG buffer. Stocks of rickettsiae have been maintained as crude yolk sac suspensions for decades at −70°C. When diluted or separated from host constituents, viability declines at rates that depend on the degree of purification and on the choice of suspending fluid. The diluent most frequently used as the maintenance medium is SPG buffer. Stability is further enhanced by the addition of Mg^{2+} and a substance such as brain-heart infusion broth (BHI), bovine serum albumin, or Renografin. Storage in liquid nitrogen is recommended for specimens of unusual value.

Rickettsiae lose viability when they are repeatedly frozen and thawed, maintained at 4°C for a few days, or kept at room temperature for several hours. However, they may be quite stable in desiccated arthropods or louse feces, which occasionally have been a source of unexpected infection (see Smadel, 1965; Snyder, 1965; Woodward and Jackson, 1965).

Differentiation of the genus *Rickettsia* from other genera

Rickettsiae can be easily differentiated from free-living bacteria by their obligately intracellular growth feature. The genus *Rickettsia* can be differentiated from *Anaplasma*, *Ehrlichia*, and *Coxiella* by its intracellular location. Rickettsiae grow free in the cytoplasm or nucleus as compared to *Anaplasma*, *Ehrlichia*, and *Coxiella*, which grow in the cytoplasm within a vacuole. The characteristics for differentiation between *Rickettsia* and *Orientia* are summarized in Table BXII.α.32.

Acknowledgments

We are indebted to Drs. David J. Silverman Department of Microbiology, School of Medicine, University of Maryland, Baltimore, Vsevolod Popov, Department of Pathology, University of Texas Medical Branch, Galveston, Akira Tamura and Hiroshi Urakami, Department of Microbiology, Niigata College of Pharmacy, Niigata, for providing the illustrations.

Differentiation of the species of the genus *Rickettsia*

The differential characteristics of the three groups of *Rickettsia* and some of the species characteristics are presented in Table BXII.α.31. Although most species display some obvious differential characteristics, final identification requires genetic and antigenic analysis.

List of species of the genus Rickettsia

1. **Rickettsia prowazekii** da Rocha-Lima 1916, 567[AL] (Nom. Cons. Opin. 19, Jud. Comm. 1958, 158.)
pro.wa.ze′ki.i. M.L. gen. n. *prowazekii* of Prowazek; named after Stanislav von Prowazek, an early investigator of the etiology of typhus who died of typhus contracted in the course of his studies.

The description of the genus and, in particular, of the typhus group within the genus is based largely on studies of this species. Although cells are generally small, variation in size and morphology is most pronounced in this species. Unusually long cells (4 µm, single or in short chains) and cells with prominent vacuoles appear with moderate frequency in stationary cultures.

Highly infectious for chicken embryos, which die within 4–13 days after inoculation, depending on the quantity of infectious organisms in the inoculum. Optimal yields of rickettsiae are obtained by inoculating the embryos with small inocula (10 viable rickettsiae per egg) and harvesting the yolk sacs 10–14 days later, just before the embryos die. Highly infectious also for monolayers of chick embryo fibroblasts, L-929 cells, and Vero cells. Plaques are usually small (0.5–1.5 mm in diameter) and turbid (see Table BXII.α.31). The virulent Breinl strain, but not the avirulent E strain, multiplies to a moderate extent in human macrophage cultures (Gambrill and Wisseman, 1973).

R. prowazekii is the etiologic agent of epidemic typhus fever, which is acquired through contact with lice. It is also the etiologic agent of recrudescent typhus (called Brill–Zinsser disease) and occasionally of sporadic typhus in individuals who have been in contact with flying squirrels or their ectoparasites (McDade et al., 1980; Duma et al., 1981). The most effective arthropod vector of epidemic typhus is the human body louse, *Pediculus humanus corporis*, possibly because it takes frequent large blood meals and because it tends to desert febrile hosts to seek new ones. The head louse is equally susceptible to infection but has not been implicated in typhus fever transmission, possibly because it imbibes only very small amounts of blood (Murray and Torrey, 1975). When the rickettsiae are ingested in an infectious blood meal, they enter in the midgut epithelial cells of the louse and undergo massive multiplication. The rickettsiae grow profusely in the cells of the gut epithelium of the louse, even when the ingested human blood contains high levels of antibodies (Wisseman and Waddell, 1975). Heavily infected epithelial cells are released into the lumen, are discharged with the feces of the louse, and are the source of human infection when the louse feces are inoculated into the skin by scratching. Lice invariably succumb to infection, usually within 1–2 weeks, rarely surviving longer than 3 weeks. When louse infestation is very heavy or when large volumes of rickettsial suspensions are processed in the laboratory, infection may occur by inhalation of aerosols.

[a]For symbols see standard definitions.

The guinea pig is highly susceptible to infection, but develops a mild disease, usually manifested only as fever lasting approximately a week. The cotton rat, *Sigmodon hispidus*, is also highly susceptible to infection, but signs of disease and death are produced only by doses in excess of 3×10^5 viable rickettsiae. Inapparent infection elicits solid immunity to the homologous species and to *R. typhi*. True infection does not occur in the mouse, but acute toxic death is produced by the intravenous injection of at least 10^6 viable rickettsiae.

Of the laboratory-induced variants of *R. prowazekii*, the most notable is strain E, isolated from a typhus patient in Madrid in 1941 and passed in rapid succession in eggs 255 times. This strain has limited virulence for the guinea pig and low virulence for man. It has been used as a living vaccine (Fox, 1956). Other laboratory-induced variants have been obtained from strain E. They include strains unaffected by erythromycin and strains of increased resistance to *p*-aminobenzoic (PABA) and to chloramphenicol (Weiss, 1960; Weiss and Dressler, 1962). Strain E easily reverts to virulence during passage in guinea pigs. The mechanisms of attenuation and reversion to virulence are not known, although virulence is associated with differences in methylation of lysine residues of OmpB (Ching et al., 1993).

Strains isolated from various geographic locations are remarkably similar to each other in biological properties. Differences in % DNA–DNA hybridization were negligible (range 92–100; mean = 97) among strains isolated in Poland, Spain, and Burundi from human sources and from flying squirrels from the United States (Myers and Wisseman, 1980). Minor differences in protein migration patterns obtained by isoelectric focusing in polyacrylamide gels can distinguish strains derived from Eastern Europe, Spain or Africa, or from American flying squirrels. Another minor difference between the attenuated E strain and the virulent strains in protein migration patterns has been noted (Dasch et al., 1978). The genome size of *R. prowazekii* is 1,111,523 bp (Andersson et al., 1998). No resident plasmid or bacteriophage has been identified in *R. prowazekii*. The *R. prowazekii* genome has 834 open reading frames.

The mol% G + C of the DNA is: 29.0 (T_m).

Type strain: Breinl strain, ATCC VR-142.

GenBank accession number (16S rRNA): M21789.

2. **Rickettsia aeschlimannii** Beati, Meskini, Thiers and Raoult 1997, 553[VP]
ae.schli.man'ni.i. L. gen. n. *aeschlimannii* of Aeschlimann, named after Andre Aeschlimann, a Swiss zoologist.

The organisms are 0.7–1.1 μm in length, with a mean diameter of 0.3 μm. *R. aeschlimannii* grows in Vero, L929, and HEL cell lines. Mouse antisera against the organism show cross-reactivity with antigens of other SFG rickettsiae. 16S rRNA gene sequence analysis can distinguish *R. aeschlimannii* from other SFG rickettsiae. The most closely related species are *R. massiliae* and *R. rhipicephali*. The sole available isolate was obtained from *Hyalomma marginatum* collected in Morocco (Beati et al., 1997). Two human patients have been reported as infected with *R. aeschlimannii* (Raoult et al., 2002; Pretorius and Birtles, 2002).

The mol% G + C of the DNA is: not determined.

Type strain: MC16 (Reference Center for Rickettsioses, Marseille, France).

3. **Rickettsia africae** Kelly, Beati, Mason, Matthewman, Roux and Raoult 1996, 612[VP]
a'fri.cae. L. gen. n. *africae* pertaining to Africa, the continent where the organism was isolated.

The dimensions of the organisms are 0.3–0.5 × 0.9–1.6 μm. Growth occurs in the yolk sacs of chicken embryos, L929, Vero, and human embryonic lung fibroblast cells. Plaque formation does not occur in infected Vero cells. Electron microscopy shows that the organisms grow free in the cytoplasm with an outer electron lucent zone and a trilaminar cell wall. The organism can be differentiated from closely related rickettsiae such as *R. parkeri*, *R. sibirica*, and *R. rickettsii* by pulsed field gel electrophoresis after digestion of the DNA with *EagI*, *SamI*, and *BssHII*. The 16S rRNA gene sequences of *R. africae* have 99.9% similarity to those of *R. conorii*, and 99.7% similarity to those of *R. sibirica*. The genome size of *R. africae* is 1.248 kb.

The reservoirs of *R. africae* are *Amblyomma hebraeum* and *A. variegatum*. Rickettsiae can be maintained transstadially and transovarially in *A. hebraeum*; 72% of *A. hebraeum* in Zimbabwe carry these rickettsiae (Kelly et al., 1996).

R. africae causes African tick bite fever. The disease has been reported from sub-Saharan Africa where boutonneuse fever is also endemic. African tick bite fever is a mild disease, whereas boutonneuse fever may be more severe. The skin rash may be sparse, vesicular, or absent. Many patients have multiple eschars and associated regional lymphadenopathy (Kelly et al., 1996).

The mol% G + C of the DNA is: not determined.

Type strain: Z9-Hu (Reference Center for Rickettsioses, Marseille, France).

4. **Rickettsia akari** Huebner, Jellison and Pomerantz 1946, 1682[AL]
a.ka'ri. Gr. neut. n. *akari* a mite.

Among SFG rickettsiae, *R. akari* is relatively distantly related to *R. rickettsii*. It grows somewhat more profusely in the yolk sac of chicken embryos than does *R. rickettsii* (Shepard and Lunceford, 1976) and is somewhat more cytotoxic when grown in cell cultures (Weiss et al., 1972; Kokorin et al., 1978). The mouse, however, is highly susceptible to infection and is the animal of choice for isolation. Differences in virulence between strains of this species and differences in susceptibility between inbred strains of mice have been demonstrated (Anderson and Osterman, 1980). The moderate virulence for the guinea pig is about the same as that of *R. conorii*.

In man, *R. akari* causes rickettsialpox. This disease is characterized by a generalized, typically vesicular rash, fever, malaise, and lymphadenitis, which resolve in about a week. The disease in man was first observed in 1946 in New York City (Huebner et al., 1946). It has been reported mainly from urban areas along the Atlantic coast of the United States, in the Crimea and southern Ukraine and Croatia (Radulovic et al., 1996). In the mid-1940s, about 180 cases were reported annually in the United States, but only sporadic cases have been recognized in recent years (Wong et al., 1979).

This species is readily distinguished from the other members of the spotted fever group by DNA sequence analysis and immunologic evaluation. The main vector is the mite, *Liponyssoides sanguineus*, which maintains the rickettsia transovarially. The nymph and adult stages of the mite feed on the house mouse, *Mus musculus*, but they may attack other animals and man. This *Rickettsia* has also been isolated

from rats and from a wild Korean rodent, *Microtus fortis pelliceus* (Jackson et al., 1957).

The genome has a size of 1,231,204 bp and contains 1677 open reading frames and 33 tRNA genes (Eremeeva et al., 2002). Differences in electrophoretic migration patterns of the solubilized proteins between *R. akari* and the other species of the spotted fever group are easily visualized (Obijeski et al., 1974; Pedersen and Walters, 1978).

The mol% G + C of the DNA is: 32.3 (determined from the genome sequence).

Type strain: Kaplan, MK, ATCC VR-148.

This strain was isolated from the blood of a patient in New York City (Huebner et al., 1946). Strain 29 isolated from a mouse by Fuller et al. (1951) and a strain isolated from a mite in the U.S.S.R. (received from Zhdanov [Zhdanov and Korenblit, 1950]) are frequently used as reference strains.

5. **Rickettsia australis** Philip 1950, 786[AL]
aus.tra′lis. L. fem. adj. *australis* southern.

R. australis is a member of a clade that also includes *R. akari* and *R. felis* and is somewhat separate from the core of the SFG2. *R. australis* is not highly virulent for the guinea pig and produces a relatively mild disease in humans. It is highly virulent for the newborn mouse, which has been successfully used for isolation (Campbell and Domrow, 1974). It causes severe, highly invasive disease in several inbred strains of mice but manifests low toxicity for the adult mouse (Bell and Pickens, 1953). Growth characteristics are not appreciably different from those of related species. Identification, as with other species, is based on DNA sequence analysis or immunologic testing.

The disease in man is called Queensland tick typhus. *R. australis* was first isolated in 1944–1945 from the blood of two military patients on field exercises in belts of dense forest interspersed in grassy savannah in North Queensland, Australia (Andrew et al., 1946). Cases have also been recognized along the southeastern coast of Queensland and near Sydney. The scrub tick, *Ixodes holocyclus*, has been implicated in these infections. A strain was also isolated from *I. tasmani* collected from a wild rat (Campbell and Domrow, 1974).

Protein migration patterns are not appreciably different from those of related species (Pedersen and Walters, 1978). The genome size of *R. australis* is 1256–1276 kbp as determined by pulsed-field gel electrophoresis (Roux et al., 1992).

The mol% G + C of the DNA is: not known.

Type strain: NIAID Phillips 32.

GenBank accession number (16S rRNA): L36101, U12459.

The type strain was isolated from a patient by Andrew et al. (1946).

6. **Rickettsia bellii** Philip, Casper, Anacker, Cory, Hayes, Burgdorfer and Yunker 1983, 105[VP]
be.lli′i. M.L. gen. n. *bellii* of Bell, named in honor of a rickettsiologist E. John Bell, who first isolated the organism.

The organisms are longer than most other rickettsiae with dimensions of 0.3–0.4 × 2.0–3.0 μm during the log phase of growth and sometimes 10–15 μm under suboptimal conditions in tissue culture. Like other rickettsiae, *R. bellii* possess an outer slime layer; however, *R. bellii* can be differentiated from other rickettsiae because it has no discernible microcapsular layer. Most strains of *R. bellii* grow poorly in yolk sacs although the type strain was originally isolated in embryonated eggs. Vero cell culture is a satisfactory system for primary isolation. Other cells such as *Xenopus laevis* (South African clawed toad) and tick cell lines have been used to isolate *R. bellii*. The cytopathic effect varies among isolates of *R. bellii*. Some isolates form characteristic and well defined but faint ring-shaped plaques, and others do not form plaques in Vero cells. Although *R. bellii* possesses antigens that cross-react with antibodies to *R. rickettsii*, *R. prowazekii*, and *R. typhi*, the protein composition of *R. bellii* differs from that of TG and SFG rickettsiae. Since 1974, 263 *R. bellii* isolates have been identified by immunofluorescence.

R. bellii has been detected in ticks from all geographic regions of the United States. In many locations, *R. bellii* is the predominant *Rickettsia* sp. in ticks. *R. bellii* comprises 39% (41/106) of isolates from *D. andersoni* in Montana, 82% (59/72) of isolates from North Carolina, and 83% (128/154) of isolates from Ohio. *R. bellii* has been identified in six species of ixodid ticks (*Dermacentor variabilis*, *D. andersoni*, *D. occidentalis*, *D. parumapertus*, *D. albipictus*, and *Haemaphysalis leporispalustris*) and two species of argasid ticks (*Argas cooleyi* and *Ornithodoros concanensis*) (Philip et al., 1983).

A symbiont of a pea aphid (*Acyrthosiphon pisum*)—a plant-feeding insect—and an organism associated with a plant disease called papaya bunch top disease are phylogenetically placed in a clade with *R. bellii* (Chen et al., 1996; Davis et al., 1998).

Rickettsia bellii is nonpathogenic for mice and guinea pigs. Limited replication may occur in voles for some strains, but these strains cannot be maintained by serial passage in voles. There is no evidence that *R. bellii* causes human illness.

The mol% G + C of the DNA is: 30 (T_m). This value is similar to that of the TG rickettsiae but lower than that of the SFG rickettsiae.

Type strain: RML 369-C (Rocky Mountain Laboratories Collection).

GenBank accession number (16S rRNA): U11014.

RML 369-C (Rocky Mountain Laboratories Collection). This strain was isolated in embryonated chicken eggs from a triturated pool of unfed adult *Dermacentor variabilis* ticks collected from vegetation near Fayetteville, Arkansas, in June of 1966. After the fifth passage in yolk sacs, this organism regularly kills chicken embryos 4–5 days after inoculation (Philip et al., 1983).

7. **Rickettsia canadensis** McKiel, Bell and Lackman 1967, 509[AL] (*Rickettsia canada* (sic) McKiel, Bell and Lackman 1967, 509.)
ca′na.den.sis. M.L. n. *canadensis* referring to Canada, the country where the organism was first isolated.

R. canadensis was previously known as *R. canada*. The name was corrected to *R. canadensis* because *canadensis* is the Latin adjective referring to Canada (Roux and Raoult, 2000).

R. canadensis can be grown in laboratory-reared ticks (Burgdorfer and Brinton, 1975), but grows sparingly in the louse (Weyer and Reiss-Gutfreund, 1973). Unlike some of the species of the spotted fever group, *R. canadensis* is not highly cytopathic and is cultivated in chicken embryos by the procedure used for the typhus group (Table BXII.α.31). Plaques on monolayers are small as are those of the typhus

group (Woodman et al., 1977). Virulence for the guinea pig and mouse is quite low. At least 10^6 viable cells are required to induce fever in the guinea pig, and 10^5 viable cells are required for seroconversion in mice (Ormsbee et al., 1978). The hemolytic activity as measured with sheep erythrocytes and the rate of CO_2 production from glutamate are approximately the same as those obtained with *R. prowazekii* and *R. typhi* (Woodman et al., 1977). *R. canadensis* reacts strongly with guinea pig and rabbit sera prepared against the typhus group rickettsiae but weakly with sera against spotted fever group rickettsiae; this weak reaction is due to the presence of epitopes in its LPS that are shared with TG rickettsiae prepared according to a particular immunization protocol (McKiel et al., 1967). Specific antigens can readily be demonstrated with mouse antisera (Philip et al., 1978). As with *R. prowazekii* and *R. typhi*, *R. canadensis* has antigens in common with *Proteus vulgaris* OX19, whereas SFG rickettsiae share antigens with the *Proteus vulgaris* OX2 antigen. Thus, *R. canadensis* was previously classified in the typhus group. However, *R. canadensis* resembles SFG rickettsiae in its other features, such as its ecological niche in the tick and its ability to grow in the nucleus of host cells. Moreover, *R. canadensis* has OmpA (Vishwanath, 1991), which is a common feature of SFG rickettsiae but not typhus rickettsiae. Thus, *R. canadensis* does not fit into either the TG or SFG of rickettsiae.

Two strains were isolated from pools of engorged rabbit ticks (*Haemaphysalis leporispalustris*) collected near Richmond, Ontario; one strain was isolated from an indicator rabbit, the other from a wild snowshoe hare (McKiel et al., 1967). Only one of these two strains is still available. Another strain was isolated in California from a *H. leporispalustris* tick feeding on a California jackrabbit (*Lepus californicus*) (Lane et al., 1981). There is serological evidence that human infection may have occurred (Bozeman et al., 1970).

Although the mol% G + C of the DNA of *R. canadensis* is identical to the values for *R. prowazekii* and *R. typhi*, the genome size is distinctly larger (1.49×10^9 Da). Thus, the extent of DNA–DNA hybridization between *R. canadensis* and the other two species of the typhus group varies somewhat owing to differences in the size of the genomes (38% and 46% hybridization with *R. prowazekii* and *R. typhi*, respectively). A degree of DNA–DNA hybridization occurs between *R. canadensis* and *R. rickettsii* that is similar to that between *R. canadensis* and *R. typhi* (Myers and Wisseman, Jr., 1981). When compared to *R. prowazekii* and *R. typhi* on the basis of migration patterns in polyacrylamide gel electrophoresis of solubilized proteins, *R. canadensis* displays a number of differences, although a basic similarity can still be recognized (Dasch et al., 1978).

The mol% G + C of the DNA is: 29 (T_m).

Type strain: 2678, ATCC VR-610.

GenBank accession number (16S rRNA): L36104.

8. **Rickettsia conorii** Brumpt 1932, 1199[AL]

co.no′ri.i. M.L. gen. n. *conorii* of Conor; named after A. Conor who, in collaboration with A. Bruch, provided the first description of boutonneuse fever.

R. conorii resembles *R. rickettsii*, but it is antigenically distinct and less virulent for guinea pigs and humans; however, the Malish 7 strain is more virulent for C3H/HeN mice. Growth in cell cultures has the basic features of other rickettsiae of the spotted fever group, including early spread between host cells (Oaks and Osterman, 1979), and it is cultivated by procedures identical to those used for *R. rickettsii*. This species can be differentiated from related species of the spotted fever group by appropriate DNA sequence analysis and serological tests (Bell and Stoenner, 1960; Bozeman et al., 1960). Differences among strains of *R. conorii* include different numbers, type, and order of tandem repeat units of OmpA. Genetic analyses reveal clustering of some isolates (e.g., those similar to Israeli isolates, those similar to Astrakhan isolates, and those similar to the Malish 7 South African isolate).

The human disease varies in severity and is fatal in 1–5% of hospitalized cases. It is called boutonneuse fever, Mediterranean spotted fever, Israeli tick typhus, Astrakhan spotted fever, Kenya tick typhus, Indian tick typhus, or other names that designate the locality of occurrence. It is normally transmitted by the bite of the tick, but may also be acquired through the skin or conjunctiva when the ticks are crushed. After a period of apparent low incidence, there was a marked rise in number of cases diagnosed during the 1970s.

R. conorii is the most geographically dispersed rickettsia of the spotted fever group. It has been recognized in most of the regions bordering on the Mediterranean Sea and Black Sea, Israel, Kenya and other parts of North, Central, and South Africa, and India. The brown dog tick, *Rhipicephalus sanguineus* is the prevailing vector. The involvement of rabbits in maintaining an infected tick population was suggested by association of the disease with large rabbit populations on endemic islands and by the drop in human disease following the myxomatosis epizootic that reduced the rabbit population in Europe (Hoogstraal, 1967, 1981).

The genome of *R. conorii* contains 1,268,755 bp (Ogata et al., 2001). No resident plasmid or bacteriophage has been identified in *R. conorii*. The electrophoretic profiles of the soluble proteins are similar but not identical to those of *R. rickettsii* and *R. sibirica* (Anacker et al., 1980).

The mol% G + C of the DNA is: 32.4 (determined from the genome sequence).

Type strain: Malish 7.

GenBank accession number (16S rRNA): AE008647 (genome segment), L36105 (Moroccan strain).

The type strain is a South African patient strain, isolated by J.H. Gear in 1946. This strain and the Moroccan strain (ATCC VR-141) are used most frequently in laboratory studies.

9. **Rickettsia felis** Bouyer, Stenos, Crocquet-Valdes, Moron, Popov, Zavala-Velazquez, Foil, Stothard, Azad and Walker 2001, 346[VP]

fe′lis. L. gen. n. *felis* of the cat; named after the cat flea, *Ctenocephalides felis*, in which the organism was first observed by electron microscopy.

In 1990 during a study investigating potential vectors for *Neorickettsia risticii*, rickettsia-like organisms were observed in adult cat fleas obtained from EL Labs. Thus, the organism was originally designated as the ELB agent. The organisms are 0.25–0.45 μm ×1.5 μm and are found in the midgut, tracheal matrix, muscles and reproductive tissues of the fleas. The organism contains a trilaminar cell wall that is characteristic of rickettsiae with a well-defined inner cell membrane and outer membrane. The dimensions of the microcapsular layer, outer and inner leaflets of the outer membrane, and the periplasmic space strongly resemble those in other *Rickettsia* species.

Phylogenetic analysis of the 17 kDa antigen gene, *ompA*, and *ompB* and other genes places *R. felis* as a member of the SFG.

R. felis has been cultivated in the XTC-2 cell line derived from *Xenopus laevis*. *R. felis* grows most rapidly at 28°C in XTC-2 cells, which die at a temperature of 32°C. The organism also grows to a lesser extent in Vero cells at 28°C or 32°C. L-929, and MRC-5 cell lines are unable to support the permanent growth of *R. felis*. Electron microscopy shows that *R. felis* is free in the cytoplasm but not in the nucleus of the cells.

The organism is maintained in the flea by transovarial transmission. Horizontal transmission or the acquisition of *R. felis* by fleas feeding on cats or artificially infected meals has not been demonstrated. *R. felis* has been associated with opossums and their fleas in Texas and California. Serological evidence and PCR detection indicate that *R. felis* infection occurs in humans in the United States, Mexico, Brazil, and Germany. The organism has also been detected in cat fleas from Spain and Ethiopia; thus, *R. felis* is likely distributed worldwide.

The mol% G + C of the DNA is: not determined.

Type strain: CNCM I-2363, Marseille-URRWFXCal2 (Reference Center for Rickettsioses, Marseille, France).

10. **Rickettsia helvetica** Beati, Peter, Burgdorfer, Aeschlimann and Raoult 1993, 524[VP]

hel.ve′ ti.ca. N.L. adj. *helvetica* pertaining to Helvetica, the Latin name of Switzerland where the organism was originally isolated.

R. helvetica, formerly called the Swiss agent, was first isolated from *Ixodes ricinus* ticks from Switzerland (Burgdorfer et al., 1979). Recently, *R. helvetica* has been isolated from *Ixodes ricinus* ticks from France (Parola et al., 1998). Rickettsial isolates from *Ixodes ovatus*, *I. persulcatus*, and *I. monospinosus* from Japan are identical or closely related to *R. helvetica* (Fournier et al., 2002). In serological tests, *R. helvetica* antigens are weakly cross-reactive with antisera to other SFG rickettsiae.

R. helvetica grows well in yolk sacs of embryonated eggs, chicken embryo fibroblasts, L929, and Vero cells. Human embryonic lung fibroblasts do not support the growth of *R. helvetica* in primarily isolation. *R. helvetica* does not cause a cytopathic effect in Vero cells, and it can be continuously subcultured by trypsinization of the monolayers. Unlike other SFG rickettsiae, *R. helvetica* does not stimulate actin tail formation when it grows inside the host cell. *R. helvetica* exhibits moderate pathogenicity in meadow voles; however, rabbits, guinea pigs, and mice are not susceptible (Fournier et al., 2000). A serological survey suggests that a portion of tick-exposed humans have antibodies reactive with *R. helvetica* in France (Nilsson et al., 1999). However, the pathogen has not been isolated from ill humans.

The mol% G + C of the DNA is: not determined.

Type strain: C3 (Reference Center for Rickettsioses, Marseille, France), ATCC VR-1375.

GenBank accession number (16S rRNA): L36214.

11. **Rickettsia honei** Stenos, Roux, Walker and Raoult 1998, 1403[VP]

ho.ne.i. L. gen. n. *honei* of Hone, named after Frank Sandland Hone, an early pioneer in Australian rickettsiology.

An SFG rickettsiosis-like ailment was identified in 1991 on Flinders Island of Australia and was named Flinders Island spotted fever (FISF). The causative agent of FISF was isolated from buffy coat preparations from the blood of two patients (Baird et al., 1992) and named *R. honei* (Stenos et al., 1998).

R. honei and the Thai tick typhus rickettsia (TT-118) are identical in DNA sequences of the gene encoding the 17 kDa protein, *gltA*, and *ompA*, and they have only 1 nucleotide difference in the 16S rRNA gene. Thus, *R. honei* and TT-118 are considered a single species (Stenos et al., 1998).

TT-118 was isolated from a pool of immature *Rhipicephalus* and *Ixodes* of unknown species collected in Thailand (Robertson and Wisseman, 1973). A *Rickettsia* identical to TT-118 has recently been detected by PCR from an *Ixodes granulatus* tick from Thailand (Kollars et al., 2001). Migratory birds have been postulated to spread *R. honei* widely. A rickettsia genetically identical to *R. honei* has been detected by PCR in *Aponoma hydrosauri* ticks from Flinders Island and Tasmania. This tick is a reptile-associated tick, but it also bites humans (Whitworth et al., 2003).

The mol% G + C of the DNA is: not determined.

Type strain: RB, ATCC VR-1472.

GenBank accession number (16S rRNA): U17645, AF060705.

The type strain of *R. honei* was isolated from buffy coat of a patient's blood by inoculation of buffalo green monkey kidney cells.

12. **Rickettsia japonica** Uchida, Uchiyama, Kumano and Walker 1992, 303[VP]

ja.po′ ni.ca. N.L. adj. *japonica* pertaining to Japan, the country from which the first isolates were identified.

The dimensions of the organisms are 0.4–0.5 × 0.8–1.5 μm. Unlike some other SFG rickettsiae, *R. japonica* can persistently infect Vero cells. *R. japonica* does not cause a cytopathic effect in Vero cells but does cause cytopathic effects in L929, BHK21/13, and primary chicken embryo fibroblast cells. The rickettsiae grow primarily in cytoplasm and rarely in nuclei. The plaque morphology produced by *R. japonica* differs from that produced by most other SFG rickettsiae except *R. rickettsii*. *R. japonica* forms target like plaques (a dye-stained inner focus of viable cells surrounded by a clear zone of necrotic cells) after 9–11 days of incubation in Vero cells. Other SFG rickettsiae form clear plaques. A variant that forms clear plaques was isolated from a guinea pig inoculated with *R. japonica*. About 0.01 to 0.001% of cells carrying strain YH produced clear plaques on Vero cells (Uchida et al., 1992).

The organisms are pathogenic for guinea pigs. Guinea pigs develop fever and scrotal swelling. C3H/He strain of inbred mice and conventional strain ddY mice are resistant to *R. japonica* infection. Chicken embryos die 5–7 days after yolk sac inoculation. Like other SFG rickettsiae, *R. japonica* does not exhibit hemolytic activity.

R. japonica is presumably transmitted by ticks. It has been cultivated from *Dermacentor taiwanensis* and *Haemaphysalis flava* (Fournier et al., 2002).

The disease caused by *R. japonica* infection is Japanese spotted fever. The disease was first found in Japan in 1984. The disease is mainly distributed along the coast of southwestern and central Japan where the climate is warm, and most cases occur between April and October. The clinical features of the disease include fever (100%), headache (80%), shaking chills (87%), skin eruption (100%), and tick bite eschars (90%) (Mahara, 1997). Serologic evidence

indicates that disease might occur in eastern Asia and adjacent islands (Feng et al., 1991; Camer et al., 2000). However, the antibodies against *R. japonica* might have been stimulated by other SFG rickettsiae in these areas.

"R. heilongjiangii", a rickettsial isolate from both ticks and humans in northeastern China, is closely related to *R. japonica*. The 16S rRNA gene sequence of *"R. heilongjiangii"* has 99.6% similarity to that of *R. japonica* (Zhang et al., 2000b). Further studies need to be performed to determine whether *"R. heilongjiangii"* should be designated a strain of *R. japonica*.

The mol% G + C of the DNA is: 31.2 (T_m).

Type strain: YH; ATCC VR-1363.

GenBank accession number (16S rRNA): L36213 (strain YM).

The YH strain was isolated from the blood of a patient in Japan by Uchida et al. (1985).

13. **Rickettsia massiliae** Beati and Raoult 1993, 839[VP]
mas.si' li.ae. L. gen. n. *massiliae* from Massilia, the Latin name of Marseille, where the organism was first isolated.

The dimensions of the organisms are 0.3–0.4 × 0.6–1 µm. Growth occurs in the cytoplasm of eucaryotic cells. *R. massiliae* can be cultivated in L929, Vero, or human embryonic lung fibroblast cells. *R. massiliae* has been isolated from *Rhipicephalus turanicus* and *R. sanguineus* ticks in France. *R. massiliae* has also been detected in ticks from Greece, Portugal, Spain, and the Central African Republic where *Rhipicephalus lunulatus*, *R. mushamae*, and *R. sulcatus* are hosts (Beati and Raoult, 1993; Babalis et al., 1994; Beati et al., 1996). Pathogenicity of *R. massiliae* for humans and animals has not been demonstrated.

The mol% G + C of the DNA is: not determined.

Type strain: Mtu1, ATCC VR-1376.

GenBank accession number (16S rRNA): L36214.

Mtu1 was isolated from the hemolymph of a *Rhipicephalus turanicus* tick collected in Marseille, France (Reference Center for Rickettsioses, Marseille, France).

14. **Rickettsia montanensis** corrig. (ex Lackman, Bell, Stoenner and Pickens 1965) *Rickettsia montana* (sic) Weiss and Moulder 1984b, 356[VP] (Effective publication: Weiss and Moulder 1984a, 697.)
mon.tan' en.sis. M.L. gen. n. *montanensis* from Montana, the state where the organism was first isolated.

Resembles other members of the spotted fever group in its growth characteristics in the chicken embryo and antigenic composition, but it is avirulent for the guinea pig and mouse. Although antibodies reactive with this species have been detected in dogs, *R. montanensis* is not associated with signs or symptoms of spotted fever in humans or experimentally inoculated dogs. It is distinguished from other rickettsiae by DNA sequence analysis and immunologic testing (Philip et al., 1978). *R. montanensis* was first isolated in eastern Montana, repeatedly from *D. variabilis*, occasionally from *D. andersoni*. It has been also isolated with notable frequency from rodents (genera *Microtus* and *Peromyscus*) and from *D. variabilis* in various parts of the U.S. (Lackman et al., 1965; Philip et al., 1978; Linnemann et al., 1980).

The mol% G + C of the DNA is: not determined.

Type strain: ATCC VR-611.

GenBank accession number (16S rRNA): L36099.

ATCC VR-611 is the tick strain of Bell et al. (1963).

15. **Rickettsia parkeri** Lackman, Bell, Stoenner and Pickens 1965, 137[AL]
par' ke.ri. M.L. gen. n. *parkeri* of Parker; named after Ralph R. Parker, a founder of the Rocky Mountain Laboratory.

This species is cultivated in eggs by the same procedure used for the other species of the spotted fever group. *R. parkeri* is identified by DNA sequence analysis or immunologic evaluation. *R. parkeri* produces a nonfatal disease in the guinea pig that is characterized by fever and reddening of the scrotum; the most abundant growth takes place in the testicular tissue (Parker et al., 1939). Human infection has not been reported. The species has been isolated from *Amblyomma maculatum* ticks collected from domestic animals in Texas, Georgia and Mississippi (Lackman et al., 1949).

The mol% G + C of the DNA is: not determined.

Type strain: NIAID maculatum 20.

GenBank accession number (16S rRNA): U12461.

The type strain was isolated in 1948 from *A. maculatum* ticks collected from sheep in Mississippi (Bell and Pickens, 1953).

16. **Rickettsia peacockii** Niebylski, Schrumpf, Burgdorfer, Fischer, Gage and Schwann 1997b, 451[VP]
pea.cock' i.i. M.L. gen. n. *peacockii* of Peacock, named after M.G. Peacock, a well-respected rickettsiologist.

R. peacockii is a endosymbiont of wood ticks (*Dermacentor andersoni*) collected from the Bitterroot Valley in the western Montana. *R. peacockii* is transstadially and transovarially transmitted in ticks. Massive infections of *R. peacockii* are observed only in *D. andersoni* ovarian tissues. The organisms are not found in tick hemocytes, salivary glands, midgut, Malpighian tubules, or hypodermal tissues. Thus, *R. peacockii* is likely unable to be transmitted to mammals.

The 16S rRNA gene sequence is most similar to *R. rickettsii* R strain and *R. slovaca* (99.7% for both species). The sequence of the *ompA* gene is most similar to *R. slovaca* (93.0%). The *ompA* gene of *R. peacockii* has a single nucleotide deletion at position 334. The deletion results in a prematurely truncated OmpA of *R. peacockii* with 110 amino acids only. Thus, presumably *R. peacockii* does not have a functional OmpA (Niebylski et al., 1997b).

R. peacockii is postulated to interfere with the stable maintenance of virulent rickettsiae in nature (Burgdorfer et al., 1981) because the distribution of *R. peacockii* coincides with a low incidence of Rocky Mountain Spotted Fever (RMSF) on the east side of the Bitterroot Valley, where early cases of RMSF were recognized on the west side of the valley. *R. peacockii* infects approximately 70% of wood ticks from the east side but is uncommon in the ticks from the west side of the valley. A plausible explanation for the *R. peacockii* interference is that infections of *R. peacockii* in tick ovarian tissues might inhibit transovarial transmission of virulent *R. rickettsii* (Niebylski et al., 1997b).

The mol% G + C of the DNA is: not determined.

Type strain: Skalkaho.

GenBank accession number (16S rRNA): U55820.

This strain was characterized directly from an infected *D. andersoni* tick (SK-594) that was used to generate the 16S rRNA gene sequence and *ompA* gene sequence. The organism has been recently co-cultured from the *D. andersoni* cells (Simser et al., 2001).

17. **Rickettsia rhipicephali** (ex Burgdorfer, Brinton, Krynski and Philip 1978) Weiss and Moulder 1988, 221^VP (Effective publication: Weiss and Moulder 1984a, 698.)
rhi.pi.ce′pha.li. M.L. gen. n. *rhipicephali* of rhipicephalus; named after its natural tick host *Rhipicephalus sanguineus.*

Although this species is isolated with difficulty in the chicken embryo and the guinea pig, it is readily recovered in male meadow voles (*Microtus pennsylvanicus*), in which it produces massive infection in the tissues of the tunica vaginalis. This species can also be cultivated on monolayers of chick embryo fibroblasts, Vero, and mouse L cells. Although growth is profuse, damage to the cells is limited, and plaques are small and turbid, reflecting a mixture of viable and dead host cells. There is no evidence that *R. rhipicephali* is pathogenic for humans. A serosurvey of acute and convalescent serum samples from 80 dogs in which Rocky Mountain spotted fever had been considered as a differential diagnosis identified one dog with a fourfold increase in antibody titer to *R. rhipicephali* (Breitschwerdt et al., 1995). *R. rhipicephali* has been detected in about 19% of the brown dog ticks (*R. sanguineus*) removed from dogs in central and northern Mississippi and from ticks collected in Texas and North Carolina (Burgdorfer and Brinton, 1975; Burgdorfer et al., 1978). It has also been isolated with high frequency from *Dermacentor andersoni* ticks collected in western Montana (Philip and Casper, 1981). The genome size of *R. rhipicephali* is 1252–1258 kb as determined by pulsed-field gel electrophoresis (Roux et al., 1992).

The mol% G + C of the DNA is: 32.2 (T_m) (Anacker et al., 1980).

Type strain: Burgdorfer 3-7-female 6.

GenBank accession number (16S rRNA): L36216.

This strain was isolated in 1973 in Mississippi by Burgdorfer et al. (Burgdorfer et al., 1975).

18. **Rickettsia rickettsii** (Wolbach 1919) Brumpt 1922, 757^AL (*Dermacentroxenus rickettsii* Wolbach 1919, 87.)
rick.ett′si.i. M.L. gen. *rickettsii* of Ricketts; named after Howard Taylor Ricketts for his classic studies of the etiology of Rocky Mountain spotted fever.

R. rickettsii is the most widely studied species of the spotted fever group. The cells are slightly smaller and more uniform in size than those of *R. prowazekii.*

Because of the high virulence of *R. rickettsii* for chicken embryos, the embryos die before extensive growth has taken place, and the procedure for optimal harvest from yolk sacs differs considerably from the one employed for the typhus group (Table BXII.α.31). It is performed as follows (Stoenner et al., 1962). Embryos, 4–5 d old, are inoculated with a sufficient number of viable cells to kill most embryos within 4–5 d. The eggs are incubated at 33.5°C (lowest temperature compatible with survival of most embryos) and maintained in an incubator at 32°C for 2 d after death of the embryos. Even under the best conditions, yields of *R. rickettsii* cells from yolk sac are smaller than those of *R. prowazekii* or *R. typhi*, but they are somewhat higher than yields obtainable from cell cultures.

Multiplication occurs primarily in the cytoplasm, but intranuclear growth is sufficiently prominent to have stimulated early investigators to use it as a criterion for the classification of the spotted fever group. Because of cell-to-cell spread via actin-based mobility and greater cytopathogenicity, plaques on monolayers occur earlier and are larger than those formed by the typhus group; however, sheep or rabbit erythrocytes are not hemolyzed (Table BXII.α.31).

Strains of this species vary considerably in virulence for the guinea pig. Virulence for humans and guinea pigs appears to vary independently.

The guinea pig is highly susceptible to infection. The more virulent strains induce fever and scrotal necrosis, and the infection is often fatal. In humans, *R. rickettsii* is the causative agent of Rocky Mountain spotted fever, the most severe disease of the spotted fever group. The disease is characterized by high fever and widespread damage to the small blood vessels; this damage results in a skin rash, increased vascular permeability associated with non-cardiogenic pulmonary edema and vascular lesions in various organs including encephalitis. Before the era of the tetracycline and chloramphenicol antibiotics, the case fatality rates were as high as 90% in the Bitterroot Valley of Montana and as low as 5% in the Snake River Valley of Idaho and 25% in Long Island. Because the disease responds well to tetracyclines, present mortality rates are relatively low, provided the disease is recognized and treated promptly. Dogs are susceptible to natural infection and develop clinical signs (Lissman and Benach, 1980). The mouse is quite resistant to infection, and doses in excess of 10^6 viable cells are required to produce a significant antibody response.

The metabolism of *R. rickettsii* is similar to that of other rickettsiae. Biochemical investigations have focused on loss and restoration of viability, and metabolic activity is best maintained under microaerophilic conditions or in the presence of reduced glutathione or protein. Reversible changes in rickettsial activity occur in the tick: prolonged refrigeration reduces the virulence of the rickettsiae for the guinea pig, but virulence is restored when the ticks have a blood meal or are incubated at 37°C for 24–48 h. Spencer and Parker (1923) postulated that virulence of *R. rickettsii* in the tick vector is linked directly to the physiological state of the tick and defined this phenomenon as "reactivation." The reactivation may result from growth of rickettsiae or differential expression of rickettsial virulence factors at the elevated temperature or after stimulation by components of the blood meal. *R. rickettsii* numbers increase 100-fold in the hemolymph of partially engorged ticks compared to unfed infected ticks (Wike and Burgdorfer, 1972). Differential expression of rickettsial proteins and ultrastructural changes has been confirmed by immunoblot and electron microscopy. Electron microscopy reveals that reactivated *R. rickettsii* in ticks incubated at 37°C or in ticks fed on animals has a discrete microcapsular layer and a discrete electron-lucent slime layer outside the microcapsular layer. In starved ticks, the microcapsular layer and the slime layer of rickettsiae are inconspicuous or ragged (Hayes and Burgdorfer, 1982). Immunoblot analysis indicates that rickettsial proteins of 42, 43, 48, 75 and 100 kDa are induced in a tick cell line when the incubation temperature is raised from 28°C to 34°C (Policastro et al., 1997).

In a series of brilliant experiments conducted in 1906 and 1907, Ricketts (1911) clearly established the basic features of the ecology of the agent of Rocky Mountain spotted fever in the tick. *R. rickettsii* is confined to the Western Hemisphere (Table BXII.α.31), but at present, it is encountered much more frequently in the southeastern and central United States, particularly in North Carolina and Oklahoma, than in the Rocky Mountains. In the western

United States, the most common human vector is the wood tick, *Dermacentor andersoni*. In the eastern two thirds of the United States and parts of the Far West, the American dog tick, *Dermacentor variabilis*, is the chief vector. The brown dog tick, *Rhipicephalus sanguineus*, and the cayenne tick *Amblyomma cajennense* have been implicated in transmission of human infections in Mexico and South America.

Although there is considerable serological evidence of widespread exposure to SFG rickettsiae among wild vertebrates and domestic dogs, demonstration of infection by recovery of the microorganisms has been difficult, presumably because sufficient numbers of rickettsiae are present in the vertebrate host only during brief periods. Natural infection among vertebrates was first demonstrated in the 1930s in Brazil in domestic and wild dogs (*Canis brasiliensis*), the opossum (*Didelphis marsupialis*), the wild rabbit (*Sylvilagus minensis*), and the Brazilian capybara (*Cavia aperea*) (Moreira and de Magalhaes, 1937). Recovery of *R. rickettsii* has been reported in the United States (Gould and Miesse, 1954) from the meadow vole (*Microtus pennsylvanicus*), opossum, cotton rat (*Sigmodon hispidus*), cottontail rabbit (*Sylvilagus floridanus*), whitefooted mouse (*Peromyscus* sp.) and pine vole (*Pitymis pinetorum*) (Bozeman et al., 1967). In the western United States, *R. rickettsii* has been isolated from the chipmunk (*Eutamias amoenus*), snowshoe hare (*Lepus americanus*) and the golden-mantled ground squirrel (*Citellus lateratis tescorum*) (Burgdorfer et al., 1962). Rickettsemic cotton rats have been demonstrated experimentally as a source of *R. rickettsii* for *D. variabilis* ticks, and cotton rats are susceptible to the infection when transmitted by tick bite.

Transmission to man occurs through the bite of an infected tick that remains attached to the skin for several hours. Although man is only an incidental host, human infection reflects a changing ecology. From 1910 to 1930 most of the cases, about 100–600 per year, were diagnosed within the area of distribution of *D. andersoni* in the Rocky Mountain region. Since 1930, there has been a decrease in incidence in the Rocky Mountain region along with increased recognition of the disease in the southeastern parts of the United States associated with transmission by *D. variabilis*. From 1948 to 1959, the number of cases decreased from an annual rate of 500 to an annual rate of 200. After 1959, the disease increased to an annual rate greater than 1000 cases by 1977. A decrease in reported cases occurred during the 1980s and early 1990s, but there were hints of an increase in the late 1990s. A strain of *R. rickettsii* has been isolated from patients in Costa Rica (Fuentes, 1979).

The genome is 1,257,710 bp in size and contains 1486 open reading frames and 33 tRNA genes (Eremeeva et al., 2002). The proteins of various strains of *R. rickettsii* have shown no differences except for minor epitope differences of the HLP strain, an isolate that has been identified only in ticks (Anacker et al., 1980).

The mol% G + C of the DNA is: 32.4 (determined from the genome sequence).

Type strain: ATCC VR-149.

GenBank accession number (16S rRNA): L36217.

Strain Sheila Smith was isolated from a patient in Montana (Bell and Pickens, 1953). Reference strain: strain R, was isolated from *Dermacentor andersoni*.

19. **Rickettsia sibirica** Zdrodovskii 1949, 20[AL]
si.bi′ri.ca. M.L. fem. adj. *sibirica* pertaining to Siberia.

This species closely resembles *R. rickettsii*, although most strains are less virulent for animals and humans. Cinematographic observations by Kokorin et al. (1978) have revealed intense mobility of the rickettsiae within their host cells, and some movement from cell to cell, but only limited cytotoxicity occurs. The species is cultivated by procedures identical to those used for *R. rickettsii*. Virulence for the guinea pig is quite variable, and in some cases, only fever of short duration is produced. An occasional strain kills mice and hamsters (Bazlikova and Brezina, 1978), and inbred strains of mice vary in susceptibility to this organism (Kekcheeva et al., 1978). The disease in humans resembles moderately severe or mild Rocky Mountain spotted fever. It is called Siberian or North Asian tick typhus.

This species is differentiated from the other strains of the spotted fever group by DNA sequence analysis of *ompA*, *ompB*, the 17 kDa lipoprotein gene, the citrate synthase gene, or the 120 kDa cytoplasmic antigen gene. Differentiation can also be achieved by immunologic analysis using IFA titration with sera prepared according to a particular protocol in mice (Philip et al., 1978). Toxicity neutralization tests in mice demonstrate the close relationship of *R. sibirica* with *R. rickettsii* (Lackman et al., 1965).

The habitat of *R. sibirica* consists of foci extending from the Pacific Coast of Russia and China in the east to Armenia in the west and from Siberia in the north to northern China in the south. The foci are usually associated with steppe landscapes with low rainfall close to foothills and mountain ranges, and they may extend to the dry slopes of the mountains. *R. sibirica* has been detected in ticks of the following genera: *Demacentor* (*D. nuttalli*, *D. marginatus*, and *D. silvarum*), *Haemaphysalis* (*Ha. punctata*, *Ha. concinna*, and *Ha. japonica*), *Hyalomma* (*Hy. dromedarii*, *Hy. asiaticum*, *Hy. detritum*, *Hy. anatolicum*, *Hy. plumbeum*, *Hy. marginatus*), *Ixodes* (*I. ricinus*, *I. persulcatus*, *I. apronophorus*, and *I. plumbeus*), and *Rhipicephalus* (*R. sanguineus*, *R. turanicus*, and *R. schulzei*). These ticks feed on birds, numerous small wild rodents, and domestic animals. Antibodies to *R. sibirica* have been detected from at least 18 kinds of mammals, including Siberian squirrels or susliks (genus *Citellus*), chipmunks (*Eutamias*), hamsters (*Cricetus*), lemmings (*Lagurus*), hares (*Lepus*), domestic and field mice, and voles (Hoogstraal et al., 1967). *R. sibirica* has been isolated from wild rodents and birds but not from domestic animals. Rodents are the main seasonal reservoir of *R. sibirica* in its natural focus, and birds may serve as the vehicle to establish new foci over long distances. Humans are infected through the bite of an infected tick.

The genome size is 1,255,665 bp in size and contains 1316 open reading frames and 33 tRNA genes (Eremeeva et al., 2002). The electrophoretic migration patterns in polyacrylamide gel of the solubilized proteins are similar but not identical to those of *R. rickettsii* (Pedersen and Walters, 1978).

The mol% G + C of the DNA is: 32.4 (determined from the genome sequence).

Type strain: 246, ATCC VR-151.

GenBank accession number (16S rRNA): L36218.

Strain 246 was isolated from *Dermacentor nuttalli* in the U.S.S.R. about 1949 (Bell and Stoenner, 1960).

20. **Rickettsia slovaca** Sekeyova, Roux, Xu, Rehácek and Raoult 1998, 1458[VP]

slo.va.ca′. L. gen. n. *slovaca* from Slovakia, the country where the organism was first isolated.

The dimensions of the organisms are 0.37–0.45 × 0.8–1.2 μm. *R. slovaca* can be propagated in yolk sacs of chicken embryos, HEL, Vero, L929, and tick cells. No cytopathologic effect is observed in any of the infected cell lines. Electron microscopy reveals that the organisms are free in the host cell cytoplasm and are surrounded by an electron-lucent zone. The organism has very low pathogenicity for mice and guinea pigs. The only observed change in inoculated mice is a slightly enlarged spleen. Guinea pigs develop brief and mild fever after inoculation of the organisms. *R. slovaca* causes asymptomatic infection in *Lepus europaeus* and hamsters. *R. slovaca* has been associated with human infections that are characterized as usually afebrile with an eschar and regional lymphadenopathy after the bite of a *D. marginatus* or *D. reticulatum* tick. *R. slovaca* was isolated from a pool of male and female *Dermacentor marginatus* ticks collected in Slovakia. Rickettsial strains closely related to *R. slovaca* have been isolated from Armenia, Crimea, France, Portugal, Switzerland, Ukraine, and Yugoslavia, in the geographic distribution of *D. marginatus* and *D. reticulatum* (Sekeyova et al., 1998).

The mol% G + C of the DNA is: not determined.

Type strain: B (Reference Center for Rickettsioses, Marseille, France).

21. **Rickettsia typhi** (Wolbach and Todd 1920) Philip 1943, 304[AL] (*Dermacentroxenus typhi* (Wolbach and Todd 1920) *Rickettsia mooseri* Monteiro 1931, 97.)
ty′phi. Gr. n. *typhus* cloud, hence stupor associated with rickettsial encephalitis; M.L. n. *typhus* fever, typhus; M.L. gen. n. *typhi* of typhus.

R. typhi is the valid name for the species, appearing on the Approved Lists of Bacterial Names (Skerman et al., 1980). However, the species has also been called "*R. mooseri*" in honor of Herman Mooser, who clearly differentiated the species from *R. prowazekii* based on its virulence for the guinea pig (Mooser, 1928).

R. typhi is more virulent than *R. prowazekii* for guinea pigs and mice (Table BXII.α.31). Unlike *R. prowazekii*, it can be passed indefinitely in the rat and may persist for months in the rat brain. Rats (*Rattus norvegicus* and *R. rattus*, especially those located in urban areas) and other rodents are the primary reservoirs. *R. typhi* has a worldwide distribution and has been reported from nearly all countries where investigators have competently searched for it. The rat louse, *Polyplax spinulosus*, and the rat flea, *Xenopsylla cheopis*, are the chief transmitters of the organism from rat to rat. The human flea, *Pulex irritans*, and the human body louse are highly susceptible to infection and may play roles in transmission in populations with high ectoparasitic infestation. The rat-rat flea cycle has been interrupted in the United States by control measures, including killing of fleas with DDT. Currently the principal *R. typhi* maintenance cycle in the United States involves the cat flea (*Ctenocephalides felis*) and opossums (*Didelphis virginianus*), and the cat flea is the apparent vector for human infections.

The human disease is a mild form of typhus and is called murine or endemic typhus, but it is also known by names that reflect the geographic location. "Tabardillo" in Mexico might be murine typhus transmitted by lice. Murine typhus is reported with variable frequency, undoubtedly largely because of DDT interruption of the transmission by fleas; for instance, in the United States, a peak of 5400 cases occurred in 1944, but the incidence was less than 100 cases in 1958. Many cases are not properly documented (Traub et al., 1978), due in part to effective treatment of the disease with antibiotics.

Some of the antigens of *R. typhi* demonstrable in serological tests are very similar, if not identical, to those of *R. prowazekii*, while others are species-specific. The antigens containing common epitopes are numerous and include LPS, OmpB, the 17kDa proteins, GroES and GroEL. OmpB-containing species-specific epitopes as well as 10–15% of the total cellular protein are released as a soluble fraction when the cells are suspended in a hypotonic solution that lacks Mg^{2+} and is incubated at 45°C for 20 min (Dasch, 1981). The two species can also be distinguished immunologically by species-specific monoclonal antibodies; cross-absorption of defined antisera and subsequent IFA titration or immunoblotting; cross-challenge of guinea pigs vaccinated with formalin-inactivated antigens; or mouse toxicity neutralization tests.

There have been no extensive attempts to isolate mutant strains of *R. typhi* in the laboratory. Differences between *R. typhi* and *R. prowazekii* in cell morphology and in the mechanism of interaction with eucaryotic cells undoubtedly exist, such as the relatively ineffective actin-based mobility of *R. typhi* as compared to absence of actin-based mobility of *R. prowazekii*; however, objective criteria of differentiation based on such characteristics have not been developed. Differences in metabolic activities have not been described, and the two species have been used interchangeably for metabolic investigations.

The mol% G + C of the DNA of *R. typhi* is similar to that of *R. prowazekii*. The genome size of *R. typhi* is 1,133 ± 44 kb (Eremeeva et al., 1993). Although no differences in the degree of DNA–DNA hybridization have been found between strains of *R. typhi*, the degree of hybridization between *R. typhi* and *R. prowazekii* is 70–79%, (Myers and Wisseman, 1980). Similarly, no differences in electrophoretic protein migration patterns have been noted between strains of *R. typhi*, but consistent differences in the migration patterns of malate dehydrogenase and of several unidentified proteins have been found between *R. typhi* and *R. prowazekii* (Dasch et al., 1978).

The mol% G + C of the DNA is: 29 (T_m).

Type strain: Wilmington, ATCC VR-144.

GenBank accession number (16S rRNA): M21789.

Strain ATCC VR-144 is that of Maxcy (1929).

Other Organisms

1. *"Rickettsia amblyommii"*

A rickettsial agent that was first described by Burgdorfer et al. (1974) was later characterized as a new SFG rickettsia and referred to as WB-8-2 (Burgdorfer et al., 1981). WB-82-2 was isolated from an *Amblyomma americanum* tick collected from vegetation in Tennessee (Burgdorfer et al., 1974). The organism invades all tick tissues but, in general, produces a mild to moderate infection except in the ovary

where it may be abundant and from where it is passed via eggs to as many as 100% of progeny. The organism grows well in avian cell cultures but very poorly in embryonated hen's eggs, which die 5–7 days after inoculation. WB-8-2 is nonpathogenic for guinea pigs. In male meadow voles (*Microtus pennsylvanicus*), it produces microscopically detectable mild and transient infections in the tunica vaginalis only after inoculation of heavily infected tissue culture suspensions. Epidemiological evidence suggests that WB-8-2 is nonpathogenic for humans (Burgdorfer et al., 1981). Weller et al. (1998) isolated another strain of this rickettsia (MOAa) from an adult female *A. americanum* tick collected in Bolling County, Missouri. The MOAa organism is highly cytopathogenic for RAE25 cells, a tick cell line. Phylogenetic analysis indicates that strains MOAa and WB-8-2 are closely related. They represent different strains of *"Rickettsia amblyommii"*. Stains MOAa and WB-8-2 are most closely related to *R. montanensis* (Weller et al., 1998).

2. *"Rickettsia cooleyi"*

A rickettsial agent exists in *Ixodes scapularis* ticks collected from Anderson County in eastern Texas. The organism has not yet been cultivated. It was identified by amplification of rickettsial genes by the polymerase chain reaction. DNA sequencing showed the highest nucleotide sequence similarity with *R. australis* for the 17-kDa protein gene, with *R. helvetica* for *gltA*, and with *R. montanensis* for *ompA*. The organism was provisionally designated as the Cooleyi agent after Dr. Robert A. Cooley, who served the Montana State Board of Entomology from 1899 to 1944 (Billings et al., 1998). Weller et al. (1998) have also sequenced *ompA* of a symbiont in ovarian tissues of *I. scapularis*. The *ompA* sequences of the *I. scapularis* symbiont and *"Rickettsia cooleyi"* are identical.

Species Incertae Sedis

1. **"Rickettsia monacensis"** Simser, Palmer, Fingerle, Wilske, Kurtti and Munderloh 2002.

mo.na.cen'sis. M.L. n. *Monacum* Munich, a German city; M.L. adj. *monacensis* from/of Munich.

The name has been proposed for a rickettsial agent that exists in *Ixodes ricinus* collected in the English Garden in Munich, Germany (Simser et al., 2002). The cell size is 1.0–1.5 × 0.3–0.4 µm. The organisms resemble SFG rickettsiae in their ultrastructure, and they reside free in the cytoplasm and occasionally within the nuclei of host cells. The slime layer is thinner (<30 nm) than that of *R. rickettsii* (30–60 nm). This rickettsia was originally isolated by using a tick cell line (ISE6) and subsequently cultivated in L-929 cells. The organisms are cytopathic for ISE6 cells and cause cell lysis after the third passage. The rickettsia induces polymerization of host actin in both tick and mammalian cells. The immunodominant proteins are OmpA and OmpB. Phylogenetically the organism is distantly related to other SFG rickettsiae. Its pathogenicity for animals and humans is unknown.

The mol% G + C of the DNA is: not determined.

Deposited strain: Type strain: IrR/Munich.

Strain IrR/Munich was isolated from a female *I. ricinus* tick (deposited by U. Munderloh at the Rickettsial and Ehrlichial Diseases Research Laboratory, University of Texas Medical Branch, Galveston, Texas, USA).

Genus II. **Orientia** *Tamura, Ohashi, Urakami and Miyamura 1995, 590^{VP}*

XUE-JIE YU AND DAVID H. WALKER

O'ri.en'ti.a. M.L. fem. n. *Orientia* pertaining to the Orient, the area where the organisms are widely distributed.

Short rods 0.5–0.8 × 1.2–3.0 µm. **Obligately intracellular. Grow free in the cytosol of the host cell**; rarely invade the nucleus. Bacterial cells are released surrounded by host cell membrane. **Cell walls lack lipopolysaccharide and peptidoglycan.** The outer leaflet of the cell wall is considerably thicker than the inner leaflet, unlike the wall of rickettsiae. The genome of *Orientia* is 1.1–1.5 × 10^9 Da, larger than that of *Rickettsia*. Maintained by transovarian transmission in its various **trombiculid mite hosts**. **Etiological agents of scrub typhus in humans.** Transmitted to humans by mite larvae. Found in Asia and Australia.

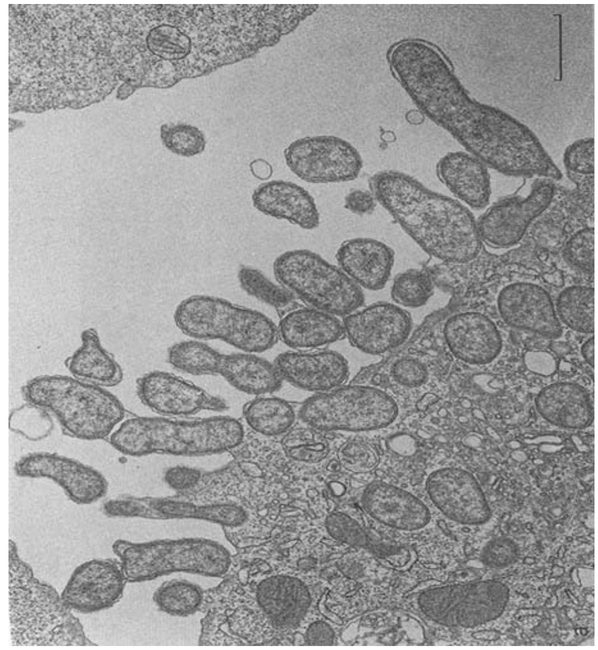
The mol% G + C of the DNA is: 28.1–30.5 (HPLC).

Type species: **Orientia tsutsugamushi** (Hayashi 1920) Tamura, Ohashi, Urakami and Miyamura 1995, 590 (*Rickettsia tsutsugamushi* (Hayashi 1920) Ogata 1931, 252; *"Theileria tsutsugamushi"* Hayashi 1920, 63.)

FURTHER DESCRIPTIVE INFORMATION

16S rRNA gene analysis indicates that the organisms are separate from the *Rickettsia* species, with a similarity value of 90.2–90.6%. This genus contains a single species, *O. tsutsugamushi*.

Cell structure *O. tsutsugamushi* is stained by a modification of the Giménez procedure used for the other rickettsiae; this modified procedure requires preliminary destaining with ferric nitrate and counterstaining with fast green. This species is also satisfactorily stained by Giemsa stain after Carnoy's fixation.



In ultrathin sections, *O. tsutsugamushi* is surrounded by a cytoplasmic membrane and a cell wall, with a clear periplasmic space between the cytoplasmic membrane and cell wall. In the cytoplasm, the electron-dense ribosome-rich area and the less dense network area with DNA fibers are distinctive. Orientiae possess an unusual Gram-negative cell wall that lacks lipopolysaccharide and peptidoglycan. The outer leaflet of the cell wall is considerably thicker than the inner leaflet, while the opposite is true of *Rickettsia* (Fig. BXII.α.36, F and G) (Silverman and Wisseman, 1978). Possibly as a result, *O. tsutsugamushi* manifests much greater tenacity of adherence to host cell components, which renders purification much more difficult. In contrast to *Rickettsia*, *O. tsutsugamushi* does not have an electron-lucent zone.

Cultivation *O. tsutsugamushi* is cultivated well in the yolk sac of 5–7 d old chicken embryos if the inoculum is relatively large

(10^4–10^6 viable cells per egg) and if the rickettsiae are harvested just before the death of the embryos. It is also cultivated well in various cell lines, including HeLa, BHK, Vero, and L929 cells. *O. tsutsugamushi* produces small plaques on cell monolayers after 11–17 d of incubation. CO_2 enrichment is not necessary for intracellular growth (Kopmans-Gargantiel and Wisseman, 1981).

Mice are highly sensitive to infection with *O. tsutsugamushi*. Mice have been used for primary isolation and passage of orientiae. Mice are more sensitive to orientiae by intraperitoneal inoculation than by subcutaneous inoculation.

Multiplication cycle in host cells Orientiae reside free in the cytosol of the host cell. They enter the host cell by attachment and induce phagocytosis. The adhesin has not been identified, but host cell surface heparan sulfate glucosaminoglycan plays a role as a receptor (Ihn et al., 2000). To escape the phagosome, orientiae have to be metabolically active (Rikihisa and Ito, 1982). Movement of orientiae within the cytoplasm to the perinuclear microtubule organizing center, where they replicate, is mediated by microtubules through interaction with dynein—the minus end-directed microtubule associated motor protein—rather than via F-actin tails (Kim et al., 2001). In mouse peritoneal mesothelial cells, *O. tsutsugamushi* multiplies in the cytoplasm, moves to the cell periphery, and separates from the cell surface surrounded by a host cell membrane (Tsuruhara et al., 1982) (Fig. BXII.α.38). Orientiae that are enveloped by the host membrane enter other mesothelial cells, apparently by a phagocytic mechanism. The organisms escape from the phagocytic vacuole as the vacuole membrane and host cell membrane coat disintegrate (Ewing et al., 1978). Cells heavily infected with orientiae undergo apoptotic cell death in association with decreased content of focal adhesion kinase and paxillin, decreased actin stress fiber polymerization, and decreased expression of anti-apoptotic Bcl-2 (Kee et al., 1999). *O. tsutsugamushi* achieves a high intracytoplasmic density, especially in the perinuclear region, and only rarely invades the nucleus.

FIGUREBXII.α.38. Electron photomicrograph of *Orientia tsutsugamushi* budding from a host cell at 72 h post infection. Photograph courtesy of A. Tamura and H. Urakami.

Nutrition and metabolism There is little information about the nutrition and metabolism of *O. tsutsugamushi*, a topic that has been neglected in the past 20–30 years. *O. tsutsugamushi*-infected cells incorporate ^{14}C labeled amino acids and adenine at a much higher level than uninfected cells during the period from 3–6 days postinoculation (Weiss et al., 1973). *O. tsutsugamushi* incorporates radiolabeled proline into rickettsial protein (Tamura et al., 1982). In contrast to *Rickettsia*, orientiae do not require CO_2 for growth (Kopmans-Gargantiel and Wisseman, 1981).

Antigenic structure The major proteins of *O. tsutsugamushi* have the following sizes: 110, 80, 70, 60, 56, 47, 42, 35, 28, and 25 kDa (Tamura et al., 1985). Except for the 70- and 60-kDa proteins, all of these are surface proteins. The 56, 28, and 25 kDa proteins are heat labile; they migrate at molecular sizes of 43, 25, and 21 kDa, respectively (Urakami et al., 1986) when they are not heat denatured. The most abundant antigens of *O. tsutsugamushi* are the 60-kDa heat shock protein and the 56-kDa surface protein. The 60-kDa protein is the homolog of the GroEL protein family (Stover et al., 1990). Genetic analysis of the DNA sequence of *groESL* of isolates from several geographic foci has revealed a limited number of variants within each focus and a diversity of strains from focus to focus. In spite of its cytoplasmic location, the 60-kDa protein stimulates antibodies in the sera of some acutely ill patients (Ohashi et al., 1988). The 56-kDa protein varies among geographic isolates of *O. tsutsugamushi* and thus is called type-specific antigen (TSA; Ohashi et al., 1992). The TSAs of six *Orientia* antigenic variants range from 55,308 to 56,745-daltons with 521–532 amino acids. TSA has the feature of transmembrane proteins with alternating hydrophobic and hydrophilic regions. Analysis of the TSAs of *Orientia* variants has revealed four variable domains with spans of 16–40 amino acids. The variable domains are located in the hydrophilic regions of the molecule that are likely surface-exposed and show different amino acid sequences among the strains (Ohashi et al., 1992). Early studies of *Orientia* isolates demonstrated three antigenic types: Gilliam, Karp, and Kato. Phylogenetic analyses based on homologies of 56-kDa type-specific antigen genes have classified *Orientia* isolates from China, Korea, Japan, and southeast Asia into seven genotypes designated Gilliam, Karp, Kato, Kawasaki, Kuroki, Shimokoshi and LX-1. All isolates originating in southeast Asia—including the prototype Gilliam and Karp strains isolated in Burma and New Guinea, respectively—are distantly located in the phylogenetic tree from the isolates originating in Japan, Korea, and China; this finding indicates that strains of *O. tsutsugamushi* distributed in northeastern and southeastern Asia are of different types (Enatsu et al., 1999). The antigenic variability of *Orientia* poses a challenge for vaccine design. Immunization with *Orientia* confers relatively strong protection that lasts only 1–3 years against challenge by the homologous strain, whereas protection is very weak and short-lived against heterologous strains (Seong et al., 2001).

The mol% G+C of the DNA of *Orientia* strains is similar to that of TG rickettsiae but lower than that of SFG rickettsiae. The genome of *O. tsutsugamushi* is $1.1–1.5 \times 10^9$ Da and consists of 2,400–2,700 kbp, as determined by pulse field gel electrophoresis. The genome of *Orientia* is larger than that of *Rickettsia*. The 16S rRNA gene sequence similarity among the antigenic variants of *O. tsutsugamushi*, including the Gilliam, Kato, Karp, Kawasaki, Kuroki, and Shiimokoshi strains, is $\geq 98.5\%$.

When injected intraperitoneally into mice, virulent strains of *O. tsutsugamushi* cause peritonitis, splenomegaly and death in 10–24 days. However, strains can vary greatly in virulence. The Karp strain, for example, is more virulent than the Gilliam strain for most outbred mice. Certain inbred mouse strains are highly resistant to the Gilliam strain; this resistance is controlled by a single, autosomal, dominant gene and does not involve susceptibility to the Karp strain (Groves et al., 1980).

Ecology *Orientia tsutsugamushi* is maintained by transovarian transmission in its various trombiculid mite hosts. Scrub typhus cases occur when larval mites (chiggers) encounter humans as a source of a tissue fluid meal taken from the skin. Each mite host species has its own geographic distribution and seasonal activity pattern that determine the occurrence of scrub typhus (Audy, 1968). Because mites feed on their host only once, the role of the rodents in the maintenance of the natural cycle of rickettsial infection appears even more remote than in the case of the spotted fever rickettsiae. Although wild rats become infected and chiggers acquire rickettsiae when feeding on rats, the chiggers do not transmit the organisms to the next generation (Traub and Wisseman, 1974). *Orientia* requires no other host than the mite in its life cycle.

Orientia tsutsugamushi is encountered in an area of the Orient that extends from India and Pakistan in the west to Japan, the northern portions of Australia, and the intervening islands in the Pacific Ocean in the east and includes southeastern Siberia, Korea, southeast Asia, southern China, the Philippines and Indonesia. These rickettsiae are usually found in circumscribed foci or "ecological islands," which have the proper vegetation and proper concentration of mites and their wild rat hosts. The habitats are usually characterized by the presence of changing ecological conditions, wrought by man or nature, and expressed by transitional types of vegetation (Traub and Wisseman, 1974).

The mite most commonly associated with scrub typhus is *Leptotrombidium deliense*, but several other trombiculid mites, including *L. fletcheri*, *L. akamushi*, *L. arenicola*, and *L. scutellare*, have been shown to be naturally infected and to transmit the rickettsia transovarially. Shortly after its emergence from the egg, the six-legged larva, or chigger, either remains in the soil or travels upward a few cm on debris or dead vegetation until it can attach and burrow into the skin of any animal it happens to contact. Following a meal of tissue juices, it returns to the soil to resume a free-living existence. The vertebrates most commonly infected are rodents of the genus *Rattus*, although isolations from temperate zone rodents, including *Apodemus* and *Microtus*, have been reported. The wide dissemination of *O. tsutsugamushi* on islands that are separated from each other and from the mainland by large bodies of water can best be explained by assuming that migrant birds play a role in the transport of the chiggers (Traub and Wisseman, 1974).

Enrichment and Isolation Procedures

Orientia tsutsugamushi is isolated by inoculation of mice, cell culture, or embryonated chicken eggs, as described above. *O. tsutsugamushi* can be identified by polymerase chain reaction amplification of the DNA of a species-specific gene, DNA sequencing of genes that are available in sequence databases, and reactivity with species-specific antibodies.

The cell wall of *Orientia* is fragile and is easily disrupted by mechanical treatment, such as strong homogenization and osmotic shock. Orientiae are also very adherent to one another, and it is difficult to resuspend them once they are pelleted. Renografin density gradient centrifugation is not suitable for the purification of orientae. Percoll density gradient centrifugation is the choice for their purification because Percoll has no osmotic effect, and the purification procedure does not involve the pelleting of the organisms until the final stage (Tamura et al., 1982).

Orientia-infected cells are harvested by centrifugation at 300 $\times$ g for 10 min and suspended in 1% of the original volume in buffer containing 0.033 M Tris hydrochloride, pH 7.4, and 0.25 M sucrose (TS). The cells are homogenized with a tissue homogenizer with 20–30 strokes. The homogenate is centrifuged at 200 $\times$ g for 10 min. The supernatant is mixed with 40% Percoll in TS buffer and centrifuged at 25,000 $\times$ g for 60 min. Two bands are formed in the centrifuge tube. The upper band (near the top) consists of cell debris and is removed by suction. The lower band (near the bottom) consists of orientiae and is collected with a capillary pipette. The orientiae are washed by centrifugation at 6,000 $\times$ g for 20 min in TS buffer.

Maintenance Procedures

Stocks of *O. tsutsugamushi* are usually preserved frozen at $-70°$ to $-80°$ or in the vapor phase of liquid nitrogen. They may also be preserved in a lyophilized state. The diluent most frequently used is SPG (0.22 M sucrose, 0.01 M potassium phosphate (pH 7.0) and 0.005 M potassium glutamate) (Bovarnick et al., 1950).

Differentiation of the genus *Orientia* from other genera

Orientiae grow free in the cytoplasm or nucleus as compared to *Anaplasma*, *Ehrlichia* and *Coxiella*, which grow in the cytoplasm within a vacuole. The characteristics for differentiation between *Rickettsia* and *Orientia* are summarized in Table BXII.α.32 in the chapter on the genus *Rickettsia*.

Taxonomic Comments

O. tsutsugamushi, formerly called *Rickettsia tsutsugamushi*, was removed from the genus *Rickettsia* based on the phylogenetic differences between the two genera (Tamura et al., 1995). Phylogenetic analysis of 16S rRNA gene sequences reveals that *O. tsutsugamushi* is located apart from the *Rickettsia* species with a similarity value of 90.2–90.6% (Tamura et al., 1995) (Fig. BXII.α.35).

List of species of the genus Orientia

1. **Orientia tsutsugamushi** (Hayashi 1920) Tamura, Ohashi, Urakami and Miyamura 1995, 590 (*Rickettsia tsutsugamushi* (Hayashi 1920) Ogata 1931, 252; *"Theileria tsutsugamushi"* Hayashi 1920, 63.)

   tsu.tsu.ga.mu.shi. M.L. n. *tsutsugamushi* popular name of the disease caused by this species, generally interpreted to mean mite disease.

   The description of the species is the same as that of the genus.

   The mol% G + C of the DNA is: 28.1–30.5 (HPLC).

   Type strain: Karp, ATCC VR-150.

   GenBank accession number (16S rRNA): D38623, U17257.

   The type strain is that of Derrick and Brown (1949). Reference strains include Gilliam, ATCC VR-312 (Bennett et al., 1949), and Kato, ATCC VR-609 (Shishido et al., 1958).

Family II. **Anaplasmataceae** Philip 1957, 980[AL] emend. Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2156

J. Stephen Dumler, Yasuko Rikihisa and Gregory A. Dasch

A.na.plas.ma.ta' ce.ae. M.L. *Anaplasma* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Anaplasmataceae* type genus of the family.

Rickettsial organisms pathogenic for certain mammals, including man, and birds; non-pathogenic for some arthropods, insects, and helminths. **The predominant mammalian host cells are of bone marrow or hematopoietic origin**, including erythrocytes, monocytes or macrophages, neutrophils, and platelets. Also may grow within tick or other invertebrate cells. Members of the family share a high degree of nucleotide sequence similarity in regard to 16S rDNA and to the *groESL* operon. The **organisms grow within a cytoplasmic vacuole, but not in the nucleus;** they appear as compact to loose inclusions containing as few as one to many individual organisms. Infected cells may contain more than one inclusion per cell. The mulberry-like appearance of the inclusions has led to the use of the term "morulae" for them. **Organisms may have two distinct morphological forms: dense-core and reticulate bodies**. Gram negative. Nonmotile. **Certain species are adapted to existence in ticks.** Some differential characteristics of the genera of *Anaplasmataceae* are shown in Table BXII.α.33.

Type genus: **Anaplasma** Theiler 1910, 7 emend. Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2157.

TABLE BXII.α.33. Key to the genera of the family *Anaplasmataceae*.

	Anaplasma	*Ehrlichia*	*Neorickettsia*	*Wolbachia*
Host cell infected	Erythrocytes, granulocytes	Mononuclear phagocytes, granulocytes	Mononuclear phagocytes, trematode cells	Arthropod ovaries
Ultrastructural morphology	Multiple bacteria in single vacuole; no intravacuolar fibrillar matrix ; vacuoles do not contact mitochondria and endoplasmic reticulum	Multiple bacteria in single vacuole; intravacuolar fibrils present; vacuoles contact mitochondria and endoplasmic reticulum	Small clusters or individuals cells within vacuoles; vacuoles divide with bacterial division	Single bacteria within vacuoles; vacuoles contact endoplasmic reticulum
Mol% G+C of the DNA	43–56	32–46	30–43	Not known

Genus I. **Anaplasma** *Theiler 1910, 7[AL] emend. Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2157*

J. Stephen Dumler, Yasuko Rikihisa and Gregory A. Dasch

A.na.plas' ma. Gr. pref. *an* without; Gr. n. *plasma* anything formed or molded; M.L. neut. n. *Anaplasma* a thing without form.

Small, often pleomorphic, coccoid to ellipsoidal cells 0.3–0.4 μm in diameter found in cytoplasmic vacuoles in mammalian host cells, often in inclusion bodies (morulae) in mature or immature hematopoietic cells, in peripheral blood, or in tissues, usually organs containing mononuclear phagocytes (spleen, liver, bone marrow) of mammalian hosts. Morulae are suspended in a nonfibrillar matrix. Two morphologic forms: larger reticulate cells and smaller "dense core" forms. In blood smears stained by Romanowsky methods, the organisms appear as dense, homogeneous, bluish-purple, round inclusions 0.3–2.5 μm in diameter. Gram negative. Nonmotile. No spores or resistant stages. **Ticks are the only known biological vectors**; mechanical vectors include biting flies or other fomites. The organisms can be propagated in tick spp. Some anaplasmas can be propagated in tick cell lines or mammalian cells of hematopoietic origin. **Cause disease in canids, humans, and ruminants.** Variably pathogenic in cattle, goats, sheep, deer, horses, and rodents. Placed in the *Alphaproteobacteria* by **16S ribosomal RNA sequence analysis; organisms possess not less than 96% 16S rRNA gene similarity**. Where studied, these bacteria possess major surface protein genes with a high degree of sequence similarity nontandemly dispersed throughout the chromosome.

The mol% G + C of the DNA is: 43 and 56.

Type species: **Anaplasma marginale** Theiler 1910, 7.

Further descriptive information

Phylogeny By 16S rRNA gene and *groESL* operon sequence analysis, the genus *Anaplasma* forms a clade distinct from *Ehrlichia*, *Wolbachia*, *Neorickettsia*, *Rickettsia*, and *Orientia* in the *Alphaproteobacteria*, Order *Rickettsiales*. When 16S rRNA gene and *groESL* operon sequences are aligned, all species in the genus are more than 96% and 74% similar, respectively. Where investigated, organisms possess multiple similar genes that encode major surface proteins that vary in molecular size from approximately 36 to 49 kDa. The bacteria are only distantly related to other obligate intracellular bacteria in genera such as *Chlamydia* and *Coxiella*, and unrelated to bacteria lacking a cell wall, such as *Eperythrozoon* and *Haemobartonella*.

Cell morphology *Anaplasma* species stain bluish-purple with Romanowsky methods. They occur in membrane-bound vacuoles in the cytoplasm of cells of hematopoietic origin, forming inclusions that contain variable numbers of organisms (Simpson, 1972, 1974; Hildebrandt et al., 1973) (See Fig. BXII.α.39). Various spe-

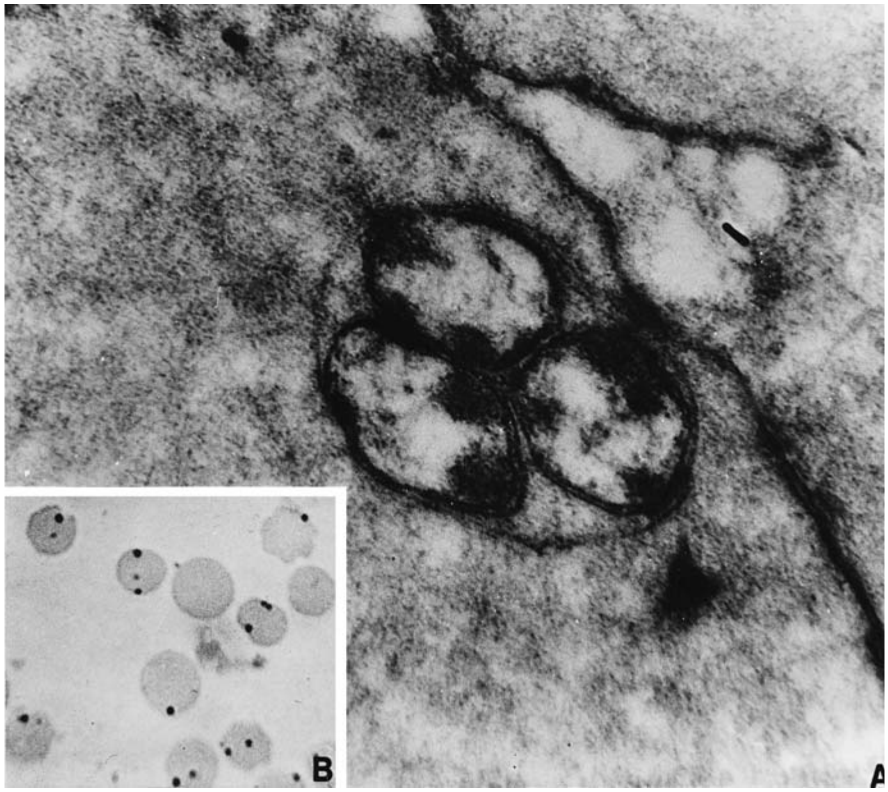


FIGURE BXII.α.39. *Anaplasma marginale. A*, Transmission electron micrograph of an infected erythrocyte. Three individual bacteria bound by cell wall and plasma membrane and lacking intravacuolar fibrils and tubules are shown within the vacuole (× 51,000). *B*, Intraerythrocytic inclusion bodies stained by a Romanowsky method (Giemsa stain, × 815).

cies infect predominantly erythrocytes, neutrophils, or mononuclear phagocytes *in vivo*. The individual organisms are approximately 0.3 μm in diameter but may vary considerably in size and shape. Inclusions (morulae) range in size up to 4.0 μm in diameter. The organisms are weakly Gram-negative. Anaplasmas are best stained with Romanowsky stains, where the organisms develop a dark blue appearance as opposed to the violet color of the eucaryotic cell nucleus. The organisms stain poorly with the Giménez method but easily with acridine orange.

Cell wall composition Little is known of the components of the cell wall of *Anaplasma* spp. Lipopolysaccharide and lipooligosaccharide have not yet been detected, and it is not known if the cell wall contains peptidoglycan.

Fine structure By electron microscopy, anaplasmas reside within membrane-bound vacuoles that are very early endosomes for *Anaplasma phagocytophilum* (Webster et al., 1998; Mott et al., 1999). The ultrastructure of the cell envelope reveals simple inner and outer leaflets similar to those of Gram-negative bacteria (Popov et al., 1998). The internal structures consisting of chromatin strands and ribosomes are readily visualized. Two distinct morphologic forms may be detected: dense-core forms that contain a relatively dense central or eccentrically-placed condensation of chromatin strands, and reticulate cell forms that contain a homogeneous loose matrix of chromatin strands, among which ribosomes are also spread. Reticulate forms are typically identified *in vivo*, and dense core forms are identified predominantly during *in vitro* propagation. Both forms undergo binary fission, suggesting that a developmental cycle associated with these morphologies is unlikely. *Anaplasma* species may produce an abundant membrane, which on occasion wraps around individual cells or invaginates into the cell. Unlike the genus *Ehrlichia*, *Anaplasma* species lack a fibrillar matrix within the vacuolar space.

Cultural characteristics *A. phagocytophilum* has been successfully propagated in primary human neutrophil cultures and in a variety of human (Goodman et al., 1996) and non-human myeloid or myelogenous lineage cell lines (HL-60, THP-1, M1). *A. phagocytophilum* and *A. marginale* have also been propagated in tick cell tissue culture (Munderloh et al., 1996a, b). Limited propagation of *A. marginale* in erythrocyte culture has also been achieved. No *Anaplasma* species has been cultivated on cell-free media. In cell culture, infection is observed at first with one or few bacteria within the vacuole, previously referred to as an initial body. With continued binary fission of the bacteria, increasingly larger intravacuolar microcolonies are formed, which are called intermediate bodies or morulae, depending upon size. Ultrastructural examination has shown that all vacuoles may contain either reticulate cells, dense-cored cells, or both, and that each of these forms undergoes binary fission; these findings argue against a well-defined intracellular life cycle, as observed for *Chlamydia* spp. Multiple infected vacuoles may exist in a single cell, presumably owing to the lack of fusion of infected endosomes.

For *A. marginale*, recent data suggest that a restricted set of major surface protein genes (*msp2*) may be transcribed during tick infection. However, these results were not corroborated when different strains were examined, which again argues against distinct life cycle-specific bacterial components.

Antigenic structure All *Anaplasma* species contain a multigene family encoding major surface proteins that are the immunodominant antigens of the genus. The genes are generally characterized by the presence of highly conserved 5′ and 3′ sequences that flank a hypervariable core region (Barbet, 1995; Zhi et al., 1998; Viseshakul et al., 2000). One or several of these genes may be transcriptionally active to produce protein antigens of various molecular sizes ranging from 36 to 49 kDa (Asanovich et al., 1997). Other antigenic components may be conserved among species, such as the heat shock proteins (GroESL), or they may be species-specific.

Antibiotic sensitivity All *Anaplasma* species are susceptible to tetracycline antibiotics. Some fluoroquinolone antibiotics, such as enrofloxacin and trovofloxacin, have *in vivo* and *in vitro* efficacy for some species (Guglielmone et al., 1996; Klein et al., 1997). Anaplasmas are not susceptible to β-lactam antibiotics, aminoglycosides, macrolides, chloramphenicol, or sulfa-containing drugs.

Pathogenicity Little is known about the mechanisms by which *Anaplasma* species cause disease. *In vitro*, infected cells undergo both necrosis and apoptosis, and erythrocytes may lyse (Goodman et al., 1996; Waghela et al., 1997). The *in vivo* infection may be associated with febrile hemolytic anemia for *A. marginale*, and with non-specific febrile illness with leukopenia, mild anemia, thrombocytopenia, and mild hepatic injury for *A. phagocytophilum*. While the anemia associated with *A. marginale* may result from direct erythrocyte lysis, it is highly unlikely that the degree of cytopenia observed with *A. phagocytophilum* infections results from direct cytolysis of infected cells (Bakken et al., 1996). *"A. platys"* is associated with febrile cyclical thrombocytopenia associated with the appearance of morulae in platelets in peripheral blood. It is likely that most infections are asymptomatic. Clinically apparent infection may be observed in a range of animals including cattle, goats, sheep, deer, llamas, dogs, horses, and humans.

Anaplasma species gain access to their host cells by adherence to surface components that generally are glycosylated scaffold proteins (McGarey and Allred, 1994; Herron et al., 2000). After adherence, the bacteria are internalized and remain within vacuoles that are early endosomes for *A. phagocytophilum* (Mott et al., 1999). Infection of granulocytic cells *in vitro* results in the secretion of chemokines (Klein et al., 2000), whereas infection of neutrophils *in vitro* results in delayed apoptosis (Yoshiie et al., 2000).

Ecology Ticks are vectors for all *Anaplasma* species that have been studied. *Dermacentor andersoni*, *Boophilus microplus*, *Ixodes scapularis*, *I. pacificus*, and *I. ricinus*, among other ticks, are important biological vectors. Mechanical vectors, such as male ticks and biting flies are also important for transmission of *A. marginale*. *Anaplasma* species are ingested by adult and nymphal stage ixodid ticks when feeding on an infected host. The bacteria are maintained in the tick by transstadial, but not transovarial transmission; thus, emergent larval ticks are not infectious. Domestic and wild ruminants—especially cervids—may be important reservoirs for all species of the genus. Other important reservoirs for *A. phagocytophilum* include small mammals such as mice and other rodents.

Enrichment and Isolation Procedures

Both *A. marginale* and *A. phagocytophilum* have been isolated by inoculation of whole blood in tick cell cultures (Munderloh et al., 1996a, b), whereas *A. phagocytophilum* is easily isolated in granulocyte cell cultures using whole blood or leukocyte preparations (Goodman et al., 1996). *Anaplasma* species are obligately intracellular bacteria that cannot be isolated by axenic methods. Isolation has also been achieved by inoculation of fresh or frozen blood from infected animals into naïve susceptible animals, such as cows for *A. marginale* and horses or mice for *A. phagocytophilum*.

Maintenance Procedures

A. marginale can be maintained for long periods in tick cell culture, and for shorter periods in erythrocyte cultures (Munderloh et al., 1996b; Waghela et al., 1997). *A. phagocytophilum* can be maintained for long periods (>1 year) by serial propagation in granulocyte cell lines such as HL-60 cells, although *in vitro* passage may alter the propensity of the bacteria to elicit clinical manifestations in susceptible animals (Goodman et al., 1996; Pusterla et al., 2000a). Cultured cells containing the bacteria may be stored in medium containing 30% fetal bovine serum and 10% dimethyl sulfoxide at −80°C for months to years, and in liquid nitrogen for years. Both *A. marginale* and *A. phagocytophilum* can be maintained by serial passage in susceptible animals hosts. Neither *A. bovis* nor *"A. platys"* have been cultivated *in vitro*.

Differentiation of the genus *Anaplasma* from other genera

Anaplasma species may be morphologically difficult to distinguish from *Ehrlichia* and *Neorickettsia* species that grow within bone marrow-derived cells. The genus is separated from related genera by its obligate intracellular growth in bone marrow-derived cells or tick cells, by its growth within a vacuole of the infected host cell, and by finding similarities of >97% in the 16S rRNA gene sequence or >74% in the *groESL* operon sequences compared to sequences of established strains.

Taxonomic Comments

Phylogenetic comparisons comprise the most objective comparators and are used as the major tool to evaluate genetic similarities and to establish objective and reproducible taxonomic criteria that cannot be achieved reliably with phenotypic or clinical data. *A. marginale* is the most distinct species in the genus in terms of phenotypic and genotypic characteristics; in fact, some authorities consider this taxon to qualify for a separate genus position.

A. marginale, *A. ovis*, and *A. centrale* are all recognized as valid species in the genus *Anaplasma*. However, the 16S rRNA gene sequences of strains of each, with the exception of a single Japanese strain, are at least 99.1% similar. Thus, it is likely that these represent single species variants, as initially suggested by Theiler (1911). Moreover, the tight clustering of erythrocytic anaplasmas with *A. marginale* is also supported by other genotypic and phenotypic characters, including shared 19, 36, and 105 kDa protein antigens (McGuire et al., 1984, Palmer et al., 1988a, Visser et al., 1992, Palmer et al., 1998). Although *A. caudatum* is proposed and listed as a unique species, some authorities believe that it is a species synonomous with *A. marginale* that represents an artifact of experimental, rather than natural, tick-transmitted infection. A strain of *A. centrale* exists that has 1.8% 16S rRNA gene nucleotide divergence from other *A. centrale* and *A. marginale* strains that were phenotypically characterized, casting significant doubt on morphological methods of taxonomy for this species and genus and suggesting that other erythrocytic *Anaplasma* species exist. Additional study will be required to delineate the precise taxonomic relationships among these closely related bacteria.

The name *Anaplasma* was selected by Dumler et al. (2001) for the emended, newly combined genus because of historical precedence (Theiler, 1910). The exact identity of the previously described *"Cytoecetes microti"* (Tyzzer, 1938) is not certain; however, there is a clear phenotypic similarity to *A. phagocytophilum*. The name *"Cytoecetes"* is not recognized on the Approved Lists of Bacterial Names, but if sufficient data become available that support the separation of *Anaplasma marginale* (and other erythrocytic anaplasmas such as *A. ovis*) from *A. phagocytophilum*, *A. bovis*, and *"A. platys"*, the designation *"Cytoecetes"* would have historical precedence and would be validly published.

Differentiation of the species of the genus *Anaplasma*

The preferred method for definitive identification of *Anaplasma* species depends upon sequence analysis of all or part of the 16S rRNA gene or the *groESL* operon or by PCR amplification using species-specific oligonucleotide primers. The full 16S rRNA gene sequence may be identified by many different methods, including commercially available systems such as the MicroSeq™ Full Gene 16S rDNA Bacterial Sequencing Kit (Applied Biosystems, Foster City, CA). Species-specific primers for *A. marginale*, *A. phagocytophilum* and *"A. platys"* are shown in Table BXII.α.34. Various methods and protocols for diagnostic identification in clinical samples have been described; the diagnostic sensitivity and specificity should be determined by each laboratory performing the clinical assay.

See Table BXII.α.35 for key features of Anaplasma species.

List of species of the genus Anaplasma

1. **Anaplasma marginale** Theiler 1910, 7[AL]

mar.gi.na′ le. L. n. *margo, marginis* edge, margin; M.L. neut. adj. *marginale* marginal, referring to location of the organism within the erythrocytes.

The characteristics are as described for the genus and as listed in Tables BXII.α.35 and BXII.α.36. See also Fig. BXII.α.39.

A. marginale is the causative agent of bovine anaplasmosis, a severe febrile hemolytic anemia of cattle that occurs after tick bites or mechanical transmission by other arthropods. The disease is worldwide in distribution.

A. marginale possesses polymorphous major surface proteins (MSPs), several of which are similar to proteins in *A. phagocytophilum* and some of which are encoded by multigene families (Barbet, 1995). A low level, cyclical, persistent infection is established and is accompanied by emergence of antigenic variants in MSP2. MSP1a, MSP1b, and MSP2 are associated with hemagglutinating activity and may represent adhesins of *A. marginale* (McGarey and Allred, 1994). Epitopes of MSP2 and MSP5 are conserved among *A. marginale*, *Anaplasma centrale*, and *Anaplasma ovis*, and both the *msp2* and *msp3* genes of *A. marginale* are present in the genome of *A. ovis*. No tick-specific antigen expression has been proven (Rurangirwa et al., 1999, 2000).

Tetracycline compounds and dithiosemicarbazone inhibit replication and ameliorate clinical manifestations. Penicillin, streptomycin, sulfonamides, and arsenicals are inactive (Barrett et al., 1965; Ristic, 1981).

Since infection results in low-level persistence, natural immunity is incomplete. Immunity that results after elimination of persistently infected state may persist for at least 8 mo. Vaccination using whole intact bacteria or subcomponents has resulted in variable levels of protective immunity (Palmer et al., 1988a; Montenegro-James et al., 1991, Tebele et al., 1991). Cross-protection between *A. marginale* and *A. centrale* has been reported (Palmer et al., 1988b). The relationship of *A. marginale* to erythrocytic anaplasmas other than *A. centrale* is not certain, although distinct sequences of the 16S rRNA genes have been reported.

A. marginale causes clinical signs with infection in cattle, occasionally sheep or goats, and giraffes (Kuttler, 1984). Inapparent infection may occur in zebu, water buffalo (*Babalus babalis*), bison (*Bison bison*), African antelopes, black wildebeest (*Connochaetes gnou*), blesbuck (*Damaliscus albifrons*), and duiker (*Sylvicapra grimmi grimmi*), American deer (southern black-tailed, Rocky Mountain mule deer, Virginia white-tailed), pronghorn (*Antilocapra americana americana*), elk, bighorn sheep (*Ovis canadensis canadensis*), and camel (*Camelus bactrianus*). *A. marginale* has not been demonstrated to be infectious for rodents or other small mammals. Persistent infection leading to a carrier "reservoir" state is best documented for cattle; other domestic and wild ungulates and ruminants may also play a role (Kuttler, 1984). Vectors for *A. marginale* include *Dermacentor andersoni* ticks in North America and *Boophilus microplus* ticks in Africa. Transstadial but not transovarial transmission occurs (Stich et al., 1989); thus, the predominant mechanism for natural maintenance involves a mammalian reservoir that is expanded by tick vectors and mechanical or fomite vectors.

Isolation is best achieved by serial passage of blood from infected to susceptible animals. The bacterium may be maintained in stable form when frozen ($\leq -70°C$) in anticoagulated blood containing dimethyl sulfoxide; such preparations can be later transfused into susceptible hosts. The bacteria may also be propagated *in vitro* by cultivation in IDE8 tick cells (Munderloh et al., 1996b). Isolated bacteria may be identified by polymerase chain reaction amplification of conserved *A. marginale* genes, by hybridization of bacterial DNA with *A. marginale* DNA probes, or with *A. marginale* monoclonal or polyclonal antibodies (McGuire et al., 1984; Barbet, 1995; Torioni et al., 1998).

A. marginale persists at low levels in the blood of infected

TABLE BXII.α.34. Species-specific oligonucleotide primers for PCR identification of *Anaplasma* species.

Anaplasma species	Targeted gene	Forward primer	Reverse primer	Hybridization probe
A. marginale[a]	*msp1*	5′-GTATGGCACGTAGTCTTGGGATCA-3′	5′-CAGCAGCAGCAAGACCTTCA-3′	
A. phagocytophilum[b]	16S rRNA	5′-AACGGATTAGGCTTTATAGCTTGCT-3′	5′-TTCCGTTAAGAAGGATCTAATCTCC-3′	
"*A. platys*"[c]	16S rRNA	5′-TGTCGTAGCTTGCTATG-3′	5′-CGTTTTGTCTCTGTGTTG-3′	5′-GAAGATAATGACGGTACCC-3′

[a]From Stich et al., 1993.

[b]From Edelman and Dumler, 1996.

[c]From Chang and Pan, 1996.

cattle (Torioni et al., 1998). During the initial infection, antigenic variants emerge because of expression of new MSP2 genes, perhaps by recombinational events at the level of the chromosome (French et al., 1998). The nucleic acid sequences of the multigenes in the genome of a single *A. marginale* isolate may be as little as 25% identical. Several of the MSPs of *A. marginale* form complexes within the membrane of the bacterium.

A. marginale is the most phylogenetically distinct species in the genus *Anaplasma*, differing from other species by between 2.3 and 3.5% identity in the 16S rRNA gene sequence and by 25% in the *groESL* operon sequence.

The mol% G + C of the DNA is: 56 (spectral analysis; Alleman et al., 1992).

Type strain: no culture isolated.

GenBank accession number (16S rRNA): M60313.

2. **Anaplasma bovis** (Donatien and Lestoquard 1936) Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2158[VP] (*Rickettsia bovis* Donatien and Lestoquard 1936, 1061; *"Ehrlichia bovis"* Moshkovski 1945, 18.)
bo′vis. L. n. *bos* the ox; L. gen. n. *bovis* of the ox.

The characteristics are as described for the genus and as listed in Tables BXII.α.35 and BXII.α.36. Cells are coccoid to ellipsoidal and are often pleomorphic. They infect mononuclear phagocytes, mostly monocytes, of cattle. The morphologic and ultrastructural appearance is not different from other members of *Anaplasma*.

A. bovis is the causative agent of bovine ehrlichiosis of Africa, the Middle East, India, and Sri Lanka, a disease that is clinically characterized by fluctuating fever, lymphadenopathy, depression, and, occasionally, death (Rioche, 1966). Infection is usually inapparent in endemic regions, except when exacerbation occurs during periods of stress, with splenectomy, or with other infections such as rinderpest.

A. bovis has not yet been cultivated *in vitro*, but may be propagated by serial passage in susceptible cattle. Identification may be achieved by sequence analysis of polymerase chain reaction-amplified DNA from animal blood or ticks.

The principal clinical manifestations include fever, anorexia and diarrhea, and—infrequently—involvement of the central nervous system with drowsiness and convulsions. Leukopenia and thrombocytopenia may occur.

A. bovis is transmitted by ticks, including *Rhipicephalus appendiculatus* and *Amblyomma variegatum*, in Africa (Rioche, 1966; Matson, 1967) and possibly by *Amblyomma cajennense* ticks in Guadaloupe and Brazil. *A. bovis*-like 16S rRNA gene sequences have been detected in *Haemaphysalis leporispalustris* and *Ixodes scapularis ("dammini")* ticks on Nantucket Island in the northeastern U.S. (Goethert and Telford, 2000). This latter observation was also associated with detection in cottontail rabbits, suggesting the existence of a non-ruminant ecological cycle. *A. bovis* infections have been described in North America, Africa, the Middle East, and Asia (India and Sri Lanka).

The 16S rRNA gene sequences are represented by two submissions in GenBank, one from South Africa and one from North America, which are ≥99.5% identical.

The mol% G + C of the DNA is: not known.

Type strain: no strain isolated.

GenBank accession number (16S rRNA): U03775.

TABLE BXII.α.35. List of diagnostic features of *Anaplasma* species.

3. **Anaplasma caudatum** (Kreier and Ristic 1963) Ristic and Kreier 1984c, 355[VP] (Effective publication: Ristic and Kreier 1984a, 722) (*Paranaplasma caudatum* Kreier and Ristic 1963, 701)
cau′da.tum. L. neut. n. *cauda* tail; *caudatum* tailed, with a tail.

Anaplasma caudatum is similar to *A. marginale* except that each cell possesses an appendage, usually in the form of a tapering tail, a loop, a disk, or ring, that can only be visualized through immunologic or ultrastructural techniques. By electron microscopy, the tails are not directly attached to the bacterium, but contain some bacterial-specific antigens and are predominantly composed of polymerized F-actin filaments of unknown origin (Kocan et al., 1978; Stich et al., 1997). The exact relationship of *A. caudatum* to *A. marginale* is uncertain.

The mol% G + C of the DNA is: unknown.
Type strain: no culture isolated.

4. **Anaplasma centrale** (ex Theiler 1911) Ristic and Kreier 1984c, 355[VP] (Effective publication: Ristic and Kreier 1984a, 722.)
cen.tra′le. L. neut. adj. *centrale* central, referring to the location of the organism within erythrocytes.

Anaplasma centrale is similar to *A. marginale*, except that the disease produced in cattle is usually mild, and the location of the bacterium within the erythrocyte cytoplasm is central and not peripheral.

This species shares many genes and antigens with *A. marginale* and *A. ovis* (Palmer et al., 1988b, 1998; Visser et al., 1992). Cross-protection between *A. marginale* and *A. centrale* has been reported (Abdala et al., 1990; Turton et al., 1998). Strains of *A. centrale* possess both specific and genus antigens; however strains of *A. marginale* differ from each other as much as they do from *A. centrale* (McGuire et al., 1984; Palmer et al., 1988b; Visser et al., 1992).

The exact relationship of *A. centrale* to *A. marginale* is uncertain, but the 16S rRNA genes are at least 99.2% identical.

The mol% G + C of the DNA is: not determined.
Type strain: Israel.
GenBank accession number (16S rRNA): AF309869.

5. **Anaplasma ovis** Lestoquard 1924, 784[AL]
o′vis. L. gen. n. *ovis* of the sheep.

Anaplasma ovis is similar to *A. marginale* except that the hosts with clinical signs are usually restricted to sheep and goats.

This species contains multiple genes that are also present in *A. marginale*, including *msp5* and multiple *msp2* and *msp3* genes (Visser et al., 1992; Palmer et al., 1998).

Cross-protection between *A. marginale* and *A. ovis* has

not been reported, although T cells from *A. marginale* immunized animals proliferate when exposed to *A. ovis* antigens (Brown et al., 1998).

The exact relationship of *A. ovis* to *A. marginale* is uncertain, but the sequences of the 16S rRNA genes are at least 99.6% identical.

The mol% G + C of the DNA is: not determined.

Type strain: Idaho.

GenBank accession number (16S rRNA): AF309865.

6. **Anaplasma phagocytophilum** (Foggie 1951) Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2158[VP] (*Rickettsia phagocytophila* Foggie 1951, 4; *Ehrlichia phagocytophila* Philip 1962, 42.)
pha.go.cy.to'phi.lum. Gr. inf. *phagein* to eat, devour; Gr. n. *kytos* a vessel, enclosure; Gr. inf. *philein* to love; M.L. adj. *phagocytophilum* fond of devouring cells (in microbiology, attractive to phagocytes).

The characteristics are as described for the genus and as listed in Tables BXII.α.35 and BXII.α.36. See also Figs. BXII.α.40 and BXII.α.41. Cell morphology is as described for the genus. Morulae can be up to 6 μm in diameter (Popov et al., 1998). Dense-core and reticulate cells occur together in vacuoles; both forms divide by binary fission. There is no fibrillar matrix; the vacuolar space may contain empty vesicles. The bacterial cytoplasmic membrane may protrude into the periplasmic space or invaginate into the interior of the cell.

A. phagocytophilum causes tick-borne fever of ruminants, mainly in Western Europe (Gordon et al., 1932; Hudson, 1950; Foggie, 1951). Strains previously known as *Ehrlichia equi* and HGE agent cause equine granulocytic ehrlichiosis (Gribble, 1969; Stannard et al., 1969; Madigan and Gribble, 1987), a form of canine granulocytic ehrlichiosis (Greig et al., 1996; Pusterla et al., 1997), and human granulocytic ehrlichiosis in northern Europe and the Western Hemisphere (Bakken et al., 1994; Chen et al., 1994; Goodman et al., 1996). Serological evidence indicates that asymptomatic infection occurs in humans and animals. Clinical signs in humans and animals include fever accompanied by leukopenia and thrombocytopenia; opportunistic infections may occur in humans and animals (Walker and Dum-

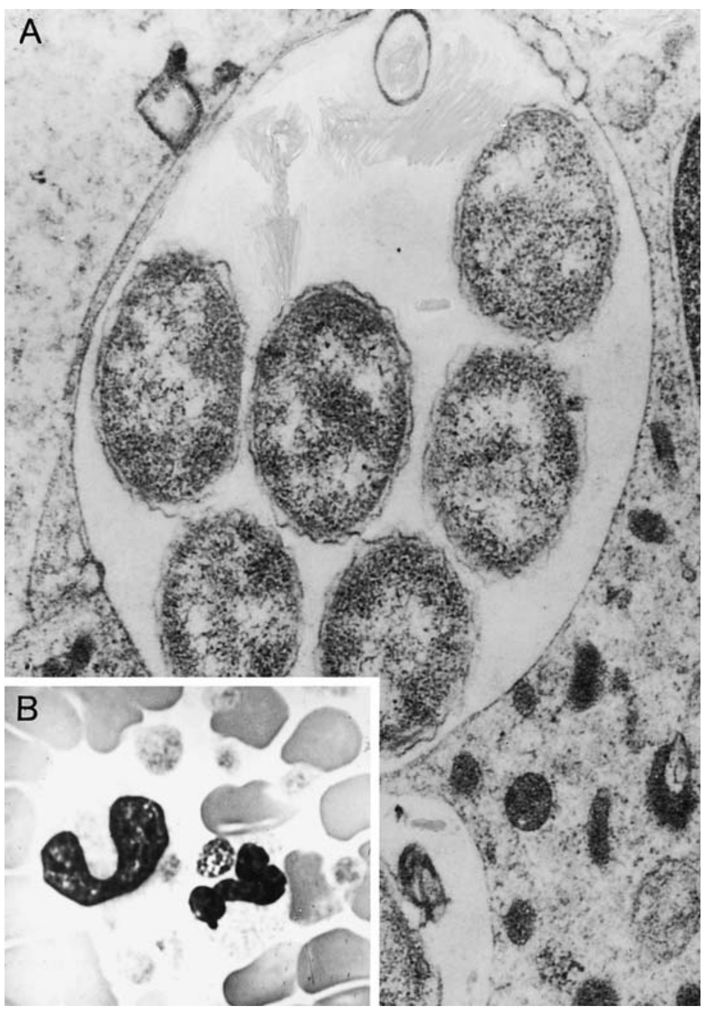

FIGURE BXII.α.40. *Anaplasma phagocytophilum A*, Transmission electron micrograph of an infected equine blood granulocyte with an intracytoplasmic inclusion body (morula). Several single bacteria bound by a rippled cell wall and plasma membrane are evident (× 51,000). (Reproduced by permission from D.M. Sells et al., Infection and Immunity, *13:* 273–280, 1976, ©American Society for Microbiology, Washington, D.C.). *B*, An intragranulocytic inclusion body stained by a Romanowsky method (Giemsa stain, × 1,020) (Courtesy of Cynthia Holland).

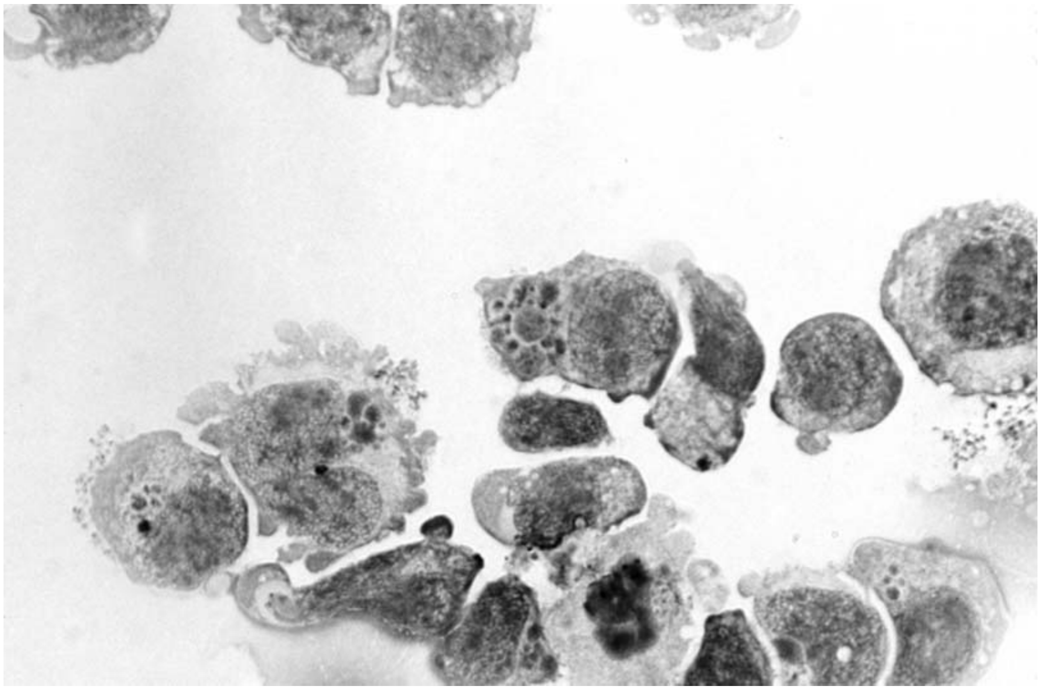

FIGURE BXII.α.41. *Anaplasma phagocytophilum* intracytoplasmic inclusions (morulae) that contain many individual bacteria in cultured human HL-60 promyelocytic leukemia cells, stained with a Romanowsky stain (LeukoStat stain, × 360).

ler, 1996). Other signs include depression and anorexia in horses and dogs and limb edema and ataxia in horses. Humans may suffer liver damage (Aguero-Rosenfeld et al., 1996; Bakken et al., 1996). The organism is widely distributed geographically.

Tick vectors include species of the *Ixodes persulcatus* complex (MacLeod and Gordon, 1933; Foggie, 1951; Richter et al., 1996; Telford et al., 1996). Organisms are maintained in ticks by transstadial but not transovarial transmission. Important reservoirs include rodents (*Peromyscus leucopus*) and potentially large mammals such as cattle and wild ruminants, including cervids and deer.

All isolates cross-react serologically and share antigens with *Ehrlichia canis*, *E. chaffeensis*, and *E. ruminantium*. Major antigens are 42–49 kDa outer membrane proteins encoded by a multigene family (Dumler et al., 1995; Asanovich et al., 1997; Zhi et al., 1997, 1998; Murphy et al., 1998). The primary structures of these antigens are similar to corresponding antigens of *A. marginale*, *E. ruminantium*, *E. canis*, *E. chaffeensis*, and *Wolbachia*.

A. phagocytophilum is susceptible to low concentrations of tetracycline antibiotics, rifamycins, and some fluoroquinolones such as trovafloxacin and resistant to moderate or high concentrations of β-lactams, aminoglycosides, macrolides, and chloramphenicol (Klein et al., 1997).

A. phagocytophilum may be isolated from infected animals by passage of fresh or dimethyl sulfoxide-treated frozen anticoagulated blood specimens or by *in vitro* cultivation in granulocyte cultures, such as HL-60 cells, or in tick cells such as IDE8 cells. Infected cells may be stored for several months at −70°C or for years in liquid N_2 if highly infected. The storage medium is RPMI 1640 medium supplemented with 10% dimethyl sulfoxide. Identification is best achieved by polymerase chain reaction amplification of *A. phagocytophilum*-specific gene targets or by immunocytochemical identification using specific polyclonal or monoclonal antibodies. The genome size is approximately 1500 kbp (Rydkina et al., 1999).

Within the species, *A. phagocytophilum* 16S rRNA gene sequences exhibit >99.5% identity, and *groESL* sequences exhibit ≥99.0% identity.

The mol% G + C of the DNA is: 43.8 (by gene sampling).
Type strain: Webster.
GenBank accession number (16S rRNA): U02521.

7. **"Anaplasma platys"** (French and Harvey 1983) Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2159 (**"Ehrlichia platys"** French and Harvey 1983, 2410.)
pla' tys. Gr. adj. *platys* flat, the word from which platelet is derived.*

The characteristics are as described for the genus and as listed in Tables BXII.α.35 and BXII.α.36. The cells are coccoid to ellipsoidal, often pleomorphic, and infect platelets of dogs. Except for the presence in platelets, the morphologic and ultrastructural appearance is not different from that of other members of *Anaplasma* (Mathew et al., 1997).

This species is the causative agent of infectious cyclic thrombocytopenia of dogs, a disease that results in decreasingly severe episodes of fever and thrombocytopenia. The bacterium may also cause inapparent infection in rumi-

Editorial Note: The name of this species has not been validly published, because the etymology of *platys* was missing from the descriptions.

nants (Allsopp et al., 1997). The principal clinical manifestation is thrombocytopenia in the absence of fever and clinical signs. Hemorrhage occurs rarely if associated with surgery or accidents.

The organisms are likely transmitted by ticks, perhaps including *Rhipicephalus sanguineus* or *Amblyomma* spp. The observation of infection in sheep and impalas suggests a potential role for ruminants as reservoirs (Allsopp et al., 1997; Du Plessis et al., 1997).

This species has not yet been cultivated *in vitro*, but it can be propagated by serial intravenous passage in susceptible dogs. Infected blood can be stored in liquid N_2 when diluted 1:2 in phosphate buffered saline containing a final concentration of 7.5% glycerol.

Identification is best achieved by polymerase chain reaction amplification of *"A. platys"*-specific or white-tailed deer *Ehrlichia*-specific gene targets (Little et al., 1997; Mathew et al., 1997) or by immunocytochemical identification using specific polyclonal antibodies (Simpson and Gaunt, 1991).

"A. platys" is serologically distinct from *Ehrlichia canis*. The relapsing nature of the infection is similar to that seen in bovine anaplasmosis and may similarly be associated with changes in surface protein expression.

The 16S rRNA gene sequences among three strains are ≥99.5% identical, including one strain originating from South African sheep.

16S rRNA gene sequences that have been amplified from the blood of white-tailed deer and an *Amblyomma americanum* tick in North America are most similar to those of *"A. platys"*, with a nucleic acid sequence identity between 96.5 and 98.1% (Dawson et al., 1996; Brandsma et al., 1999). The 16S rRNA gene sequences indicate that the "white-tailed deer" group forms a reproducible and unique clade that is between 96.9% and 98.6% identical to other members of the *Anaplasma* genus, but is not more than 92.3% identical to any member of the genera *Ehrlichia*, *Wolbachia*, *Neorickettsia*, *Orientia*, or *Rickettsia*. The "white-tailed deer" bacteria have never been morphologically identified or cultivated *in vitro*. *"A. platys"* has not yet been cultivated *in vitro*.

The mol% G + C of the DNA is: not known.

Deposited strain: no strain isolated.

GenBank accession number (16S rRNA): M82801.

Species Incertae Sedis

1. **"Anaplasma mesaeterum"** Uilenberg, van Vorstenbosch and Perie 1979, 21.

mes.ae.ter′ um. L.

The taxonomic relationship of this organism to the genus *Anaplasma* is not known. The organisms were identified in sheep in The Netherlands. The description is similar to that of *A. ovis* except for an increased pathogenicity for sheep and a decreased proportion of peripherally located bacteria in the infected erythrocytes.

Transmission is by either *Ixodes ricinus* or *Haemaphysalis punctata* ticks.

Genus II. **Ehrlichia** *Moshkovski 1945, 18*[AL] *emend. Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2157*

J. Stephen Dumler, Yasuko Rikihisa and Gregory A. Dasch

Ehr.lich′ i.a. M.L. fem. n. *Ehrlichia* named after Paul Ehrlich, a German bacteriologist.

Coccoid to ellipsoidal cells. Found in cytoplasmic vacuoles in endothelial or hemopoietic mammalian host cells, including macrophages, monocytes, neutrophils, and cells of the bone marrow, liver, spleen, or lymph nodes. Often occur in clusters (morulae). Pleomorphic; occur as **reticulate cells and "dense core forms" with condensed cytoplasm** (Popov et al., 1998). Gram negative. Nonmotile. Some species grow in cultured tick cells or in cultured mammalian monocytes, macrophages, or endothelial cells. **Cause disease in ruminants, canids, rodents, and humans. Ticks are the primary vectors and hosts.** Belong to the *Alphaproteobacteria* by 16S rDNA gene sequence analysis; the organisms exhibit ≥ 97.6% 16S rRNA gene sequence identity with one another. Where studied, these bacteria possess surface protein antigen genes that are tandemly arranged in the chromosome and have a high degree of sequence similarity (Ohashi et al., 1998a, b; Reddy et al., 1998; McBride et al., 2000; Yu et al., 2000a).

The mol% G + C of the DNA is: 30–56.

Type species: **Ehrlichia canis** (Donatien and Lestoquard 1935) Moshkovski 1945, 18 (*Rickettsia canis* Donatien and Lestoquard 1935, 419) emend. Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2159.

Further descriptive information

Phylogeny By 16S rRNA gene and *groESL* operon sequence analysis, the genus *Ehrlichia* forms a clade distinct from *Anaplasma*, *Wolbachia*, *Neorickettsia*, *Rickettsia*, and *Orientia* in the *Alphaproteobacteria*, Order *Rickettsiales*. All species in the genus show more than 97.6% and 86.3% similarity in the 16S rRNA gene and *groESL* operon sequences, respectively. Where investigated, the organisms possess multiple similar genes that encode surface protein antigens varying in molecular size from approximately 28–32 kDa (Ohashi et al., 1998a, b; Reddy et al., 1998; McBride et al., 2000; Yu et al., 2000a). The bacteria are only distantly related to other obligate intracellular bacteria in genera such as *Chlamydia* and *Coxiella* and are unrelated to cell-wall-free bacteria such as *Eperythrozoon* and *Haemobartonella*.

Cell morphology Ehrlichiae occur in membrane-bound vacuoles in the cytoplasm of host cells of hematopoietic origin and, for some species, in endothelial cells. The bacteria form inclusions (morulae) that contain variable numbers of organisms (Simpson, 1972, 1974; Hildebrandt et al., 1973) (See Figs. BXII.α.42 and BXII.α.43). The individual organisms are approximately 0.5 μm in diameter, but size may vary considerably. The morulae range in size up to 4.0 μm in diameter. The organisms are weakly Gram negative. Ehrlichiae are best stained with Romanowsky stains, where the organisms develop a dark blue appearance as opposed to the violet color of the host cell nucleus. Organisms stain poorly with the Giménez method but easily with acridine orange.

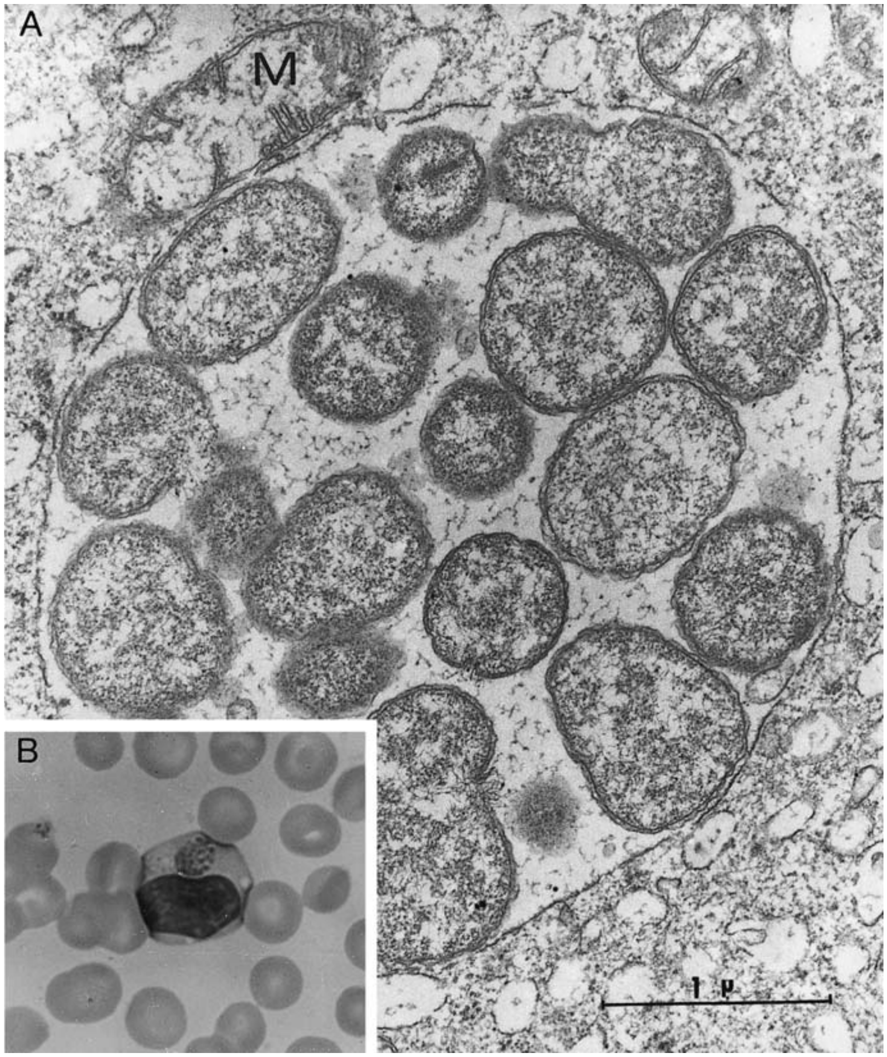

FIGURE BXII.α.42. *Ehrlichia canis. A*, Transmission electron micrograph of an infected canine blood monocyte with an intracytoplasmic inclusion body (morula). Numerous bacteria with distinct plasma membranes and rippled outer cell walls are shown. Note the presence of fibrils and occasional tubules within the intravacuolar, extrabacterial space. *M* = mitochondrion (× 60,000). (Reproduced with permission from P.K. Hildebrandt et al., Infection and Immunity, *7:* 265–271, 1973, ©American Society for Microbiology, Washington, D.C. *B*, An intramonocytic inclusion body stained by a Romanowsky method (Giemsa × 680) (Courtesy of S.A. Ewing, Veterinary Medicine, Oklahoma State University, Stillwater).

Cell wall composition Little is known of the components of the cell wall in *Ehrlichia*. Lipopolysaccharide and lipooligosaccharide have not yet been detected, and it is not known if the cell wall contains peptidoglycan.

Fine structure By electron microscopy, ehrlichiae reside within membrane-bound vacuoles that are early endosomes for *E. chaffeensis* (Mott et al., 1999). The ultrastructure of the cell envelope reveals simple inner and outer leaflets similar to those of Gram-negative bacteria (Popov et al., 1998). Internal structures consisting of chromatin strands and ribosomes are readily visualized. Two distinct morphologic forms may be detected, dense-core forms that contain a relatively dense central or eccentrically located condensation of chromatin strands, and reticulate cell forms that contain a homogeneous loose matrix of chromatin strands among which ribosomes are spread. Reticulate cells are typically identified *in vivo*, and dense core cells are identified predominantly during *in vitro* propagation. Both forms undergo binary fission, suggesting that a developmental cycle associated with these morphologies is unlikely. *Ehrlichia* species may produce an abundant membrane that on occasion wraps around individual ehrlichiae or invaginates into the ehrlichial cell and occasionally forms tubule and vesicle profiles in the vacuolar space. Unlike the genus *Anaplasma*, *Ehrlichia* species possess a fibrillar matrix within the vacuolar space.

Cultural characteristics *E. canis*, *E. chaffeensis*, *E. ruminantium*, and *E. muris* have been successfully propagated *in vitro*. Most species may be propagated in primary monocyte cultures established from blood or in macrophage/histiocyte cell lines derived from humans, dogs, and mice (e.g. THP-1, DH82, and P388D1, among others). *E. canis* has been successfully cultivated in primary canine monocyte cultures and in canine-mouse hybrid cells (Nyindo et al., 1971; Stephenson and Osterman, 1977; Hemelt

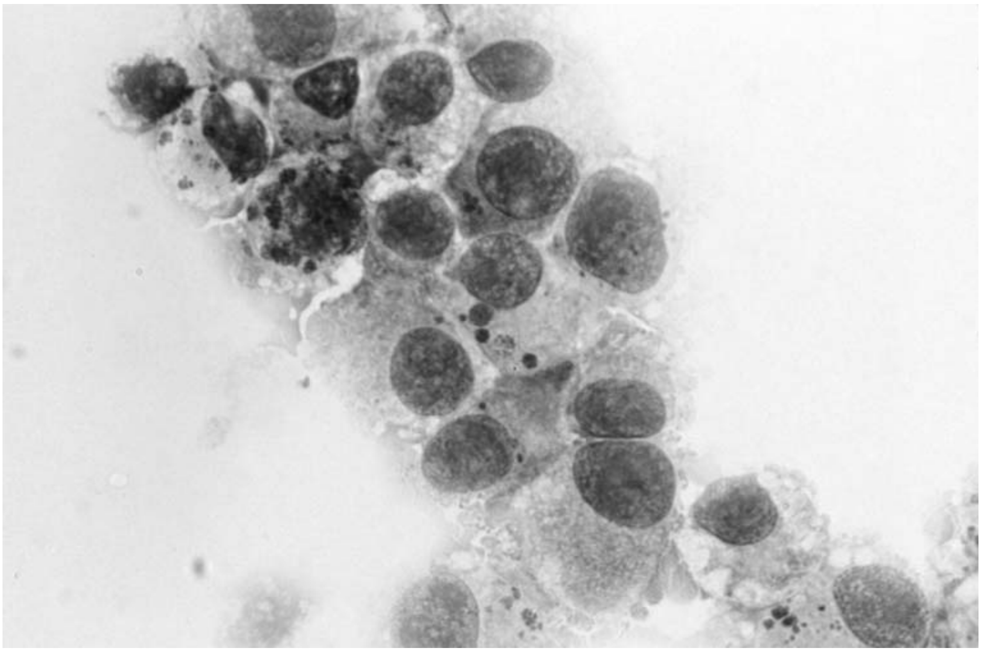

FIGURE BXII.α.43. *Ehrlichia chaffeensis*. Intracytoplasmic inclusions that contain many individual bacteria in cultured canine DH82 histiocytes, stained with a Romanowsky stain (LeukoStat stain, × 340).

et al., 1980; Dawson et al., 1991). *E. chaffeensis* has also been propagated in fibroblast cell lines (Vero, HEL, BGM) and in endothelial cell lines (Dawson et al., 1993; Brouqui et al., 1994; Chen et al., 1995b). *E. ruminantium* is often propagated in primary bovine aortic endothelial cell cultures (Martinez et al., 1993; Yunker, 1995; Perez et al., 1997). *E. canis* has also been propagated in tick cell tissue culture (Ewing et al., 1995). No *Ehrlichia* species has been cultivated on cell-free medium. In cell culture, infection is observed at first with one or few bacteria within the vacuole, previously referred to as an "initial body". With continued binary fission of the bacteria, increasingly larger intravacuolar microcolonies are formed, which are called intermediate bodies or morulae, depending upon size. Ultrastructural examination has shown that all vacuoles may contain either reticulate or dense-cored cells or both and that each of these forms undergoes binary fission; these findings argue against a well-defined intracellular life cycle as observed for *Chlamydia* spp. Multiple infected vacuoles may exist in a single cell, presumably owing to the lack of fusion of infected endosomes.

Antigenic structure All *Ehrlichia* species contain a multigene family that encodes major surface proteins. These proteins are the immunodominant antigens of the genus, and the genes encoding them have a relatively high degree of similarity to corresponding genes in the genera *Anaplasma* and *Wolbachia*. The genes are usually characterized by the presence of several highly conserved sequences that flank several variable sequences. B cell epitopes map to the amino acids encoded by the variable regions, suggesting a role in immune evasion. *In vitro*, from one to many of these genes are transcriptionally active and yield protein antigens of various molecular sizes ranging from 28–32 kDa. Other antigenic components may be conserved, such as the heat shock proteins (GroESL), or they may be species specific.

Antibiotic susceptibility Ehrlichiae are most strongly inhibited during *in vitro* propagation by rifampin and tetracycline antibiotics, including tetracycline hydrochloride, oxytetracycline, and doxycycline. Other antibiotics are ineffective, including aminoglycosides, macrolides, fluoroquinolones, chloramphenicol, and β-lactams. Patients with human monocytic ehrlichiosis have a shorter duration of fever and hospitalization when treated with either a tetracycline or chloramphenicol than with other antibiotics.

Pathogenicity The mechanisms by which *Ehrlichia* species cause disease are poorly understood. During *in vitro* propagation, infected mononuclear phagocytes undergo both necrosis and apoptosis. The *in vivo* infection presents as a non-specific febrile illness with leukopenia, mild anemia, thrombocytopenia, and mild hepatic injury for most species. By contrast, *E. canis* infection in some dog breeds results in a persistent infection that terminates with recrudescence months to years later and is often fatal. Infections and ehrlichial loads appear to be more severe in immunocompromised hosts (splenectomized, corticosteroid therapy, HIV infection, transplant recipients, severe combined immunodeficiency); however, under most other circumstances, the degree of cytopenia observed is out of proportion to the quantity of ehrlichiae detected. An exception may occur in *E. ruminantium* infections, where a significant proportion of the pathogenesis may be related directly to vascular injury after endothelial cell infection, particularly in the cerebral microvascular beds. The proportion of infections that result in clinical signs is still not known, but among those with clinical signs, the proportion with severe morbidity may be as high as 10–50%. Clinically evident infection may be observed in a range of animals including cattle, goats, sheep, deer, other domestic and wild ruminants, dogs and other canidae, mice and other small rodents, and humans.

Ehrlichia species gain access to host cells by adherence to surface proteins that are usually glycosylated. The bacteria are then internalized within early endosomes; for *E. chaffeensis* these endosomes selectively accumulate transferrin receptors, effectively

sequestering the infected vacuole into a receptor salvage pathway that precludes lysosome fusion. Infection of macrophages *in vitro* results in low-level secretion of proinflammatory cytokines, whereas binding of immunoglobulin-opsonized *E. chaffeensis* to the macrophage surface results in a high-level release of proinflammatory cytokines.

Ecology Ticks are the primary vectors and hosts for *Ehrlichia* species. Although the microorganisms are passed transstadially in ticks, definite transovarial transmission of identified ehrlichiae has not been demonstrated. The range of potential vertebrate hosts for *Ehrlichia* species is not completely defined owing to a lack of clinical signs in many reservoir hosts, including deer and small mammals. Some mammalian hosts, such as white-tailed deer, some ruminants, and dogs, maintain infectivity for long intervals (months to years) in the absence of clinical signs, whereas other mammals, such as some dog breeds and humans, develop sterile immunity after clinically apparent primary infection. Thus, natural maintenance of ehrlichiae is dependent upon horizontal transmission involving acutely and persistently infected mammals and ticks.

Enrichment and Isolation Procedures

Some species of *Ehrlichia* can be isolated and propagated in cell culture. For isolation, blood is the most appropriate specimen for inoculation. Blood is fractionated into component leukocyte fractions or inoculated directly into appropriate cell cultures, including primary monocyte cultures or cell lines of macrophages (canine DH82, human UL37 or differentiated HL-60, murine P388D1), myelomonocytic cells (human THP-1), fibroblasts (Vero, L929), or endothelial cells. Cultured cells are examined by Romanowsky staining, immunofluorescent staining, or by nucleic acid detection methods to establish the presence of the infectious agent. Primary isolation may require intervals as short as several days or longer than 30 d. Partially purified ehrlichiae may be prepared by density gradient centrifugation using diatrizoate meglumine (Renografin), sucrose, or Percoll gradients.

Maintenance Procedures

E. canis, *E. ewingii*, *E. ruminantium*, and *E. muris* can be serially passed by animal inoculation using blood, spleen, or other tissues. Infectious blood can be stored by suspension with glycerol or dimethyl sulfoxide at 4°C for several days to one week, at −80°C for weeks or months, and in liquid nitrogen for years. Cultured cells containing the bacteria can be stored in media containing 30% fetal bovine serum and 10% dimethyl sulfoxide at −80°C for months to years and in liquid nitrogen for years.

Differentiation of the genus *Ehrlichia* from other genera

Characteristics useful for the differentiation of the genus *Ehrlichia* from the other genera of the family *Anaplasmataceae* are listed in Table BXII.α.33 of the section describing the family. *Ehrlichia* species may be morphologically difficult to distinguish from *Anaplasma* and *Neorickettsia* species that grow within bone marrow-derived cells. By ultrastructural examinations, *Ehrlichia* spp. tend to form large morulae containing many cells suspended in an intravacuolar, extrabacterial fibrillar matrix, whereas *Anaplasma* spp. tend to lack additional intravacuolar structures and form smaller morulae containing low numbers of bacteria. Differentiation is best achieved by using DNA sequence analysis of the 16S rRNA gene or the *groESL* operon.

Taxonomic Comments

Historically, *Ehrlichia* species were detected as intracytoplasmic clusters of bacteria (morulae) within peripheral blood leukocytes. An essential characteristic was the presence of the bacteria within membrane-bound vacuoles. Other important characteristics included the host mammalian species infected, the geographic distribution of the infectious agent, and a minor degree of antigenic cross-reactivity among proposed species. Most species were recognized as transmissible by the bite of a tick vector.

With the advent of molecular biological methods, a more accurate understanding of the phylogenetic and potential taxonomic positions of *Ehrlichia* species has emerged. Taxonomic placements in the genus *Ehrlichia* are now largely determined by nucleotide sequence analysis of the 16S rRNA genes and nucleotide and amino acid sequence analyses of the *groESL* operon and GroEL proteins. This information is used in conjunction with an assessment of the degree of antigenic cross-reactivity, the presence of similar outer membrane protein antigens, the tropism for mammalian cell hosts derived from bone marrow precursors, and the range of mammalian and tick hosts.

Members of the genus *Ehrlichia* share greater than 97.6% 16S rRNA gene nucleotide sequence similarity. The branching order established in dendrograms and phylogenetic analyses mimics similar arrangements predicted by the sequence analysis of the *groESL* operon and by antigenic analysis of the GroEL proteins. The specific host cell type, the infected host mammalian species, and the geographic distribution do not correlate with predicted genetic relationships; however, residence within an intracytoplasmic endosome and transmissibility by tick vectors are characteristic of all species. Although clear differences in the types of clinical manifestations are observed in appropriate infected mammalian hosts, the weight of objective genetic, antigenic, and pathogenic features provides unequivocal evidence of an evolutionary linkage. The current genetic taxonomic system has yielded several significant changes from previous methods of classification; these changes include the removal of several species from the genus *Ehrlichia* into the genera *Anaplasma* or *Neorickettsia*, and the integration of the genus *Cowdria* into the genus *Ehrlichia* (Dumler et al., 2001). It is anticipated that whole genome sequences may further still refine the genetic classification and yield new combinations not currently considered.

Differentiation of the species of the genus *Ehrlichia*

The preferred method for definitive identification of *Ehrlichia* species depends upon sequence analysis of all or part of the 16S rRNA gene or the *groESL* operon or upon PCR amplification using species-specific oligonucleotide primers. The full 16S rRNA gene sequence may be identified by many different methods, including commercially available systems such as the MicroSeq™ Full Gene 16S rDNA Bacterial Sequencing Kit (Applied Biosystems, Foster City, CA). Species-specific primers for *E. canis*, *E. chaffeensis*, *E. muris*, and *E. ruminantium* are shown in Table BXII.α.37. Various methods and protocols for diagnostic identification in clinical samples have been described; the diagnostic sensitivity and specificity should be determined by each laboratory performing the clinical assay.

function of the polymorphic proteins that vary from 28–32 kDa is not known, but owing to the presence of multiple copies, it is speculated that these proteins might play a role in immune evasion.

Tetracycline antibiotics are effective at eliminating infection *in vitro* but may have some limitations *in vivo*. Other antibiotics, including imidocarb dipropionate, are not effective.

Infection by *E. canis* stimulates the production of antibodies that also strongly react with *E. chaffeensis*, *E. muris*, *E. ruminantium*, and *E. ewingii* and react more weakly with *Anaplasma phagocytophilum* and *Neorickettsia* spp. Since infection results in low-level persistence, natural immunity is often incomplete, and recrudescence can occur months to years after primary infection. Immunity resulting in elimination of a persistent infection may occasionally occur. Different strains of *E. canis* may not induce homologous or heterologous cross-protection. Protection against other *Ehrlichia* species, including *E. chaffeensis*, is not induced by infection with *E. canis*.

E. canis is the causative agent of canine monocytic ehrlichiosis, a severe febrile infection of canids that occurs after tick bites and is associated with pancytopenia. The disease is worldwide in distribution. Asymptomatic human infection has been documented in one case.

Clinical signs of infection occur in canids—including dogs, coyotes, foxes, and wolves, among others. The organisms have not been demonstrated to be infectious for rodents or other small mammals. Persistent infection leading to a carrier "reservoir" state may develop in canids. The major worldwide vector for *E. canis* is *Rhipicephalus sanguineus*, the brown dog tick. Transstadial but not transovarial transmission occurs; thus, the predominant mechanism for natural maintenance involves a mammalian reservoir that is expanded by tick vectors.

Isolation can be achieved by inoculation of leukocytes from infected dogs onto monolayers of canine DH82 histiocyte cells. Infected cells may be stored for months or years frozen at −80°C or for years in liquid nitrogen if maintained in a medium with at least 30% serum and 10% dimethyl sulfoxide. Isolated bacteria may be identified by reaction with polyclonal or monoclonal antibodies or by polymerase chain reaction amplification of conserved *E. canis* genes.

The mol% G + C of the DNA is: 35.3 (by gene sampling).

Type strain: Oklahoma.

GenBank accession number (16S rRNA): M73221.

2. **Ehrlichia chaffeensis** Anderson, Dawson, Jones and Wilson 1992a, 327[VP] (Effective publication: Anderson, Dawson, Jones and Wilson 1991, 2841.)
chaf'fe.en.sis. N.L. fem. adj. *chaffeensis* of Chaffee; pertaining to Fort Chaffee in western Arkansas, where the patient from whom the first isolate was prepared was identified; L. adj. *-ensis* derived from; M.L. adj. *chaffeensis* from Chaffee.

The characteristics are as given for the genus and as listed in Tables BXII.α.38 and BXII.α.39. See also Fig. BXII.α.43. *E. chaffeensis* forms a phylogenetically distinct clade in the genus *Ehrlichia*; it differs from other species by 1.0–1.9% in 16S rRNA gene sequence and by 6.4–17.7% in the *groESL* operon sequence. Possesses polymorphic major surface proteins of approximately 28 kDa. These proteins are encoded by 21 distinct genes in a multigene family. These genes are similar to those in other ehrlichiae and are more distantly related to those of *Anaplasma* and *Wolbachia* spp. The nucleic acid sequences of the genes encoding the proteins vary between strains. The function of these polymorphic proteins is not known, but it is speculated that they play a role in immune system evasion. The organisms also possess genes that encode major membrane glycoproteins ranging from 120–140 kDa.

Tetracycline and rifamycin are effective at eliminating infection *in vitro*. Aminoglycosides, fluoroquinolones, macrolides, sulfa-containing, and β-lactam antibiotics are not effective *in vitro*.

E. chaffeensis induces strong cross-reactive serologic responses to *E. canis*, *E. ewingii*, *E. muris*, and *E. ruminantium*, and weaker responses to *Anaplasma phagocytophilum*, and possibly to *Rickettsia rickettsii* and *R. typhi*. Serologic responses can be differentiated by protein immunoblotting.

Infection in deer, goats, and dogs may be persistent, and these animals may be important natural reservoirs. Infection in humans is generally self-limited, and persistence is exceedingly rare. Second infections and recrudescence have not been well investigated in animals, but are probably rare in humans.

E. chaffeensis is a causative agent of monocytic ehrlichiosis in humans and dogs. Infection can result in a severe illness with fever, pancytopenia, and occasionally other manifestations after tick bites. The disease appears to be limited to North America although serologic evidence of infection has been reported in humans in Europe and Africa. Asymptomatic and symptomatic canine infections and asymptomatic human infection are well documented. Persistent infection leading to a carrier "reservoir" state may develop in canids and cervids. The major vector for *E. chaffeensis* is *Amblyomma americanum*, the Lone Star tick, although limited data suggests that *Dermacentor variabilis*, the American dog tick, may also play a role in transmission. Transstadial transmission occurs, but transovarial passage has not been documented; thus, the predominant mechanism for natural maintenance involves a mammalian reservoir that is expanded by tick vectors.

Isolation can be achieved by inoculation of infected leukocytes onto monolayers of canine DH82 histiocyte cells. Infected cells can be stored for months or years frozen at −80°C or in liquid nitrogen for years if maintained in medium with at least 30% serum and 10% dimethyl sulfoxide. Isolated bacteria can be identified by reaction with polyclonal or monoclonal antibodies or by polymerase chain reaction amplification of conserved *E. chaffeensis* genes.

The mol% G + C of the DNA is: 33.9 (by gene sampling).

Type strain: Arkansas, ATCC CRL-10679.

GenBank accession number (16S rRNA): M73222.

3. **Ehrlichia ewingii** Anderson, Greene, Jones, and Dawson 1992b, 301[VP] emend. Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2159.
ew.in'gi.i. N.L. gen. n. *ewingii* of Ewing, named in honor of Sidney A. Ewing for his pioneering work with this agent.

The characteristics are as given for the genus and as listed in Tables BXII.α.38 and BXII.α.39. *E. ewingii* occupies a distinct clade in the genus *Ehrlichia*, with at least 99.7% 16S rRNA gene sequence similarity among strains. *E. ewingii*

differs from other species by 1.0–1.4% in the 16S rRNA gene sequence and by 9.9–15.1% in the *groESL* operon sequence. *E. ewingii* also contains at least one copy of a homolog of the p28 gene family of *E. chaffeensis*.

E. ewingii induces antibodies that strongly cross-react with *E. canis* and *E. chaffeensis* by indirect fluorescent antibody tests but can be differentiated from those species by protein immunoblot analysis.

E. ewingii is a causative agent of granulocytic ehrlichiosis in humans and dogs; infections can result in a mild to moderate illness with fever, pancytopenia, and occasionally other manifestations after tick bites. Dogs develop polyarthritis more often than with *E. canis* infection. The disease has been described only in North America. *E. ewingii* may be transmitted by *Amblyomma americanum* (Lone Star tick) under experimental conditions.

No *in vitro* isolation has been accomplished, although limited *in vitro* replication of *ex vivo*-infected neutrophils has been described. The organism may be maintained by intravenous inoculation of dog blood that contains infected neutrophils or from "carrier" dogs.

The mol% G + C of the DNA is: 40.6 (by gene sampling).

Type strain: Stillwater.

GenBank accession number (16S rRNA): M73227.

4. **Ehrlichia muris** Wen, Rikihisa, Mott, Fuerst, Kawahara and Suto 1995b, 254[VP] emend. Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2159.
mu′ris. L. gen. n. *muris* of the mouse; the species was first isolated from a mouse.

The characteristics are as given for the genus and as listed in Tables BXII.α.38 and BXII.α.39. *E. muris* occupies a distinct clade in the genus *Ehrlichia*, with at least 99.7% 16S rRNA gene sequence similarity among different strains. *E. muris* differs from other species by 1.0–1.9% in the 16S rRNA gene sequence and by 6.4–15.3% in the *groESL* operon sequence. The organisms possess polymorphic major surface proteins of approximately 28 kDa that are encoded by at least two distinct genes; these genes are similar to those in other *Ehrlichia* and more distantly related to those of *Anaplasma* and *Wolbachia* spp.

Tetracyclines effectively prevent infection of mice, but penicillin, aminoglycosides, and sulfonamides do not.

E. muris induces antibodies that cross-react strongly with *E. canis* and *E. chaffeensis* by indirect fluorescent antibody tests and weakly with *Neorickettsia sennetsu*. Antibodies stimulated by *E. muris* infection may be differentiated by protein immunoblot analysis from those elicited by other *Ehrlichia* spp.

E. muris is a pathogen that causes mild to severe clinical signs—including splenomegaly and lymphadenopathy—in wild mice of Japan and perhaps other regions in Asia. The organisms can be detected in splenic and peritoneal macrophages of infected mice. *E. muris* can be transmitted by *Haemaphysalis flava* ticks under natural conditions.

E. muris can be cultivated in the canine histiocyte cell line DH82 maintained in minimal essential medium supplemented with 10% fetal bovine serum and 2 mM L-glutamine; cultures are incubated at 37°C under an air atmosphere enriched with 5% CO_2. No growth occurs in chicken embryo yolk sacs.

The mol% G + C of the DNA is: 38.5 (by gene sampling).

Type strain: AS145, ATCC VR-1411.

GenBank accession number (16S rRNA): U15527.

5. **Ehrlichia ruminantium** (Cowdry 1925) Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2158[VP] (*Rickettsia ruminantium* Cowdry 1925, 231; *Cowdria ruminantium* Moshkovski 1947, 62.)
ru.mi.nan′ ti.um. M.L. gen. pl. n. *ruminantium* of *Ruminantia*, formerly a common name for cud-chewing animals.

The characteristics are as given for the genus and as listed in Tables BXII.α.38 and BXII.α.39. *E. ruminantium* forms a distinct clade in the genus *Ehrlichia*, sharing at least 99.1% nucleotide sequence similarity in the 16S rRNA gene among strains. *E. ruminantium* differs from other species by 1.3–1.6% in the 16S rRNA gene sequence and by 14.5–17.7% in the *groESL* operon sequence. The organisms possess polymorphic major surface proteins encoded by multigene families similar to those in other *Ehrlichia* species and more distantly related to those in *Anaplasma* and *Wolbachia* spp. The function of the polymorphic proteins, which average approximately 32 kDa, is not known, but it is speculated that they might play a role in immune evasion.

Tetracycline antibiotics are effective at eliminating infection *in vivo*.

Infection by *E. ruminantium* stimulates the production of antibodies that also strongly react with *E. chaffeensis* and *E. canis* but react more weakly with *Anaplasma phagocytophilum*, *A. marginale*, *Rickettsia* spp., *Coxiella burnetii*, and *Neorickettsia* spp. Since infection results in low-level persistence, natural immunity is often incomplete and may result in recrudescence months or years after primary infection. Different strains of *E. ruminantium* may not induce homologous or heterologous cross-protection potentially owing to antigenic diversity in this species.

E. ruminantium is the causative agent of heartwater or cowdriosis, a severe febrile infection of ruminants that occurs after tick bites. The disease is associated with fever, organ dysfunction, and severe neurological signs. The disease is limited to sub-Saharan Africa and the Caribbean. Infection of exotic and domestic ruminants is generally severe, although some native ruminant species are refractory to clinical signs or develop only mild illness. Some strains are pathogenic for mice. Persistent infection leading to a carrier "reservoir" state often develops.

The major vectors for *E. ruminantium* are *Amblyomma* ticks, in particular *A. variegatum* and *A. habreum.* Transstadial but not transovarial transmission occurs; thus, the predominant mechanism for natural maintenance involves horizontal transmission through vertebrates.

Isolation can be achieved by inoculation of blood from infected animals onto monolayers of cultured endothelial cells. Infected cells can be stored for months or years when frozen at −80°C or for years in liquid nitrogen. Isolated bacteria can be identified by reaction with antibodies or by polymerase chain reaction amplification of conserved *E. ruminantium* genes.

The mol% G + C of the DNA is: 32.2 (by gene sampling).

Type strain: Welgevonden.

GenBank accession number (16S rRNA): X61659 (Crystal Springs strain).

Genus III. **Neorickettsia** *Philip, Hadlow and Hughes 1953, 257[AL] emend. Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2157*

Yasuko Rikihisa, J. Stephen Dumler and Gregory A. Dasch

Ne.o.rick.ett' si.a. Gr. pref. *neo-* new; M.L. fem. n. *Rickettsia* type genus of the family, *Rickettsiaceae*; M.L. fem. n. *Neorickettsia* the new *Rickettsia*

Coccoid or pleomorphic cells that reside in cytoplasmic vacuoles within monocytes and macrophages of dogs, horses, bats, and humans. Small (0.2–0.4 µm) electron dense forms and relatively large (0.8–1.5 µm) lighter forms may occur. Tissues of adult **trematode (fluke) vectors** and all other fluke stages—eggs, miracidia, rediae, sporocysts, cercariae, and metacercariae—produce infection when injected into susceptible hosts, indicating transovarial transmission in the vector. Transstadial transmission also occurs. Gram negative. Nonmotile. Most species are cultivable in peripheral blood monocytes, myelomonocytic cell lines, or promyelocytic cell lines. Some species are pathogenic to laboratory mice. **Etiologic agents of diseases of dogs and other canids, horses, and humans.** Where studied, these bacteria possess an antigenically cross-reactive group-specific protein gene with a high degree of sequence identity. Sensitive to tetracycline antibiotics. The estimated genome size is 860–900 kb.

The mol% G + C of the DNA is: 42.

Type species: **Neorickettsia helminthoeca** Philip, Hadlow and Hughes 1953, 257.

Further descriptive information

Phylogeny By 16S rRNA gene and *groESL* sequence analysis, the genus *Neorickettsia* forms a clade distinct from *Anaplasma*, *Ehrlichia*, *Wolbachia*, *Rickettsia*, and *Orientia* in the *Alphaproteobacteria*. When 16S rRNA gene sequences are aligned, all species in the genus are more than 95% similar. The amino acid sequence identity between GroEL of *N. sennetsu* and *N. risticii* is 97.6%; however, the identity of this gene between *Neorickettsia* spp. and *Ehrlichia* spp. or *Anaplasma* spp. is no greater than 59.2%.

Cell morphology *Neorickettsia* species are found in the cytoplasm of monocytes in the blood and in macrophages of lymphoid tissues of infected *Canidae*, humans, bats, and horses. In Romanowsky-stained preparations the organisms are dark blue to purple. Individual round forms are most common, but small clusters (microcolonies) of bacteria in inclusions called morulae are also present. These may be mistaken for large bacteria. The morulae are less compact and are smaller than those of *Ehrlichia* spp. in DH82 cells (Rikihisa et al., 1991).

Ultrastructure By electron microscopy small (0.2–0.4 µm) dense forms and relatively large (0.8–1.5 µm) light forms have been recognized in several species of *Neorickettsia* (Rikihisa et al., 1985, 1991; Rikihisa, 1990b). Ribosomes, fine DNA strands, and two layers (outer and inner) of membrane, are present in the organisms (Rikihisa, et al., 1991) (see Fig. BXII.α.44). Neorickettsiae, like the members of the genera *Ehrlichia* and *Anaplasma*, show no thickening of the inner leaflet of the outer membrane or the outer leaflet of the inner membrane (Rikihisa, 1990b; Rikihisa et al., 1985, 1991). *Neorickettsia* species multiply by binary fission and are found in early endosomes enriched with transferrin receptors in the cytoplasm (Barnewall et al., 1999). Individual organisms or groups of organisms are tightly enveloped by the endosomal membrane. Genes encoding lipid A biosynthesis were not detected, and most genes required for biosynthesis of peptidoglycan were absent (Lin and Rikihisa, 2003).

Cultural characteristics *Neorickettsia* species have not been grown in ordinary bacteriological media or in yolk sacs. Where tested most species are cultivable in peripheral blood monocytes, peritoneal macrophages, myelomonocytic cell lines, or promyelocytic cell lines such as P338D, DH82, and U937 (Rikihisa, 1991b).

Metabolism Members of the genus *Neorickettsia* possess an aerobic type of metabolism and are asaccharolytic. The metabolic activities of *N. risticii* and *N. sennetsu* have been investigated. Neorickettsiae can utilize glutamine and glutamate and can generate ATP (Weiss et al., 1988, 1989) as rickettsiae do, but unlike rickettsiae, neorickettsiae prefer to use glutamine rather than glutamate. They exhibit this preference because the organisms are enveloped by the host membrane and because glutamine enters endosomes more readily than glutamate. Like the genus *Rickettsia*, the genus *Neorickettsia* cannot utilize glucose-6-phosphate or glucose. The greatest metabolic activity of the *Neorickettsia* is observed at pH 7.2 to 8.0 and declines rapidly below pH 7 (Weiss et al., 1988); thus the genus *Neorickettsia* is not acidophilic.

Genetics Genome sizes of *N. sennetsu* and *N. risticii* are approximately 880 and 870 kb, respectively (Rydkina et al., 1996). The sequences of the 16S rRNA genes of *N. helminthoeca*, *N. sennetsu*, and *N. risticii* have been determined. *GroESL* has been cloned from *N. sennetsu* (Zhang et al., 1997), *N. risticii* (Sumner et al., 1997), and from SF agent and *N. helminthoeca* (Rikihisa, et al., unpublished data). The unique feature of the *groESL* operon of *Neorickettsia* spp. is that there is no spacer between *groES* and *groEL* (*groES* and *groEL* overlap by one base). The HSP70 gene of *N. sennetsu* has been cloned (Zhang et al., 1998).

The genes encoding the 51-kDa protein antigen have been identified in various strains of *N. risticii* from horses and trematodes (Barlough et al., 1998; Dutta et al., 1998; Reubel et al., 1998; Kanter et al., 2000) and in other *Neorickettsia* spp. (Rikihisa et al., unpublished data). Amino acid sequence identities of the 51-kDa protein among *N. risticii* strains are greater than 77% (Kanter et al., 2000). Another antigenic protein, 50/85 kDa in size, shows strain-dependent polymorphism, being 50 kDa in strain 25-D and 85 kDa in strain 90-12 by SDS-PAGE, the higher value is due to the presence of tandem repeat nucleotide sequences which vary in size, number and type of repeats (Biswas et al., 1998). Genes encoding a type IV secretion apparatus and two-component regulatory systems were identified (Rikihisa, unpublished data).

Antigenic structure Indirect fluorescent antibody (IFA) and Western immunoblot analyses of purified cells of *N. helminthoeca*, *N. sennetsu* and *N. risticii* using antisera from infected animals have shown that the surface antigens of these organisms are highly cross-reactive (Rikihisa et al., 1991). The cross-reactive antigens between *N. risticii* and *N. sennetsu*, as detected by Western immunoblot analysis, are proteins 51–55 kDa in size (Rikihisa, 1996). The 55-kDa GroEL homolog, the 50/85-kDa strain-specific antigen, and the 51-kDa antigen are in this range (Vemulapalli et al., 1998). The 51- and 50/85-kDa proteins are apparently unrelated. The 51-kDa protein has a putative signal peptide se-

quence and is thus a potential outer membrane protein (Vemulapalli et al., 1998), whereas the 50/85-kDa protein does not. GroEL is also a dominant antigen in *Neorickettsia* spp. and has been shown to cross-react with the GroEL of *Ehrlichia* spp., *Orientia* spp. and *Rickettsia* spp. but not with the GroEL of *Escherichia coli* (Zhang et al., 1997).

Pathogenicity *N. helminthoeca* is the causative agent of salmon poisoning disease of the *Canidae*, *N. sennetsu* is the agent of human Sennetsu ehrlichiosis, and *N. risticii* is the causative agent of Potomac horse fever or equine monocytic ehrlichiosis. When examined with an *in vitro* cultivation assay system, professional phagocytes—monocytes and macrophages—of host animal species have no intrinsic resistance to infection with *Neorickettsia* spp. *Neorickettsia* spp. also cause systemic febrile illness with thrombocytopenia and leukopenia, with or without lymphadenopathy. *Neorickettsia* spp. induce intestinal manifestations, which are especially severe with *N. risticii*, which causes watery diarrhea. Evidence of a severe inflammatory reaction is usually absent at necropsy. Pathogenicity has been studied most extensively for *N. risticii*. *N. risticii* specifically binds to macrophages, and both the host cell receptor and the *N. risticii* ligand appear to be proteins (Messick and Rikihisa, 1993). Neorickettsiae enter macrophages by receptor-mediated endocytosis, not by phagocytosis, and reside in the early endosomes that do not fuse with lysosomes (Wells and Rikihisa, 1988; Messick and Rikihisa, 1993, Rikihisa et al., 1994). Neorickettsial internalization and proliferation are dependent on Ca^{2+}-calmodulin-signaling and protein tyrosine phosphorylation (Rikihisa et al., 1995; Zhang and Rikihisa, 1997). *N. sennetsu* resides in early endosomes enriched with transferrin receptor and upregulates transferrin receptor mRNA by activating iron-responsive protein 1 (Barnewall et al., 1999). This activation might be a mechanism to facilitate iron uptake by neorickettsiae.

Neorickettsial release appears to occur not only by cell lysis but also through exocytosis by fusion of the inclusion membrane with the plasma membrane. In the case of intestinal epithelial cells, which make a monolayer tightly connected by circumferential zones of intercellular junctions, neorickettsiae appear to be transmitted between adjacent cells *in vitro* by a coupled exocytosis in one cell and endocytosis in an adjacent cell (Rikihisa, 1990a). *N. risticii* can be consistently reisolated from equine peripheral blood monocytes from days 1–28 after infection and 8 days after spontaneous resolution of clinical signs (Mott et al., 1997). *N. risticii* may persist much longer, since in a pregnant mare-fetus system, *N. risticii* has been isolated from the aborted fetus of a mare that was experimentally infected up to 3.5 months prior to the abortion (Dawson et al., 1987; Long et al., 1995).

Mouse pathogenicity of *Neorickettsia* spp. varies. *N. sennetsu* is pathogenic for mice. Clinical signs are ruffled fur, inactivity, and mild diarrhea followed by death in about 3–4 weeks after inoculation (Misao and Kobayashi, 1954). Necropsy of mice reveals marked enlargement of the spleen, the liver, and lymph nodes throughout the body. All human isolates have been obtained from the peritoneal macrophages of the mouse after intraperitoneal inoculation of patient's blood. *N. helminthoeca* is not pathogenic for mice. *N. risticii* can establish infection in mice and horses with or without causing apparent clinical illness. Based on a murine model for Potomac horse fever, the disease is apparently dose-dependent, i.e., with a low dose of *N. risticii*, innate defense mechanisms appear to contain *Neorickettsia* cells below a threshold level. Only at higher doses can the organism cause disease and pathological changes (Rikihisa et al., 1987). Horses that recover are immune to Potomac horse fever for up to 20 months after infection (Palmer et al., 1990). Exposure to killed organisms can protect mice from *N. risticii* infection (Rikihisa, 1991a). Both humoral and cell-mediated immune responses appear to play significant roles in this protection. The presence of neutralizing antibodies and antibody-dependent cellular toxicity has been demonstrated using a cell culture system (Messick and Rikihisa, 1992a; Rikihisa et al., 1993, 1994) and a murine model (Rikihisa et al., 1993). Polyclonal antiserum to *N. risticii* does not inhibit binding of *N. risticii* cells to P388D macrophages or their internalization, but internalized antibody-coated *N. risticii* fails to survive (Messick and Rikihisa, 1994). Because macrophages bear the Fc receptor, the Fab fragment of the antibody was used to analyze the inhibitory mechanism. Since the Fab fragment of the anti-*N. risticii* IgG blocks the binding of *N. risticii* to macrophages, antibody-coated *N. risticii* most likely enters macrophages via the Fc receptor. Fc-receptor-mediated uptake may deliver *N. risticii* to the intracellular compartment that is susceptible to lysosomal fusion. Alternatively, because ^{14}C-L-glutamine metabolism by purified host cell-free *N. risticii* is blocked by polyclonal antibody, direct metabolic inhibition may make *N. risticii* unable to survive in the macrophage (Messick and Rikihisa, 1994). *N. risticii* is very sensitive to nitric oxide, which is generated by macrophage cytoplasmic nitric oxide synthase induced by interferon gamma (IFN-γ) (Park and Rikihisa, 1991, 1992). Activities of T cells that generate IFN-γ are, however, generally severely depressed in infected mice in a time- and dose-related manner (Rikihisa et al., 1987). One cause for depressed T-cell response was found in macrophages. Class II histocompatibility antigen (Ia antigen) induction on the surface of *N. risticii*-infected macrophages (antigen-presenting cells) is suppressed *in vitro* (Messick and Rikihisa, 1992b), suggesting inhibition of antigen-specific T-cell activation in *N. risticii* infection. *N. risticii* induces only low levels of tissue necrosis factor alpha (TNF-α) and prostaglandin E2 production in murine macrophages *in vitro* (van Heeckeren et al., 1993). In contrast, infected macrophages produce significant amounts of interleukin 1 (IL-1).

Ecology Where known, *Neorickettsia* spp. are transmitted and maintained in trematodes found in *Pleuroceridae* snails (Nyberg et al., 1967; Millemann and Knapp, 1970). Infection of mammals is required for completion of the life cycle of the trematodes, but it is not directly required for maintenance of *Neorickettsia* spp. Dogs, horses, bats, and humans accidentally acquire *Neorickettsia* spp. by ingestion of the metacercaria stage of trematodes in fish or adult aquatic insects. The life cycle of *N. helminthoeca* includes growth in eggs of a digenetic microcercous trematode, *Nanophyetus salmincola*, in the redia stage of the trematode in the snail *Oxytrema silicula*, in the metacercaria stage of the trematode in salmonid fish, and in monocytes and macrophages in the dog. *N. helminthoeca* infects neither the fish nor the snail carrying the trematode. The disease has been reported from the Pacific Coast of Northern California, Oregon, and Washington. Additionally, several salmon poisoning cases have been reported in Vancouver Island, Canada (Booth et al., 1984).

N. risticii has been found in digenetic and virgulate trematodes of the family *Lecithodendoriidae*, which infect snails in the *Pleuroceridae* family, namely, *Elimia* and *Juga* spp., in the midwestern and northeastern U.S. and in California, respectively (Barlough et al., 1998; Reubel et al., 1998; Kanter et al., 2000). *N. risticii*-infected trematodes then penetrate and develop into metacer-

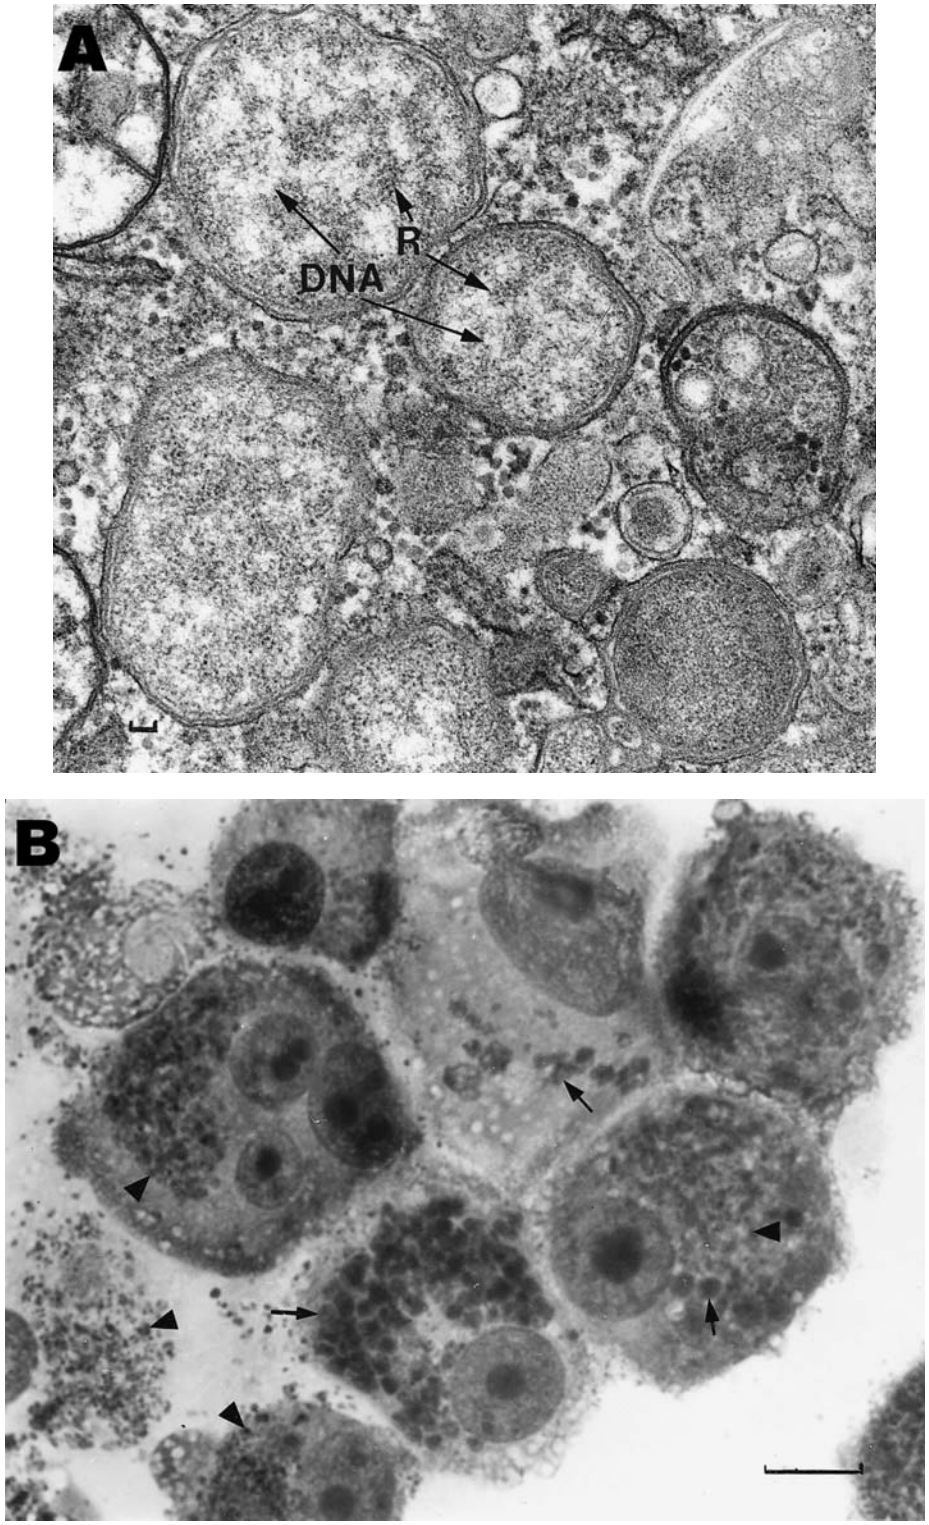

FIGURE BXII.α.44. *Neorickettsia helminthoeca. A*, Ultrathin section of an infected, cultured, canine monocytic cell (cell line DH82). *N. helminthoeca* organisms are tightly enveloped by a host cell membrane (*arrowheads*). Each bacterium is surrounded by a distinct plasma membrane and an outer membrane. Fine DNA strands and ribosomes (*R*) are evident in the organisms. (× 37,000). *B*, *N. helminthoeca* are seen in the cytoplasm of DH82 cells as small inclusions containing several organisms (*arrows*), as individual organisms (*arrowheads*), and as extracellular organisms. Preparation stained by Diff-Quik stain (× 1,275) (Reproduced with permission from Y. Rikihisa, et al., Journal of Clinical Microbiology *29:* 1928–1933, 1991, American Society for Microbiology, Washington, D.C.)

cariae in nymphs of a variety of aquatic insect including mayflies, caddis flies, and stone-flies (Chae et al., 2000). *N. risticii* survives through metamorphosis of insects and persists in adult insects; horses can acquire Potomac horse fever by ingestion of infected adult caddis flies (Madigan et al., 2000a; Mott et al., 2002). Despite epidemiological evidence that patients acquire Sennetsu fever by eating raw gray mullet fish, *N. sennetsu* has not been isolated from trematodes. However, the *Stellantochasmus falcatus* (SF) agent, which is more closely related to *N. risticii* than to *N. sennetsu*, has been isolated directly from metacercariae of the *S. falcatus* trematode in the gray mullet fish in a Sennetsu fever-endemic region in Japan (Fukuda et al., 1973; Yamamoto, 1978; Wen et al., 1996).

Antibiotic sensitivity All *Neorickettsia* spp. are sensitive to tetracycline antibiotics; however, they are not susceptible to β-lactam antibiotics, aminoglycosides, macrolides, chloramphenicol, or sulfonamides (Rikihisa and Jiang, 1988, 1989).

Enrichment and Isolation Procedures

N. helminthoeca has been isolated from the blood, spleen, and liver of dogs that have been infected by feeding them metacercariae-infected salmon; the organism was then propagated in the canine myelocytic leukemia cell line DH82 (Rikihisa et al., 1991). *N. risticii* has been isolated from the blood of horses infected with canine peripheral blood monocytes, U937 cells, or P388D cells (Rikihisa and Perry, 1984, 1985; Dutta et al., 1985; Holland et al., 1985). *N. risticii* has also been isolated from the blood of horses infected by oral administration of adult caddis flies or by subcutaneous inoculation of cercaria or sporocysts obtained from snails collected in an endemic area (Madigan et al., 2000a; Pusterla, et al., 2000b). *N. sennetsu* was isolated by intraperitoneal inoculation of patients' blood into laboratory mice (Fukuda et al., 1954; Misao and Kobayashi, 1954). The SF agent has been directly isolated by oral or intraperitoneal inoculation of mice with metacercariae excised from gray mullet fish (Fukuda et al., 1973).

Maintenance Procedures

The organism can be preserved by storing infected primary blood monocyte cultures or infected DH82 or P388D cell cultures in liquid nitrogen. The organism can also be preserved by storage at -80°C of a 20% suspension of homogenized infected lymph node or spleen tissue in RPMI 1640 medium containing 10% dimethyl sulfoxide and 15% fetal bovine serum (Rikihisa et al., 1991).

Differentiation of the genus *Neorickettsia* from other genera

Neorickettsiae are distinguished from *Ehrlichia*, *Anaplasma*, and *Wolbachia* spp. by their 16S rRNA gene sequences or *groESL* gene sequences, by the presence of a 51-kDa protein gene unique to *N. risticii*, *N. sennetsu*, and SF agent, by the lack of *msp2* or p44 homologs of *Anaplasma* spp. (Zhi et al., 1999) or OMP-1 homologs of *Ehrlichia* spp. (Ohashi et al., 1998a), by not being tickborne, and by their life cycle in trematodes.

Taxonomic Comments

Sequence comparisons of almost complete 16S rRNA genes revealed that the sequence similarity of a horse isolate of *N. risticii*—isolate 081—to *N. sennetsu* Miyayama is 99.7%—slightly greater than the similarity to either the *N. risticii* type strain (99.6 %) or to *N. risticii* Kentucky. The 16S rRNA gene sequence similarities between *N. helminthoeca* and *N. sennetsu* strains or *N. risticii* strains are 95.4–95.8% (Wen et al., 1996). According to Stackebrandt and Goebel (1994), a 16S rRNA gene sequence similarity of less than 97% between strains indicates that they represent different species, but at 97% or higher 16S rRNA gene sequence similarity, DNA relatedness must be used to determine whether strains belong to different species. Therefore, *N. sennetsu* and *N. risticii* belong to the same species based on 16S rRNA gene sequences.

The 16S rRNA gene sequence similarity between *N. risticii*, the agent of Rocky Mountain spotted fever, and *Neorickettsia* spp. is low (80%) (Pretzman et al., 1995).

Differentiation of the species of the genus *Neorickettsia*

Diagnostic features of *Neorickettsia* spp. are shown in Table BXII.α.40. The preferred methods for definitive identification of *Neorickettsia* species are sequence analysis of all or part of 16S rRNA gene, the *groESL* operon, or the *gltA* gene, or alternatively, amplification of portions of these genes by the polymerase chain reaction using species-specific oligonucleotide primers. Species-specific primers for *N. helminthoeca* and *N. risticii* and *N. sennetsu* are shown in Table BXII.α.41.

[a]Anderson et al. (1992c); Pretzman et al. (1995); Kanter et al. (2000).

[b]Sumner et al. (1997); Zhang et al. (1997).

The characteristics are as described for the genus and as listed in Table BXII.α.40. *N. helminthoeca* is the most phylogenetically distinct species in the genus *Neorickettsia*, differing from other species by approximately 4.5% in the 16S rRNA gene sequence. *N. helminthoeca* causes salmon poisoning disease, an acute and highly fatal disease of domestic and wild canidae. Clinical signs are fever, anorexia, inactivity, depression, vomiting, and diarrhea. In infected dogs, the major lymph nodes are enlarged. Although the trematode vector infects a wide variety of species of animals, salmon poisoning disease occurs chiefly in *Canidae* (dogs, coyotes, foxes) and is occasionally seen in immunosuppressed individuals of other animal species. Venereal transmission from an infected male to a female has also been reported. Rectal and aerosol transmission is also possible. Blood, feces, and lymph node aspirates are infectious; thus infected dogs must be isolated and care used so as not to induce iatrogenic transmission.

Ingested metacercariae in salmonid fish mature in 5–6 days in the gut, and the adult stage attaches deep in the interior of intestinal mucosa, inducing inflammation, i.e., hyperemia, inflammatory cell migration, and edema around the parasites. By an unknown mechanism, *N. helminthoeca* is transferred to monocytes and macrophages, which migrate through blood and lymphatic vessels and lodge in somatic and visceral lymph nodes. *N. helminthoeca* circulates in the blood of orally infected dogs starting day 8–12 after infection, as evidenced by the successful reisolation of *N. helminthoeca* from the blood from day 8–11 after infection until death (Rikihisa et al., 1991). Lymph nodes appear to be the primary site of multiplication of neorickettsiae. Like *N. risticii*, *N. helminthoeca* appears to exhibit intestinal tissue tropism, since not only the oral route of infection but also the intravenous inoculation of cell-cultured organisms induces severe hemorrhage throughout the small intestine. Nonsuppurative meningitis or meningoencephalitis and brain lesions have also been noted in both natural and experimental *N. helminthoeca* infections. The severe central nervous system depression seen in salmon poisoning disease is probably related to these brain lesions. Dogs experimentally infected with *N. helminthoeca* P.O. develop IgG antibody 13–15 days after infection as detected by IFA testing (Rikihisa et al., 1991).

Clinical signs are characterized by anorexia, inactivity, depression, and sudden onset of fever above 39.8°C and up to 42.7°C, followed by hypothermia over the next 4–8 days. Vomiting may precede the typical watery yellowish diarrhea that is sometimes tinged with blood. Rapid weight loss is evident and the lack of ingestion of water, coupled with fluid loss through vomiting and diarrhea, results in severe dehydration with both electrolyte and acid-base imbalances. Serous nasal and ocular discharges are sometimes seen. Lymphadenopathy of the major nodes is easily palpable.

Microscopically, lesions are generally mild and proliferative in character, with very little evidence of degeneration and necrosis in the various organs including the brain, although extensive necrosis may accompany the proliferative response in lymphoid tissue. Lesions consist of mononuclear cell infiltration. Generalized lymph node enlargement is due to marked infiltration of macrophages, accompanied by severe depletion of small lymphocytes and a loss of germinal centers.

Elokomin fluke fever agent was reported to occur along the Elokomin River in the state of Washington. The agent has a wider host range than *N. helminthoeca* and is reported to infect bears, raccoons, and ferrets in addition to the Canidae. Clinical signs of Elokomin fluke fever are milder than those of salmon poisoning disease. The agent has not been cultured in a continuous cell line. It is currently considered a strain of *N. helminthoeca* but much information is lacking (Rikihisa and Zimmerman, 1995).

The mol% G + C of the DNA is: 42 (by gene sampling).

Type strain: no culture isolated.

GenBank accession number (16S rRNA): U12457.

2. **Neorickettsia risticii** (Holland, Weiss, Burgdorfer, Cole and Kakoma 1985) Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2159[VP] (*Ehrlichia risticii* Holland, Weiss, Burgdorfer, Cole and Kakoma 1985, 524.)
ris.ti' cii. M.L. n. *ristic* from Miodrag Ristic, meaning Ristic' s.

The characteristics are as described for the genus and as listed in Table BXII.α.40. *N. risticii* cells are generally round, sometimes pleomorphic, and may be elongated, especially in tissue culture. The cells divide by binary fission. As determined by electron microscopy and immunoperoxidase staining, the organisms are found in membrane-lined vacuoles within the cytoplasm of infected eucaryotic host cells, primarily macrophages, mast cells, and glandular epithelial cells in the intestine of the horse (Rikihisa et al., 1984, 1985; Steele et al., 1986). *N. risticii* cells are shed into the intestinal lumen (Rikihisa et al., 1985) and are found in feces (Mott et al., 1997). Morulae and individually enveloped forms appear to transform into one another. An intermediate stage has been described (Rikihisa et al., 1985); it appears similar to a moderately electron-dense ehrlichia that is tightly enveloped by a host membrane. The membrane is continuous with a membrane surrounding a morula. *N. risticii* cells are primarily seen as individual forms in the T-84, P388D, and U-937 cell lines, in primary equine monocyte culture, and in infected equine tissues. The individual form is especially common in intestinal epithelial cells.

N. risticii is the causative agent of Potomac horse fever, which is also called equine monocytic ehrlichiosis. The disease may also be called equine ehrlichial colitis and acute equine diarrhea syndrome, depending on the clinical signs displayed in a given horse. Serological data indicate that Potomac horse fever occurs in 43 of the United States, in two provinces in Canada (Ontario and Saskatchewan), and in France, Italy, Venezuela, India, Brazil, and Australia (Rikihisa et al., 1990; Ristic, 1990).

Clinical signs are an acute onset of fever (up to 107°F), depression, anorexia, decreased borborygmi in all abdominal quadrants, subcutaneous edema of the legs and ventral abdomen, dehydration, and diarrhea (Rikihisa, 1997). Laminitis and severe abdominal pain occur in 15–25% and 5–10% of cases, respectively. Development of these signs is the most common reason for euthanizing infected horses. Laminitis may progress, even when other clinical signs resolve. Diarrhea may be mild to severe (pipestream), and occurs in 10–30% of cases. In some horses diarrhea is transient; in others, it persists for several days. Some horses may have no diarrhea. The case fatality rate ranges from 5–30%. Transplacental transmission of *N. risticii* occurs and the organism may induce abortion or resorption of the fetus or infect foals, which then require extensive neonatal care. Leukopenia and rebound leukocytosis are prominent hematological changes. Anemia, plasma protein concentration, and packed cell volume may increase. Thrombocytopenia may also be observed. Pathogenicity in laboratory mice varies among strains.

Watery diarrhea is caused by a reduction in electrolyte transport (Na^+, Cl^-); thus, there is lack of water resorption, mainly in the large and small colons (Rikihisa et al., 1992). Infected intestinal epithelial cells lose microvilli, which may contribute to the reduced electrolyte transport and water resorption. An increase in intracellular cyclic AMP (cAMP) is found in both infected mouse macrophages and infected horse intestinal tissues. This change in cAMP content may also contribute to the reduced luminal absorption of Na^+ and Cl^- in the colon, and thus to the lack of water absorption and diarrhea.

Genetic and antigenic divergence among strains has been examined (Chaichanasiriwithaya et al., 1994). The Ohio 081 strain was significantly different from Maryland, Virginia, Kentucky, or other Ohio strains in protein composition and 16S rRNA gene sequence. In agreement with these findings, the identity of the P51 amino acid sequences between the type strain and the Ohio 081 strain is 80.6%, the lowest among all P51s examined (Kanter et al., 2000). The greatest 16S rRNA gene sequence difference was between the type strain of *N. risticii* and the Bunn strain, followed by the Ohio 081 strain (14 and 10 bases, respectively) (Wen et al., 1995a). Genetic comparisons of strains do not show segregation of strains among those from the blood of horses, those from snails or trematodes, or those from aquatic insects. Thus, it appears that strains that affect horses are also present in trematodes in snails and insects. The genome size is 880 kb (Rydkina et al., 1996).

The mol% G + C of the DNA is: 42 (by gene sampling).
Type strain: HRC-IL, Illinois, ATCC VR-986.
GenBank accession number (16S rRNA): M21290.

3. **Neorickettsia sennetsu** (Misao and Kobayashi 1956) Dumler, Barbet, Bekker, Dasch, Palmer, Ray, Rikihisa and Rurangirwa 2001, 2159[VP] (*Rickettsia sennetsu* Misao and Kobayashi 1956) *Ehrlichia sennetsu* Ristic and Huxsoll 1984, 355.
sen' ne' tsu. M.L. n. *sennetsu* from Japanese, meaning glandular fever.

The characteristics are as described for the genus and as listed in Table BXII.α.40. The morphology is similar to that of *N. risticii*. *N. sennetsu* is the causative agent of human sennetsu rickettsiosis fever, also called Hyuga fever and Kagami fever. The clinical aspects may vary from mild headache, slight back pain, and a low-grade fever to a severe form of the disease characterized by persistent high fever, anorexia, lethargy, lymphadenopathy, and prominent hematologic abnormalities. The disease is limited to Western Japan and Malaysia (Ristic, 1990). *N. sennetsu* is not pathogenic for horses, but horses infected with it are protected from developing Potomac horse fever when challenged with *N. risticii* (Rikihisa et al., 1988). The 16S rRNA gene sequences and the *groESL* gene sequences (Zhang et al., 1997) are similar in *N. risticii* and *N. sennetsu*. The mode of transmission of *N. sennetsu* is unknown, although metacercariae that parasitize the gray mullet fish are suspected as the vector because of the association of the disease with the consumption of a raw fish of this type (Fukuda et al., 1973). Mice are highly susceptible to *N. sennetsu* and are used to isolate the organism from human specimens (Fukuda et al., 1954; Misao and Kobayashi, 1954). The genome size is 859 kb based on whole genome sequencing (Rikihisa, unpublished data).

The mol% G + C of the DNA is: 42 (by genome sequencing).
Type strain: Miyayama, ATCC VR-367.
GenBank accession number (16S rRNA): M73219.

Genus IV. **Wolbachia** *Hertig 1936, 472*[AL]

Bernard La Scola, Claudio Bandi and Didier Raoult

Wol.ba'chia. M.L. fem. n. *Wolbachia* named after S. Burt Wolbach, who described the rickettsial agent of Rocky Mountain spotted fever and, in collaboration with Marshall Hertig, studied the rickettsia-like microorganisms of insects.

Pleomorphic bacteria that appear as small rods (0.5–1.3 µm in length) and coccoid forms (0.25–1 µm); large forms (1–1.8 µm in diameter) may be observed. Grow in vacuoles of host cells. Do not grow outside of cells. **Associated with arthropods and filarial nematodes.** Responsible for reproductive alterations in arthropods. With few exceptions, not pathogenic for the host. **Strains associated with nematodes responsible for indirect pathogenesis in humans. Susceptibility to doxycycline and rifampin demonstrated *in vitro* and *in vivo*.**

The mol% G + C of the DNA is: not determined.

Type species: **Wolbachia pipientis** Hertig 1936, 472.

Further descriptive information

Discovered in 1924 and described in 1936 by Hertig (Hertig and Wolbach, 1924; Hertig, 1936), *Wolbachia pipientis* is currently regarded as the sole species of the genus *Wolbachia* (Dumler et al., 2001). *Wolbachia* is a member of the *Alphaproteobacteria*.

Older descriptions of the genus *Wolbachia* included two species, *Wolbachia persica* and *Wolbachia melophagi*, that have characteristics distinct from *W. pipientis* (Fig. BXII.α.45). *Wolbachia persica* belongs to the *Gammaproteobacteria* (Weisburg et al., 1989; Forsman et al., 1994) and should be reclassified as *"Francisella persica"* (Niebylski et al., 1997a). The exact taxonomic position of *Wolbachia melophagi* has yet to be determined, but its description as an extracellular bacterium in the lumen of its host, *Melophagus ovinus*—a wingless fly commonly called sheep ked (Weiss et al., 1984)—is not in accordance with the strictly intracellular location of bacteria of the family *Anaplasmataceae*. In addition, a 16S rDNA gene sequence obtained from *W. melophagi* shows high homology with the 16S rRNA gene of species in the genus *Bartonella* (R.J. Birtles and D.H. Molyneux, unpublished GenBank accession X89110). A formal proposal to remove *W. persica* and *W. melophagi* from the genus *Wolbachia* has recently been published (Dumler et al., 2001). Descriptions of *Wolbachia persica* and

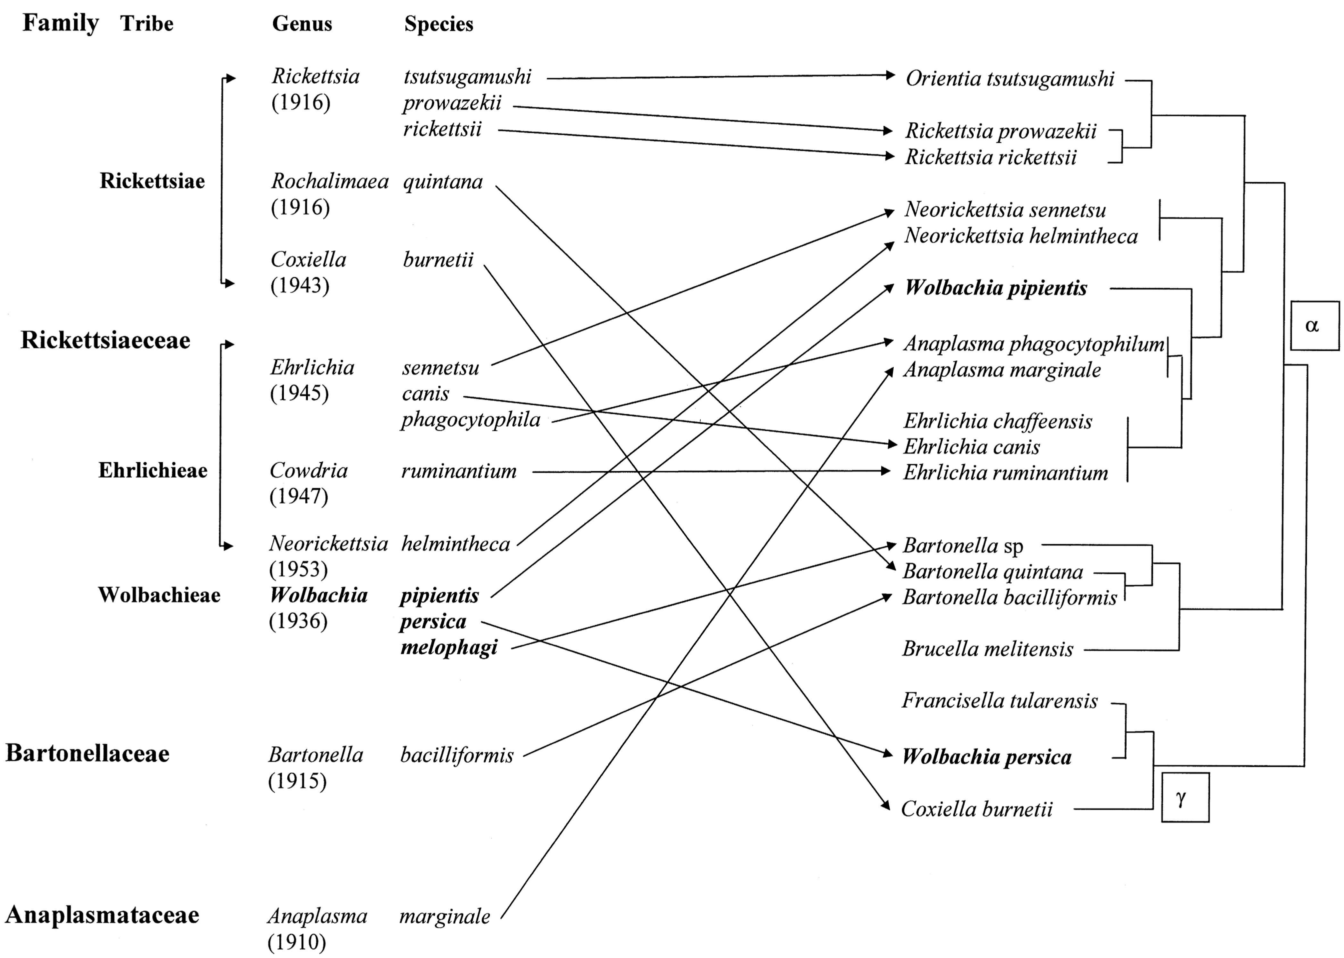

FIGURE BXII.α.45. The left-hand side of the figure indicates the classification of the *Rickettsiae* in *Bergey's Manual.* (Reproduced with permission from E. Weiss et al., *In* Krieg and Holt (editors), *Bergey's Manual of Systematic Bacteriology*, ©Williams & Wilkins Co., 1984, pp. 711–713). The classification on the right-hand side is based on a comparison of 16s rRNA gene sequences including the recent reorganization in the families *Rickettsiaceae* and *Anaplasmataceae* (Dumler et al., 2001).

Wolbachia melophagi can be found in the chapters on *Francisella* and *Bartonella*, respectively.

Additional *Wolbachia*-like organisms have been described, including *"Wolbachia postica"*, *"Wolbachia trichogrammae"*, and *"Wolbachia popcon"* (Hsiao and Hsioa, 1985; Louis and Nigro, 1989; Min and Benzer, 1997).

W. pipientis is not visible by Gram staining in spite of its Gram-negative cell wall structure (Fig. BXII.α.46). The organisms can be stained using conventional Giemsa's stain or rapid staining such as Diff-Quick (Fig. BXII.α.47). With the Gimenez stain, the bacteria can be visualized, but they appear as dark blue structures within a blue-green cytoplasm and not as pink-red structures as do rickettsiae. A peptidoglycan layer has not been observed and the cells display some plasticity (Yen and Barr, 1974; Wright et al., 1978; Wright and Barr, 1980). Association with bacteriophage-like particles has been described previously (Wright et al., 1978). More recently, a bacteriophage-like genetic element, named bacteriophage WO, has been identified in *Wolbachia* (Masui et al., 2000).

W. pipientis multiplies by binary fission in the vacuoles of host cells and is surrounded by a membrane of host origin (Fig. BXII.α.46). In arthropods, the bacteria are present mostly in the cytoplasm of cells in the reproductive organs, but they can also be observed in other tissues, including nervous tissue and hemocytes (Louis and Nigro, 1989; Rigaud et al., 1991). In filarial nematodes, *Wolbachia* is present in the lateral cords and in the female reproductive apparatus (Kozek, 1977; Kozek and Marroquin, 1977). In both arthropods and nematodes, *Wolbachia* is transovarially transmitted to the offspring (Werren, 1997; Bandi et al., 2001).

A strain of *W. pipientis* has recently been established in an *Aedes albopictus*-derived cell line that allows production of signif-

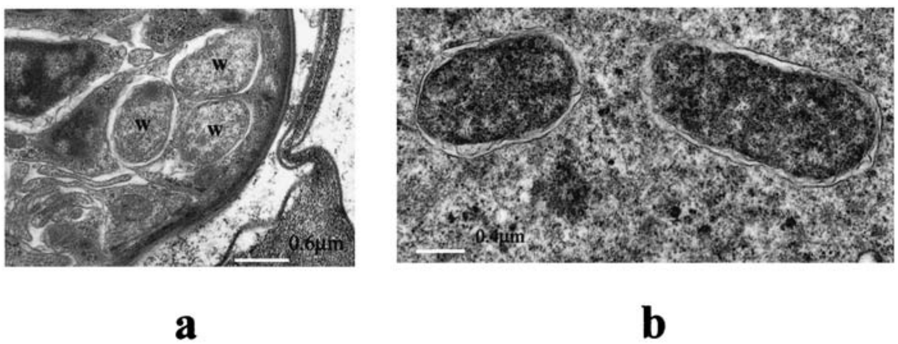

FIGURE BXII.α.46. *Wolbachia pipientis* in filarial nematodes. (*a*) *Wolbachia* (*W*) inside an embryo of the dog heartworm *D. immitis*. (*b*) Details of *Wolbachia* endosymbionts inside an oocyte of the lymphatic filarial worm *Brugia pahangi* (photographs courtesy of Luciano Sacchi).

icant amounts of the bacteria (O'Neill et al., 1997). This strain has been deposited at the American Type Culture Collection (ATCC VR-1529).

W. pipientis was originally observed in the gonads of the mosquito *Culex pipiens* (Hertig and Wolbach, 1924; Hertig, 1936). Later surveys showed *Wolbachia* to be present in at least 16% of sampled insect species (Werren et al., 1995a). The organism has also been found in representatives of other classes of arthropods (Rousset et al., 1992) and more recently in filarial nematodes of the family *Onchocercidae* (Sironi et al., 1995). Several species of filarial nematodes are known to be infected by *Wolbachia* (Table BXII.α.42). *Wolbachia*-infected taxa and the prevalence of infection have been reviewed recently (Taylor and Hoerauf, 1999; Bandi et al., 2001; Stevens et al., 2001) (Table BXII.α.42). In arthropods, *Wolbachia* is patchily distributed among insect populations and species (e.g., both infected and uninfected populations can be observed in the same species; Werren, 1997). In infected nematode species, all individuals and populations thus far examined are infected (Bandi et al., 2001). *Wolbachia* strains that infect arthropods can tolerate the cellular environment of diverse hosts, as demonstrated by studies with microinjection in various host cells (Boyle et al., 1993; Braig et al., 1994). In addition, there is evidence for horizontal transmission of *Wolbachia* in arthropods, and the same host may be infected by different strains of *Wolbachia* belonging to different genomic groups (Werren, 1997; Jamnongluk et al., 2002). Horizontal transmission and multiple infections have not been documented for nematode-infecting wolbachiae (Bandi et al., 1999, 2001; Casiraghi et al., 2001a).

Wolbachia does not usually cause obvious damage to its host cell. Nevertheless, a variant strain detected in *Drosophila melanogaster* showed massive proliferation in adult cells leading to widespread degeneration of tissues followed by early death of the insect (Min and Benzer, 1997). In addition, the male-killing *Wolbachia* strains present in arthropods (see below) are obviously pathogenic to male embryos (Hurst et al., 1999).

In arthropods, *Wolbachia* infection is usually associated with alterations in host reproduction, which include killing of male embryos, induction of parthenogenesis, feminization of genetic males, and cytoplasmic incompatibility (CI) (reviewed in Werren, 1997; Stouthamer et al., 1999; Stevens et al., 2001). It must be noted that *Wolbachia* is transmitted to the offspring by females, whereas males are usually not involved in transmission. All the reproductive alterations effected by *Wolbachia* in arthropods are interpreted as having the overall effect of increasing the transmission rate of *Wolbachia* (Werren, 1997). For example, parthenogenesis and feminization cause a *Wolbachia*-infected female to generate more female offspring, which will in turn transmit the bacterium. In CI, embryonic death is observed after mating between males that are infected by certain strains of *Wolbachia* and females that are either uninfected or infected with an incompatible *Wolbachia* strain. i.e., males infected by *Wolbachia* do not

TABLE BXII.α.42. Prevalence of *Wolbachia* in arthropods and filarial nematodes[a]

Host taxa	*Wolbachia* prevalence	Reference
Arthropods:		
Arthropoda	76%	Jeyaprakash and Hoy, 2000
Arachnida	(1/2)	
Insecta	(47/61)	
Arthropoda	18.4%	Werren and Windsor, 2000
Arachnida	(1/12)	
Insecta	(28/145)	
Arthropoda	16.5%	Werren et al., 1995a
Arachnida	(0/3)	
Insecta	(26/154)

Dirofilaria repens	*Wolbachia* observed	Bandi et al., 1998
Litomosoides sigmodontis	*Wolbachia* observed	Bandi et al., 1998; Hoerauf et al., 1999
Mansonella ozzardi	*Wolbachia* observed	Casiraghi et al., 2001a
Onchocerca flexuosa	No *Wolbachia* observed	Henkle-Dührsen et al., 1998; Plenge-Bönig et al., 1995
Onchocerca gibsoni	*Wolbachia* observed	Bandi et al., 1998
Onchocerca gutturosa	*Wolbachia* observed	Bandi et al., 1998
Onchocerca lupi	*Wolbachia* observed	Egyed et al., 2002
Onchocerca ochengi	*Wolbachia* observed	Bandi et al., 1998
Wuchereria bancrofti	*Wolbachia* observed	Bandi et al., 1998; Taylor et al., 1999

[a]Data from Taylor and Hoerauf (1999), Bandi et al. (2001), and Stevens et al. (2001). For filarial nematodes, the *Wolbachia*-infected species included in the table are those for which positive *Wolbachia* PCR and *Wolbachia* gene sequences have been obtained; the *Wolbachia*-negative filarial species included in the table (*A. viteae* and *O. flexuosa*) are those for which the evidence for the absence of intracellular bacteria or *Wolbachia* has been reported in independent experimental studies based on different approaches (e.g., electron microscopy and PCR); for other filarial species that may be either infected or uninfected by *Wolbachia*, see the tables published by Taylor and Hoerauf (1999) and Bandi et al. (2001).

transmit it, but they sterilize those females that do not carry *Wolbachia* or those that carry a different compatibility type of *Wolbachia*. This reduction in the fitness of uninfected females implies an increase of the fitness of infected ones, thereby favoring the spread of the CI-inducing *Wolbachia* in the host population.

The molecular mechanisms of the reproductive alterations caused by *Wolbachia* are not known, even though the events leading to phenomena like CI have been described at the cytological level (e.g., Tram and Sullivan, 2002). In addition to the effects on arthropod reproduction, there is one case of a wasp (*Asobara tabida*) in which *Wolbachia* is required for oogenesis (Dedeine et al., 2001). *Wolbachia* has also been shown to rescue a deleterious genetic mutation that affects oogenesis in *Drosophila melanogaster* (Starr and Cline, 2002). Moreover, the number of *Wolbachia* cells in filarial nematodes has been shown to be positively associated with longevity (Taylor, personal communication).

There are different lines of evidence implicating *Wolbachia* in the pathogenesis of filariasis and in the side effects of anti-filarial therapy. In particular, extracts of filariae harboring wolbachiae stimulate human and mouse monocytes to produce pro-inflammatory cytokines and other mediators of inflammation (Brattig et al., 2000; Taylor et al., 2000), and they also attract granulocytes to the cornea in an animal model of river blindness, with thickening and opacity of the corneal stroma (Saint Andrè et al., 2002). Both corneal alterations and monocyte stimulation have been shown to be dependent on receptors required for the host cell response to lipopolysaccharide (LPS). In addition, monocyte stimulation is inhibited by an LPS antagonist/inhibitor, but not by heat treatment of the filarial extract (Taylor et al., 2000). Thus, there is overall evidence that filariae that harbor *Wolbachia* strains also contain LPS, which might play an important role in the immunopathogenesis of filariasis. The presence of LPS in these filariae is supported by a positive *Limulus* amebocyte lysate assay on filarial extracts (Brattig et al., 2000; Taylor et al., 2000). However, the LPS of *Wolbachia* has not yet been purified. The fact that *Wolbachia* actually interacts with the host immune system is further documented by the presence of antibodies against the *Wolbachia* surface protein (WSP) in animals infected with filarial nematodes (Bazzocchi et al., 2000b; Punkosdy et al., 2001). In addition, real-time PCR has allowed quantification of the release of *Wolbachia* DNA after microfilaricidal treatment of patients affected by onchocerciasis. There is a correlation between the PCR signal for *Wolbachia*, the release of mediators of inflammation, and the side effects of therapy (Keiser et al., 2002). It must be noted that post-treatment reactions in filariasis partially resemble those observed in acute bacteremia, both at the clinical level and in terms of markers of inflammation (Haarbrink et al., 2000; Keiser et al., 2002).

Susceptibility of *W. pipientis* to tetracycline was first demonstrated by addition of 17-50 μg/ml of tetracycline to the diet of larvae, resulting in the elimination of *Wolbachia* from the insects (Weiss et al., 1984). Studies of antibiotic susceptibility of *W. pipientis* were extended by studies of the susceptibility of the O'Neill strain in the Aa23 cell line to five antibiotic agents (Hermans et al., 2001) (Table BXII.α.43). *In vivo* studies in filarial nematode models have also demonstrated the activity of rifampicin and doxycycline and the inactivity of ciprofloxacin against *Wolbachia* (Hoerauf et al., 2000a; Towson et al., 2000). Treatment with tetracycline and tetracycline derivatives has also been shown to have detrimental effects on filariae that harbor *Wolbachia* (Bandi et al., 1999; Hoerauf et al., 1999, 2000a, b; McCall et al., 1999; Langworthy et al., 2000; Towson et al., 2000; Casiraghi et al., 2002). These detrimental effects include inhibition of worm development, infertility, and adulticidal effects (reviewed in Bandi et al., 2001). Since tetracycline treatment has no detrimental effect on the *Wolbachia*-free filarial worm *A. viteae*, it is assumed that, in infected species, *Wolbachia* is needed by the host nematode (Hoerauf et al., 1999; McCall et al., 1999). The discovery that filarial nematodes are susceptible to antibiotics has opened new prospects for the control of filariasis: clinical trials have already demonstrated the potential utility of doxycycline for the control of river blindness (Hoerauf et al., 2000b).

TABLE BXII.α.43. Effects of antibiotics on the O'Neill strain of *Wolbachia pipientis*[a, b]

Antibiotic	MIC (mg/l)	MBC (mg/l)
Doxycycline	0.0625	0.25
Oxytetracycline	4	1
Rifampicin	0.0625	2
Ciprofloxacin	>8	>8
Penicillin	>256	>256

[a]Data from Hermans et al. (2001).

[b]MIC, minimal inhibitory concentration; MBC, minimal bacteriocidal concentration.

Enrichment and Isolation Procedures

The sole isolation of *W. pipientis* reported to date is that of cells grown successfully in an Aa23 cell line from *Aedes albopictus* mosquitoes. The cell line was established as described by Tesh and Modi (1983). These cells (both infected ones and ones freed of *W. pipientis* by antibiotic treatment) are routinely grown at 28°C in a mixture (1:1 v/v) of Mitsuhashi-Maramorosh insect medium and Schneider's insect medium supplemented with 10–15% bovine fetal serum. Cells are grown in 25-cm^3 flasks containing 5 ml of medium. The cells are passaged every week by shaking the flask and centrifuging the resulting cell suspension at low speed. The cell pellet is resuspended in the same amount of medium, and a new flask is seeded with 20% of the resuspended cells. For production of large amounts of bacteria, infected cells from one flask may be harvested every five days and inoculated into three cell culture flasks with fresh medium. The O'Neill strain can be propagated on human embryonic lung (HEL) fibroblast monolayers (CCL-137, American Type Culture Collection, Rockville, MD) at 28 and 37°C under previously described conditions (Raoult et al., 2001). The strain can also be propagated in C6/36—(CRL-1660, ATCC)—another mosquito cell line (from *A. albopictus*) grown in Leibowitz-15 medium with L-glutamine and L-amino acids, 5% (v/v) fetal bovine serum and 2% (v/v) tryptose phosphate at 28°C (Fenollar, La Scola, Taylor, and Raoult, unpublished data).

Maintenance Procedures

The O'Neill strain is preserved by rapid freezing and storage at −80°C.

Differentiation of the genus *Wolbachia* from other genera

Wolbachia are differentiated from *Anaplasma*, *Ehrlichia*, and *Neorickettsia* because they do not form morulae and because they infect only arthropods and filarial nematodes, not mammals. They are also distinguished by their 16S rRNA gene sequence.

Taxonomic Comments

A phylogenetic analysis of the 16S rRNA gene clearly assigned *W. pipientis* to the *Alphaproteobacteria* and revealed a close relationship to the genera *Ehrlichia*, *Anaplasma* and *Neorickettsia* (Fig. BXII.α.45) (O'Neill et al., 1992). This study showed that *W. pipientis sensu stricto* (i.e., the bacterium present in the ovaries of *C. pipiens*) formed a monophyletic clade with other insect-associated microorganisms, and the authors suggested that this analysis supported the provisional "classification of these bacteria as members of the same species" (O'Neill et al., 1992). Further analyses based on the 16S rRNA gene and other genes identified other bacteria found in arthropods and in filarial nematodes as close relatives of *W. pipientis* (Rousset et al., 1992; Stouthamer et al., 1993; Werren et al., 1995b; Bandi et al., 1998; Vandekerckhove et al., 1999; Lo et al., 2002). All these bacteria form a coherent, monophyletic clade composed of at least six different main clusters (Fig. BXII.α.48), which have been indicated as supergroups A–F (Lo et al., 2002). In agreement with the opinion expressed by O'Neill et al. (1992), it has been suggested that the six supergroups be provisionally regarded as belonging to the sole valid species of the genus, *W. pipientis*, until formal proposals are made to elevate these clusters at the species rank (Bandi et al., 2001; see also discussion in Dumler et al., 2001).

At a finer taxonomic scale, a system based on the level of similarity in the *wsp* gene sequence has been proposed for strain grouping (Zhou et al., 1998). However, evidence for recombination between *Wolbachia* strains of supergroups A and B has raised questions about the usefulness of strain assemblages based

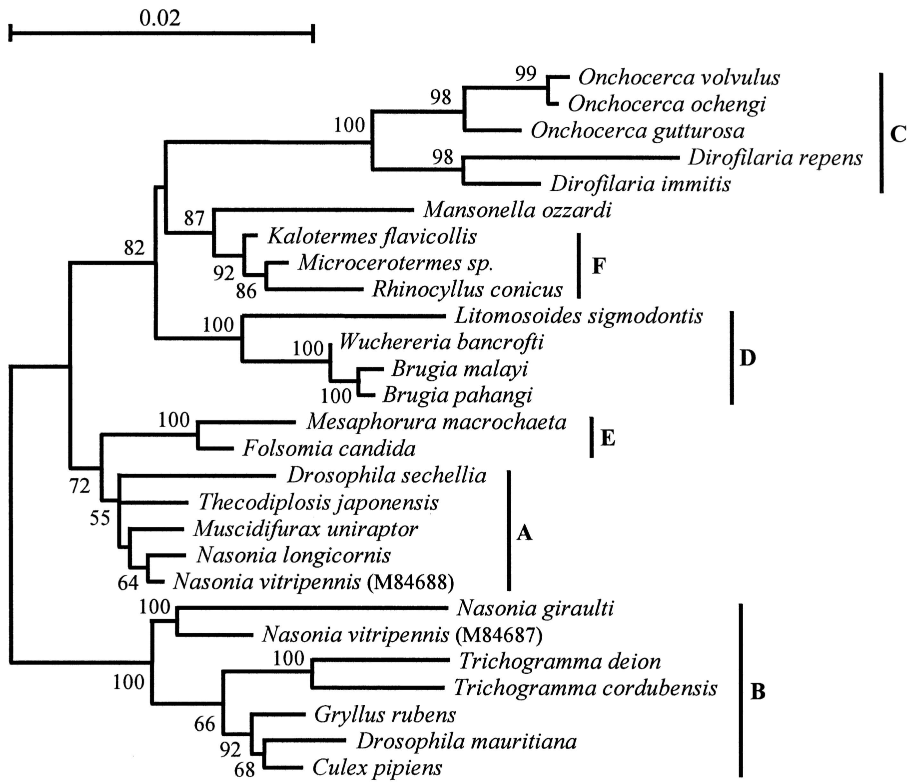

FIGURE BXII.α.48. Unrooted phylogenetic tree showing the six supergroups of *Wolbachia pipientis* (A–F) Lo et al., 2002. Names at the terminal nodes are those of the host species. The scale bar indicates distance in substitutions per nucleotide. Numbers at the nodes are the bootstrap confidence values based on 100 replicates (values below 50% are not indicated). Supergroups A, B, E, and F are found in arthropods. Supergroups C and D are found in filarial nematodes. The positioning of the *Wolbachia* found in the filarial nematode *Mansonella ozzardi* as a sister group of F wolbachiae is still to be evaluated, since only the 16S rRNA gene is available for this symbiont. The tree (neighbor-joining method; Kimura correction) is based on the gene coding for the 16S rRNA. This tree includes *Wolbachia* sequences derived from: *Nasonia vitripennis*, GenBank accession number M84688; *Mesaphorura macrochaeta*, GenBank accession number AJ422184; *Grillus rubens*, GenBank accession number U83092; *Muscifidurax uniraptor*, GenBank accession number L02882; *Rhinocyllus conicus*, GenBank accession number M85267; *Nasonia longicornis*, GenBank accession number M84691; *Nasonia vitripennis*, GenBank accession number M84687; *Nasonia giraulti*, GenBank accession number M84689; *Trichogramma cordubensis*, GenBank accession number L02883; *Trichogramma deion*, GenBank accession number L02884; *Culex pipiens*, GenBank accession number X61768; *Drosophila mauritania*, GenBank accession number U17060; *Drosophila sechellia*, GenBank accession number U17059; *Folsomia candida*, GenBank accession number AF179630; *Thecodiplosis japonensis*, GenBank accession number AF220604; *Kalotermes flavicollis* Y11377; *Microcerotermes* sp., GenBank accession number AJ292347; *Brugia pahangi*, GenBank accession number AJ012646; *Brugia malayi*, GenBank accession number AJ010275; *Wuchereria bancrofti*, GenBank accession number AF093510; *Onchocerca ochengi*, GenBank accession number AJ010276; *Dirofilaria immitis*, GenBank accession number Z49261; *Mansonella ozzardi*, GenBank accession number AJ279034; *Dirofilaria repens*, GenBank accession number AJ276500; *Litomosoides sigmodontis*, GenBank accession number AF069068; *Onchocerca volvulus*, GenBank accession number AF069069; *Onchocerca gutturosa*, GenBank accession number AJ276498.

on single gene sequences (Jiggins et al., 2001; Werren and Bartos, 2001).

The inference of phylogenetic relationships among strains of *Wolbachia* and the description of the six supergroups have been based on the analyses of 16S rRNA and *ftsZ* genes (Werren et al., 1995b; Bandi et al., 1998; Lo et al., 2002). At the level of supergroup definition, analyses of other genes (*wsp*; *groESL*) have led to results that are generally congruent with those based on 16S rDNA and *ftsZ* genes (Masui et al., 1997; Bazzocchi et al. 2000a). However, most of the phylogenetic trees thus far published for *Wolbachia* are actually unrooted (e.g., Werren et al., 1995a; Bandi et al., 1998; Zhou et al., 1998). In the absence of a reliable rooting for the overall phylogeny of *Wolbachia* and of suitable outgroup sequences, the relationships among the six supergroups are indeed not yet established. The possibility that one of the supergroups is paraphyletic cannot be excluded.

Supergroups A, B, E, and F contain the wolbachiae found in arthropods, whereas supergroups C and D contain the wolbachiae of filarial nematodes. One possible exception is the *Wolbachia* strain harbored by the filarial nematode *Mansonella ozzardi*; this strain appears to be more closely related to members of supergroup F (Lo et al., 2002). In supergroups A and B the phylogeny of *Wolbachia* is not always congruent with the host phylogeny (O'Neill et al., 1992; Werren et al., 1995b); this finding suggests that *Wolbachia* can be horizontally transmitted among arthropod hosts (Werren, 1997). In supergroups C and D the phylogeny of *Wolbachia* is consistent with the phylogeny of the host nematodes, which suggests strict vertical transmission of the symbionts (Casiraghi et al., 2001b). In a single infected nematode species, all the individuals thus far examined have been shown to harbor *Wolbachia* strains with identical *wsp* gene sequences, while *Wolbachia* strains from different nematode species possess differences in this gene (Bazzocchi et al., 2000b). This result supports the hypothesis of strict vertical transmission and suggests that the association with *Wolbachia* is species-specific in filarial nematodes.

List of species of the genus Wolbachia

1. **Wolbachia pipientis** Hertig 1936, 472[AL]

pi.pi.en′ tis. M.L. n. *pipiens* specific epithet of the host mosquito, *Culex pipiens*; M.L. gen. n. *pipientis* of pipiens.

The characteristics are as described for the genus.

The mol% G + C of the DNA is: unknown.

Type strain: no type strain.

Additional Remarks: The sole available strain for *in vitro* growth is O'Neill strain (see above).

Genus Incertae Sedis V. **Aegyptianella** *Carpano 1929, 12[AL]*

YASUKO RIKIHISA AND JULIUS P. KREIER

Ae.gyp′ ti.a.nel′ la. dim. ending *-ella* M.L. fem. dim. n. *Aegyptianella* named after Egypt where the organism was described in 1929.

In blood smears stained by Romanowsky methods, the inclusions **appear in erythrocytes as purple intracytoplasmic bodies** of 0.3–4 µm in size. By electron microscopy, each inclusion contains between 1 and 26 pleomorphic cocci with trilaminar outer membranes. They are obligate parasites of domestic and wild birds. Transmitted by ticks.

The mol% G + C of the DNA is: not known.

Type species: **Aegyptianella pullorum** Carpano 1929, 12.

FURTHER DESCRIPTIVE INFORMATION

Phylogeny By 16S rRNA gene and *groEL* operon sequence analysis, *Aegyptianella pullorum* belongs to the family *Anaplasmataceae* (Rikihisa et al., 2003). Identities of 16S rRNA genes and *groEL* operon sequences of *A. pullorum* to those of *Anaplasma* species were 92.7–93.3% and 71.4–73.3%, respectively. Identities of 16S rRNA gene and *groEL* operon sequences of *A. pullorum* to those of *Ehrlichia* species were 86.0–88.2 and 68.3–69.2%, respectively. Identities of 16S rRNA gene and *groEL* operon sequences of *A. pullorum* to those of *Neorickettsia* species were 78.2–79.2% and 40.0–41.5%, respectively.

Cell morphology In blood smears stained with Giemsa, the inclusions appear in the host's erythrocytes in a variety of forms: compact, round or oval, ring- or horseshoe-shaped, polygonal or polymorphic. They are violet-reddish in color, with a diameter of 0.3–4.0 µm. In larger inclusions, clearly defined small cocci of 0.25–0.4 µm resembling *Anaplasma* sp. can be distinguished by electron microscopy. The organisms reproduce by binary fission. These bacteria may also be found free in the plasma and in phagocytic cells. Organisms in phagocytic cells are probably phagocytosed and not growing, but undergoing digestion (Gothe, 1967b, 1971).

Fine structure In erythrocytes, the inclusions are separated from the erythrocyte cytoplasm by a single membrane presumably of erythrocyte origin. The bacterial cytoplasm contains ribosomes and DNA strands. The organisms are enveloped in a trilaminar outer membrane (Gothe, 1967a, 1971; Bird and Garnham, 1969; Castle and Christensen, 1985) (Fig. BXII.α.49). Scanning electron microscopy of infected erythrocytes revealed that the mode of entrance of organisms into erythrocytes may be

endocytosis followed by formation of an erythrocytic vesicle. The exit of the organisms from parasitized erythrocytes may be the reverse of the invasive mechanism, an exocytosis. Generally, however, the affected erythrocytes are injured by the parasites, resulting in release of the parasites into the plasma by host cell lysis (Gothe and Burkhardt, 1979).

Cultural characteristics and antibiotic susceptibility Multiplication of *A. pullorum* has not been observed to occur in cell-free media or in tissue cultures. Attempts at continuous propagation of the organism in chicken embryos have not been successful (Gothe, 1971). Only broad-spectrum antibiotics of the tetracycline series, dithiosemicarbazones, and pleuromutilins have a bacteriocidal efficacy with a significant chemotherapeutic influence on the course of the infection in chickens (Gothe, 1971; Gothe and Mieth, 1979).

Ecology Chickens are naturally infected with *A. pullorum* by the ticks *Argas (Persicargas) persicus*, *A. (P.) walkerae*, *A. (P.) sanchezi*, and *A. (P.) radiates*. The tick is a biological vector. Experimental infection can be achieved by subcutaneous, intramuscular, intravenous, and intraperitoneal inoculation of infected blood or by scarification followed by application of the infected blood to the scarified area. In addition to infection of chickens, natural infections have been described in geese, ducks, quail, and ostriches. Wild birds that have been experimentally infected are *Turtur erythrophrys* and *Balearica pavonina* (Curasson and Andrjesky, 1929), *Turtur senegalensis*, *Milvus aegyptiacus*, and *Vidua principalis* (Curasson, 1938).

Infection is transstadial in ticks (Gothe, 1967c, 1971; Hadani and Dinur, 1968). Transovarial transmission has also been observed (Hadani and Dinur, 1968; Gothe, 1971).

Maintenance Procedures

The infectivity of *A. pullorum* in chicken blood can be preserved up to nearly 7 years by storage in liquid nitrogen (Raether and Seidenath, 1977). Cryopreservation does not affect the ability of the parasites to propagate in the vector tick *Argas (Persicargas) walkerae* (Gothe and Hartmann, 1979).

Differentiation of the genus *Aegyptianella* from other genera

Characteristics useful for differentiating *Aegyptianella* from the other members of the family *Anaplasmataceae* are provided in the key to this family (see Table BXII.α.33 of the chapter describing the family *Anaplasmataceae*).

Taxonomic Comments

At present several species have been described in the genus *Aegyptianella* including those bacteria infecting erythrocytes of poikilotherms (Gothe, 1978). Detailed morphological and biochemical investigations have only been carried out with *A. pullorum*.

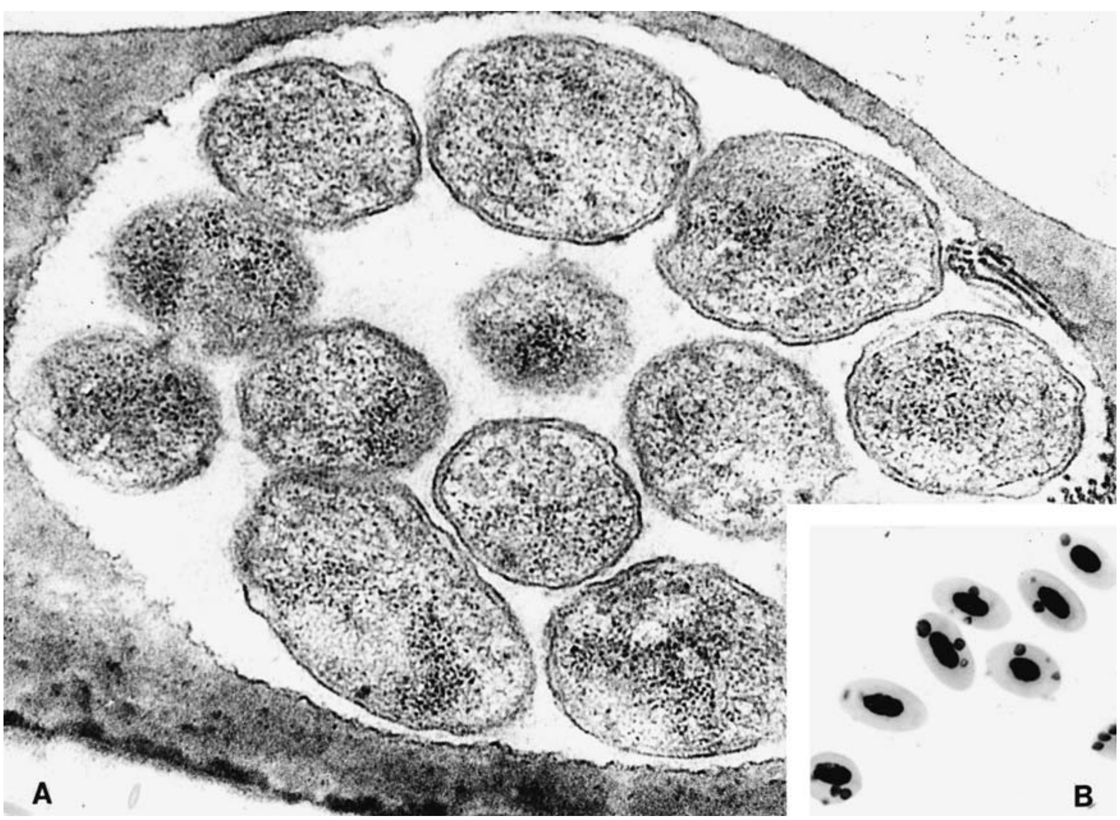

FIGURE BXII.α.49. *Aegyptianella pullorum. A*, ultrathin section of an infected erythrocyte, showing an inclusion body containing 12 parasites (× 90,000). *B*, intraerythrocytic inclusion bodies stained by the Giemsa method. (Reproduced with permission from R. Gothe, Zeitschrift für Parasitenkunde, *29:* 119–129, 1967, ©Springer-Verlag, Berlin.)

Electron microscopy studies have been performed for *"Aegyptianella botuliformis"*, *"Aegyptianella ranarum"*, and *"Aegyptianella bacterifera"*, which show that these three spp. are different from *A. pullorum*. Other species have been described but, except for *"A. ranarum"*, neither their true identify nor their relationship to *A. pullorum* has been established (see *Species incertae sedis*).

Differentiation of the species of the genus *Aegyptianella*

The following species are tentatively classified in the genus *Aegyptianella*; genetic studies are required to learn how similar they are. Except for *A. pullorum*, these species have not been formally described and therefore do not presently have standing in nomenclature. Characteristics are listed in Table BXII.α.44.

List of species of the genus Aegyptianella

1. **Aegyptianella pullorum** Carpano 1929, 12[AL]
pul.lo' rum. L. gen. pl. n. *pullorum* of young fowls.

The characteristics are as described for the genus.
The mol% G + C of the DNA is: unknown.
Type strain: No culture isolated.
Additional Remarks: At the time of publication, the only available 16S rRNA gene sequence for *A. pullorum* was AY125087.

Species Incertae Sedis

1. **"Aegyptianella bacterifera"** Barta, Boulard and Desser 1989, 14 ("Cytamoeba bacterifera" Labbé 1894, 104.)
bac.te.ri' fe.ra. Gr. dim. n. *bacterium* a small rod; L. suffix *-fer (-ferus),* from L. v. *fero* to bear; M.L. adj. *bacterifera* bearing small rods.

Up to 12 rod-shaped organisms that are 2.3–4.9 × 0.5 µm are found in membrane-bound inclusions of erythrocytes of *Rana esculata* in Corsica and *R. nigromaculata* in China.

2. **"Aegyptianella botuliformis"** Huchzermeyer, Horak, Putterill and Earle 1992, 100.
botuli' formis. L. gen. n. *Botulus* sausage; L. n. *forma* shape, form; M.L. adj. *botuliformis* sausage-shaped.

In small inclusions it resembles *A. pullorum*, but in larger inclusions organisms are sausage-shaped with up to eight organisms tightly packed in an inclusion. It does not infect chickens but produces a high and long-lasting parasitemia in guinea fowl. Infection is associated with *Amblyomma hebraeum* or *A. marmoreum* infestation.
Type strain: no culture isolated.
The mol% G + C of the DNA is: unknown.

3. **"Aegyptianella carpani"** Battelli 1947, 212.
Found in the snake *Naia nigricollis*.

4. **"Aegyptianella elgonensis"** Mutinga and Dipeolu 1989, 410.
Found in the lizards collected near Mt. Elgon.

5. **"Aegyptianella ranarum"** Desser 1987, 53.
rana' rum. L. n. *rana* frog; M.L. adj. *ranarum* of frog.

Up to 120 rod-shaped organisms that are 150–200 nm × 1–1.7 µm are found in membrane-bound inclusions of erythrocytes of bullfrogs (*Rana catesbeiana*), green frogs (*R. clamitans*), and mink frogs (*R. septentrionalis*).
Identity of the 16S rRNA gene sequence of *"A. ranarum"* (AY208995) to that of *A. pullorum* (AY125087) is 60.9%, showing that *"A. ranarum"* does not belong to the genus *Aegyptianella* or even to the family *Anaplasmataceae* (Rikihisa, unpublished results).

6. **"Sogdianella moshkovskii"** (Laird and Lari 1957) Schurenkova 1938, 936 (*"Babesia moshkovskii"* Laird and Lari 1957, 794.)
Found in various wild birds.

7. **"Tunetella emydis"** Brumpt and Lavier 1935, 548.
Found in the tortoise *Emys leprosa*.

TABLE BXII.α.44. Differential characteristics of the species of the genus *Aegyptianella*

Family III. **Holosporaceae** *fam. nov.*

HANS-DIETER GÖRTZ AND HELMUT J. SCHMIDT

Ho.lo' spo.ra.ce.ae. Gr. fem. adj. *holos* whole, complete; Gr. n. *sporus* seed; M.L. n. *spora* spore; M.L. fem. n. *Holospora* whole spore; *-ceae* ending to denote family; *Holosporaceae* family of *Holospora* bacteria.

Bacteria are present specifically in the **micronucleus or macronucleus of** *Paramecium* species. Exists in two forms: the **reproductive form** is a short rod 1.0–3.0 × 0.5 µm. It undergoes binary fission and may give rise to the **long infectious form**, measuring 5.0–20.0 µm with rounded or tapered ends, that can infect *Paramecium* and become established in the nucleus. The infectious form has a voluminous periplasm filled with fine, granular material with a less electron-dense pale tip, called the special tip. The condensed-looking bacterial protoplasm of the infectious form contains ribosomes and mesosome-like structures. The cytoplasm is polarly positioned opposite to the special tip in one half of the cell (Fig. BXII.α.50). The cytoplasm stains with DNA-specific dyes. Gram-negative, nonmotile, obligate symbiont. No toxic effects of *Holospora*-bearing paramecia on paramecia lacking the symbiont were observed. Paramecia can outgrow *Holospora* species, but reinfection occurs readily; mass cultures show up to 100% infection.

Type genus: **Holospora** (ex Hafkine 1890) Gromov and Ossipov 1981, 351.[VP]

FURTHER DESCRIPTIVE INFORMATION

The family currently contains only the single genus *Holospora*. In 1890 the genus *Holospora*, containing three species, was described by Hafkine (1890). Nine species have now been identified, but only four of them were validly published (see list of the species of the genus *Holospora*). Holosporas share a number of unique features. All invade the nuclei of *Paramecium* (Fig. BXII.α.51) (Ciliophora, Protozoa) (Hafkine, 1890; Gromov and Ossipov, 1981; Görtz, 1983, 1986; Fokin, 1989). They are host specific, infecting only certain species of the genus *Paramecium*. All species show a developmental cycle with an infectious and a reproductive form (Fig. BXII.α.52). Only the infectious form is infectious and even short infectious forms were found to be fully infectious (Kawai and Fujishima, 2000). The infectious form shows a unique cellular organization (Fig. BXII.α.50).

Holosporas are truly parasitic. Infectious forms of the bacteria are regularly released by the host cells into the surrounding medium and may infect new host cells. If the macronucleus of a paramecium (see Fig. BXII.α.53 for the organization of the ciliate cell) is infected, this may affect its growth rate and under unfavorable conditions even kill the cell. Under favorable conditions, host cells are not damaged, and some natural populations have been found stably infected for years with infection rates of close to 100%.

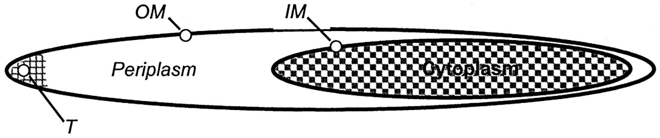

FIGURE BXII.α.50. Diagram of the infectious form of *H. obtusa*. The cytoplasm is condensed and shifted towards one pole. The electron-dense material of the periplasm fills more than half of the cell, with less electron-dense material (*T*) at the pole opposite to the cytoplasm. *IM*, inner membrane; *OM*, outer membrane.

Micronuclear-specific infections are different. In an infection of the micronucleus with *Holospora elegans*, host cell conjugation (sexual propagation) was no longer successful (Görtz and Fujishima, 1983) and exconjugant cells were not viable. Apparently, new macronuclei were not functional. The inhibition of successful conjugation renders the host cells genetically dead.

The individual host cell is not necessarily killed by infection with *Holospora*. Rather, bacteria and host appear to be well adapted. In starving *Paramecium* or after inhibition of host protein synthesis, most bacteria differentiate into the infectious form (Fujishima, 1993), which is a resting stage and does not multiply. In addition, paramecia seem to have mechanisms to cure themselves of endonuclear symbionts. Skoblo et al. (1990), Ossipov et al. (1993), and Fokin and Skovorodkin (1991, 1997) have discovered that *Holospora* may be synchronously and completely lysed in the host nuclei of certain strains of *Paramecium* after an infection. This lysis may be due to an unknown defense mech-

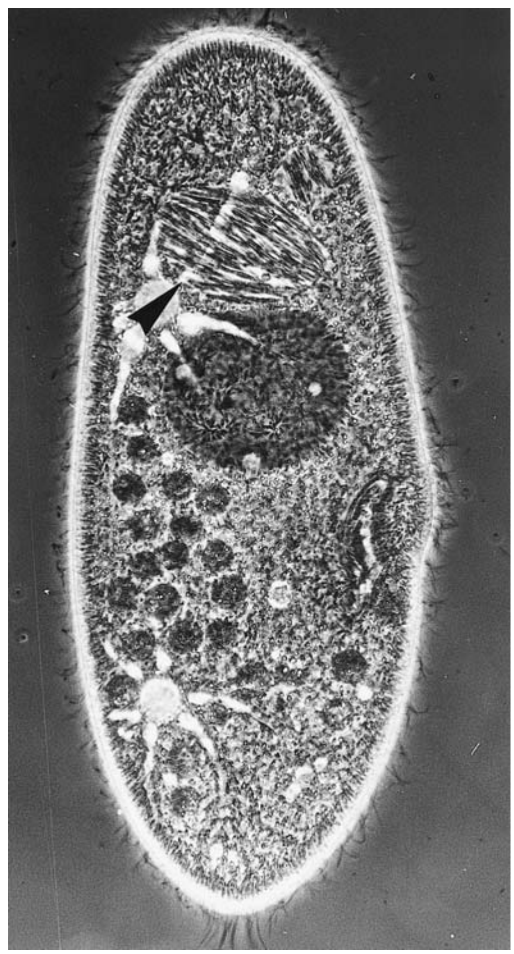

FIGURE BXII.α.51. *Holospora elegans* in the micronucleus (*arrow*) of *Paramecium caudatum*. Due to the infection, the micronucleus has almost reached the size of the macronucleus.

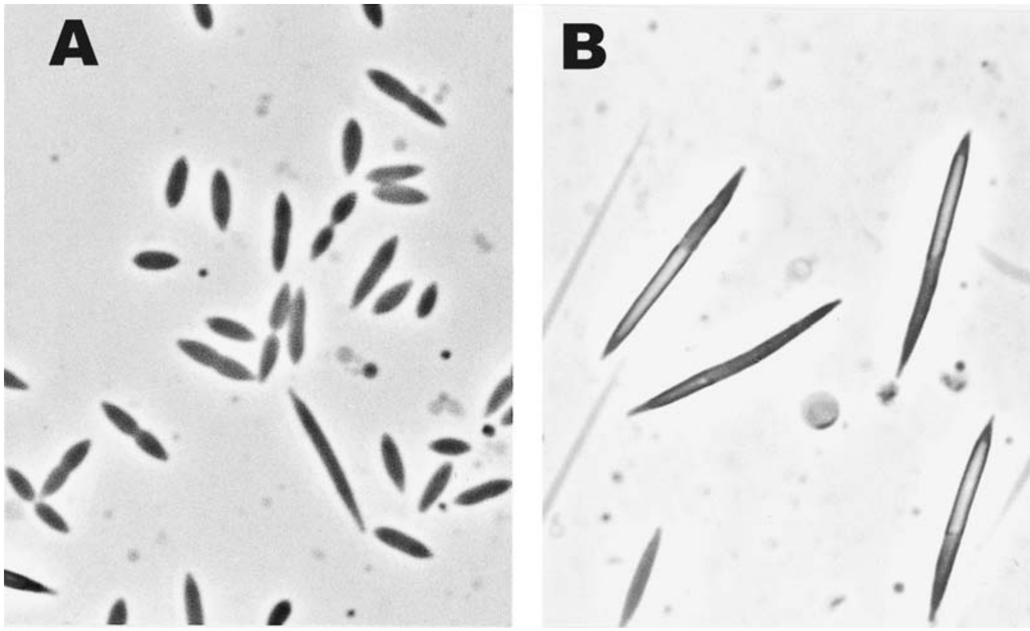

FIGURE BXII.α.52. Reproductive (*A*) and infectious (*B*) forms of *Holospora elegans* released from the micronucleus of *Paramecium caudatum*.

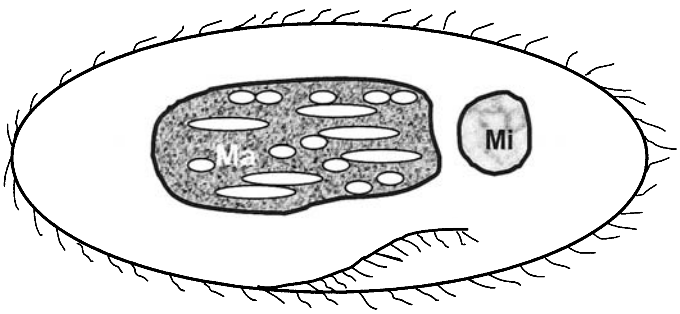

FIGURE BXII.α.53. Diagram of a ciliate cell infected by a *Holospora* species in the macronucleus (schematic representation). *Mi*, micronucleus; *Ma*, macronucleus. The micronucleus is the generative nucleus and transcriptionally inactive. The macronucleus is the somatic nucleus and transcriptionally active. After conjugation, a new macronucleus is developed from the new micronucleus, both deriving from the syncaryon.

anism against intracellular infections evolved in ciliates. After lysis of the bacteria, the host cells are cured and remain viable.

Developmental cycle *Holospora* show a developmental cycle with a specialized infectious form (Figs. BXII.α.50, BXII.α.52). After division of the host cell, only infectious forms are released into the medium, while the reproductive forms remain in the host nuclei. Some reproductive forms may then develop into further infectious forms. The developmental cycle is described in Fig. BXII.α.54.

A new infection may begin with the ingestion of an infectious form. The bacterium leaves the phagosome, is transported through the cytoplasm, and is taken into the host nucleus by fusion of the two membranes of the transport vesicle with those of the nuclear envelope (Görtz and Wiemann, 1989). Transport to the nucleus, and within the nucleus during its division, appears to be mediated by the cytoskeleton of the host cell (Ossipov and Podlipaev, 1977; Görtz and Wiemann, 1989).

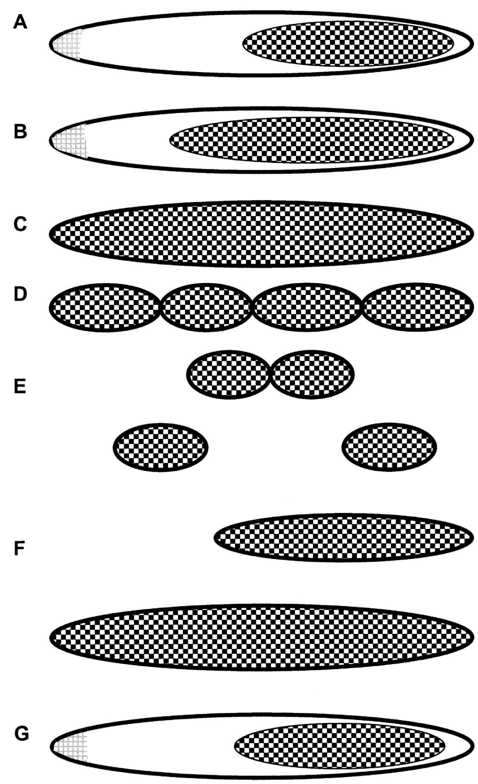

FIGURE BXII.α.54. Diagram of the development of *H. obtusa*. In early stages of invasion, the cytoplasm of the infectious form extends into the periplasmic space, while the volume of periplasm decreases (*A, B*); after the bacterium arrives in the host nucleus, the whole volume of the cell is occupied by the cytoplasm (*C*); the cell constricts at several points and divides into small cells (*D*); by this point, the reproductive form is established and multiplies by binary division (*E*); reproductive forms may grow out in the host nucleus (*F*). The resulting long cells develop into the infectious forms by depositing periplasmic material and condensing the cytoplasm (*G*).

Holospora "species group"[b]	I	I	II	I	I	I		II	II

[a]For symbols see standard definitions.

[b]*Holospora* species group: I, infectious forms are collected in the connecting piece of the dividing host nucleus and released by the host cell; those species tested were labeled by *in situ* hybridization using a *Holospora*-specific probe (Fokin et al., 1996); II, infectious forms are not collected in the connecting piece of the dividing host nucleus but remain distributed in the dividing nucleus; those species were not labeled by *in situ* hybridization using a *Holospora*-specific probe.

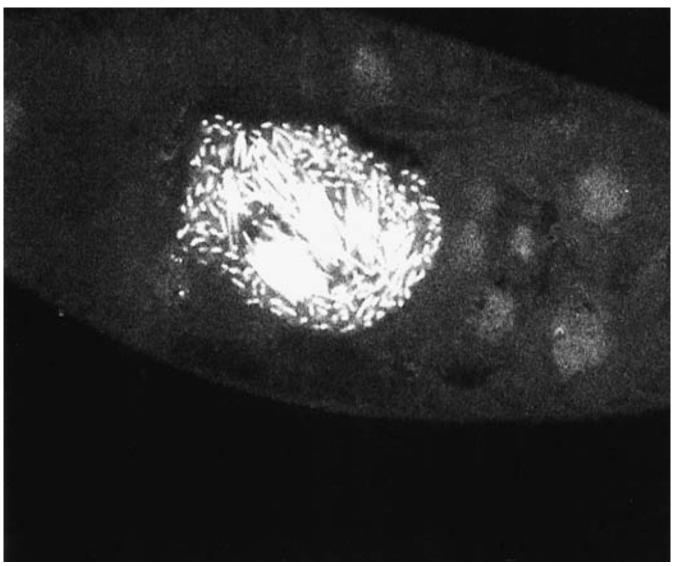

FIGURE BXII.α.55. *Holospora obtusa* in the macronucleus of *Paramecium caudatum*. As a result of hybridization with an *H. obtusa*-specific probe, the bacteria are labeled (Reproduced with permission from S.I. Fokin, European Journal of Protistology Supplement 1, *32:* 19–24, 1996, ©Urban & Fischer Verlag GmbH & Co.)

The infectious form has a voluminous periplasm that contains a number of stage-specific proteins, some of which appear to be released during the infection process (Görtz and Wiemann, 1989; Fujishima et al., 1990, 1997; Wiemann and Görtz, 1991; Dohra et al., 1994). Some proteins that were immuno-localized in the periplasm of the infectious form were found on the surface of the bacteria after their ingestion into the phagosome, or associated with the phagosome membrane. This is what would be expected if such proteins were used for communication with host membranes. Released periplasmic proteins could also protect the bacteria against lysosomal enzymes of the host or inactivate such enzymes.

The gene of a small periplasmic protein of 5.4 kDa was sequenced by Dohra et al. (1997). Northern blot hybridization showed that the gene is highly expressed in the intermediate form, a transitional stage in the development from the reproductive into the infectious form of the bacterium. Amino acid sequence similarities with other polypeptides have not been found (Dohra et al., 1997). It has been suggested that the protein may function in the recognition process in the early phase of infection. Dohra et al. (1998) have also identified a GroEL-like protein in *H. obtusa*. The gene is selectively expressed in the reproductive form.

The infectious form is polarly organized (Figs. BXII.α.50, BXII.α.52) (Dohra and Fujishima, 1999). Half of the cell is occupied by the voluminous periplasm that contains a number of stage-specific proteins. The proteins appear to be released during the infection process. Some proteins were immunolocalized in the periplasm of the infectious form and during the invasion process were found on the surface of the bacteria after their ingestion into the phagosome, associated with the phagosome membrane (Fujishima et al., 1990, 1997; Görtz et al., 1990; Wiemann and Görtz, 1991; Dohra et al., 1994; and unpublished results).

Phylogeny of the *Holosporaceae* *Holospora* species were the first intracellular bacteria in *Paramecium* for which the phylogenetic position was determined (Amann et al., 1991). *H. obtusa*, *H. elegans*, and *H. undulata* belong to the *Alphaproteobacteria*. The closest relative among other symbionts in ciliates was found to be *Caedibacter caryophilus*, and the closest relatives among other bacteria found to date were *Rickettsia* and *Ehrlichia* species (Amann et al., 1991; Springer et al., 1993). It is tempting to regard the striking biology (developmental cycle; host specificity for *Paramecium*, etc.) and the unique morphology of the infectious form as homologous features, proving the close relationship and monophyletic origin of these bacteria. New observations, however, cast doubt on this possibility (Fokin et al., 1996).

The behavior of the infectious forms of certain *Holospora* species, assembling as they do in the connecting piece of the dividing host nucleus, is certainly highly advanced and must be regarded as an apomorphic feature. This behavior ensures that the infectious forms are specifically collected and released by the host cell. *H. caryophila*, *H. bacillata*, and *H. curvata* do not share this feature with the other holosporas. It is not known how the infectious forms of these species leave their host nuclei. They are

either more primitive than the other holosporas, as a quantitative separation of infectious forms and reproductive forms is not observed, or they are not closely related phylogenetically. Two species groups may presently be distinguished in the genus *Holospora* (Table BXII.α.45). It has been hypothesized that the unique behavior of the infectious form to polarly deposit enormous amounts of periplasmic materials could be encoded on a plasmid or phage genome. However, no plasmid or phage genome has been found (Rautian et al., unpublished results). It is consistent with this observation that the "more advanced" species tested (in which the infectious forms are collected in the separation spindle) gave a positive result after *in situ* hybridization (Fig. BXII.α.55) using an oligonucleotide probe designed for *H. obtusa* (Amann et al., 1991; Fokin et al., 1996).

Genus I. **Holospora** *(ex Hafkine 1890) Gromov and Ossipov 1981, 351*[VP]*

Hans-Dieter Görtz and Helmut J. Schmidt

Ho.lo'spo.ra. Gr. fem. adj. *holos* whole, complete; Gr. n. *sporus* seed; M.L. n. *spora* spore; M.L. fem. n. *Holospora* whole spore.

The description of the genus is that of the family. Diagnostic characteristics are given in Table BXII.α.45.

Type species: **Holospora undulata** (ex Hafkine 1890) Gromov and Ossipov 1981, 351.

Taxonomic Comments

The species listed under "Other Organisms" have not been validly published. They show the typical features of the genus, namely the expression of a life cycle with infectious and reproductive forms and a strong infectivity for the host nuclei. They share a number of biological features with the validated *Holospora* species and are therefore listed in this chapter. Except for *"H. recta"*, where this has been questioned (see below), the bacteria appear to be good species with a distinct host specificity, nucleus-specificity, and clear morphology.

List of species of the genus Holospora

1. **Holospora undulata** (ex Hafkine 1890) Gromov and Ossipov 1981, 351[VP]
un.du.la'ta. L. fem. adj. *undulatus* undulated, with waves.

Lives in the micronucleus of *P. caudatum*. Reproductive form short, spindle shaped; infectious form long, spiral shaped. Diagnostic characteristics are given in Table BXII.α.45.

The mol% G + C of the DNA is: not determined.

Type strain: original description and illustration of Hafkine (1890).

Additional Remarks: Clone M1-48 of *P. caudatum* containing *H. undulata* has been deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, State University of St. Petersburg, Russia.

2. **Holospora caryophila** (ex Preer, Preer and Jurand 1974) Preer and Preer 1982, 141[VP] (*Cytophaga caryophila* Preer, Preer and Jurand 1974, 156.)
ca.ry.o'phi.la. G. n. *caryum* nut, kernel, nucleus; Gr. adj. *philus* loving, M.L. fem. adj. *caryophila* nucleus loving.

Lives in the macronucleus (Figs. BXII.α.56 and BXII.α.57) of *P. biaurelia* or *P. caudatum*. Reproductive form thin, fusiform rod, 0.3–0.5 × 1.0–3.0 µm; spiral infectious form, 0.2–0.3 × 5–6 µm, tapered ends. Is highly infective to a few stocks of *Paramecium biaurelia* and *P. caudatum*. Known previously as alpha (Preer, 1969).

Recent observations may cast some doubt upon the inclusion of *H. caryophila* in the genus *Holospora*. It was observed that the behavior of *H. caryophila* in dividing host nuclei is different from that of *H. undulata*, *H. elegans*, *H. obtusa*, and *"H. acuminata"*. While in those species the infectious forms are collected in the connecting piece of the dividing nucleus and are then released from the nucleus, infectious forms of *H. caryophila* leave the host nucleus by an unknown mode (Fokin et al., 1996). Moreover, in contrast to *H. undulata*, *H. elegans*, and *H. obtusa*, *H. caryophila* is not recognized by the *Holospora* probe in *in situ* hybridization (*"H. acuminata"* not tested; Fokin et al., 1996). Because of these differences to *H. undulata*, *H. obtusa*, and *H. elegans*, *H. caryophila* has been considered to belong to a second group of *Holospora* (Table BXII.α.45).

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 30694.

Additional Remarks: The type strain of *H. caryophila* is in stock 562 of *P. tetraurelia* (ATCC 30694) (Preer et al., 1974).

3. **Holospora elegans** (ex Hafkine 1890) Preer and Preer 1982, 141[VP]
e'le.gans. L. adj. *elegans* choice, elegant.

Lives in the micronucleus of *P. caudatum*. Reproductive form short, spindle-shaped; infectious form long rod with tapered ends. Diagnostic characteristics are given in Table BXII.α.45.

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 50008.

Additional Remarks: The type strain of *H. elegans* is in stock C101 of *P. caudatum* (ATCC 50008) (Görtz and Dieckmann 1980).

4. **Holospora obtusa** (ex Hafkine 1890) Gromov and Ossipov 1981, 351[VP]
ob.tu'sa. L. fem. adj. *obtusa* obtuse, blunt.

Short, fusiform, reproductive rod about 3.0 µm long that undergoes binary fission and grows in infective form up to 20 µm long. Ends of rod rounded (Fig. BXII.α.58). Found in *P. caudatum* in the macronucleus. Diagnostic characteristics are given in Table BXII.α.45.

The mol% G + C of the DNA is: not determined.

**Editorial Note:* This genus was described by J. R. Preer, Jr. and L. B. Preer (1984) in the first edition of *Bergey's Manual of Systematic Bacteriology*. We have used their descriptions and figures and have added newer information.

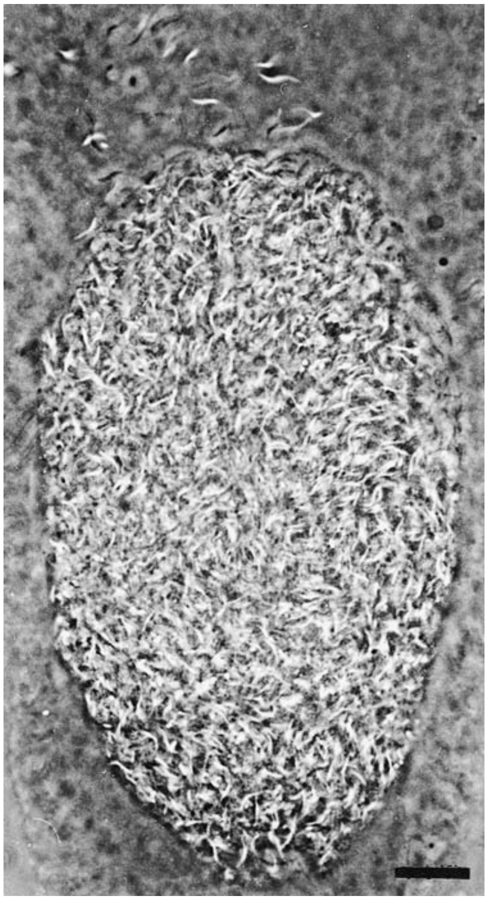

FIGURE BXII.α.56. Macronucleus of *Paramecium biaurelia* stock 562. The spiral endosymbiont filling the macronucleus is *Holospora caryophila*. Osmium–lacto–orcein preparation, whole mount, bright phase-contrast. Bar = 10 μm. (Reproduced with permission from L.B. Preer, Journal of Protozoology *16:* 570–578, 1969, ©Society of Protozoologists.)

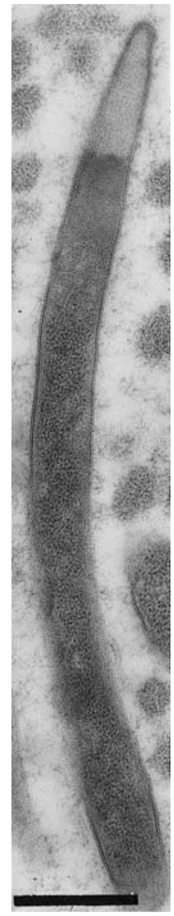

FIGURE BXII.α.57. *Holospora caryophila* of *Paramecium biaurelia* stock 562, spiral form. Longitudinal section. Bar = 0.5 μm. (Reproduced with permission from L.B. Preer, Journal of Protozoology *16:* 570–578, 1969, ©Society of Protozoologists.)

Type strain: The original description and illustration was given by Hafkine (1890).

Additional Remarks: Clone M.115 of *P. caudatum* containing *H. obtusa* in its macronuclei has been deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, St. Petersburg State University (Gromov and Ossipov, 1981).

5. **"Holospora acuminata"** Ossipov, Skoblo, Borchsenius, Rautian and Podlipaev 1980, 927.

Lives in the micronucleus of *Paramecium bursaria* (Ossipov et al., 1980). Reproductive form short fusiform rod; infectious form 5.0–8.0 × 0.5–0.6 μm, straight, both ends tapered. The species name has not been validly published. There is, however, little doubt that it belongs to the genus *Holospora*, because of many biological features shared with the three species *H. undulata*, *H. obtusa*, and *H. elegans*. In addition, they are recognized with an oligonucleotide probe designed for *H. obtusa*.

The mol% G + C of the DNA is: not determined.

Deposited strain: AC61-10.

Additional Remarks: In stock AC61-10 of *P. bursaria* (deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, State University of St. Petersburg, Russia).

Other Organisms

1. *"Holospora bacillata"* Fokin and Sabaneyeva 1993, 393.

Lives in the macronucleus of *Paramecium calkinsi* (Fokin and Sabaneyeva, 1993) and *Paramecium woodruffi* (Fokin et al., 1996; Fokin and Sabaneyeva, 1997). Infectious form 5–17.0 × 0.7–0.8 μm, straight, both ends rounded. Diagnostic characteristics as given in Table BXII.α.45.

The mol% G + C of the DNA is: not determined.

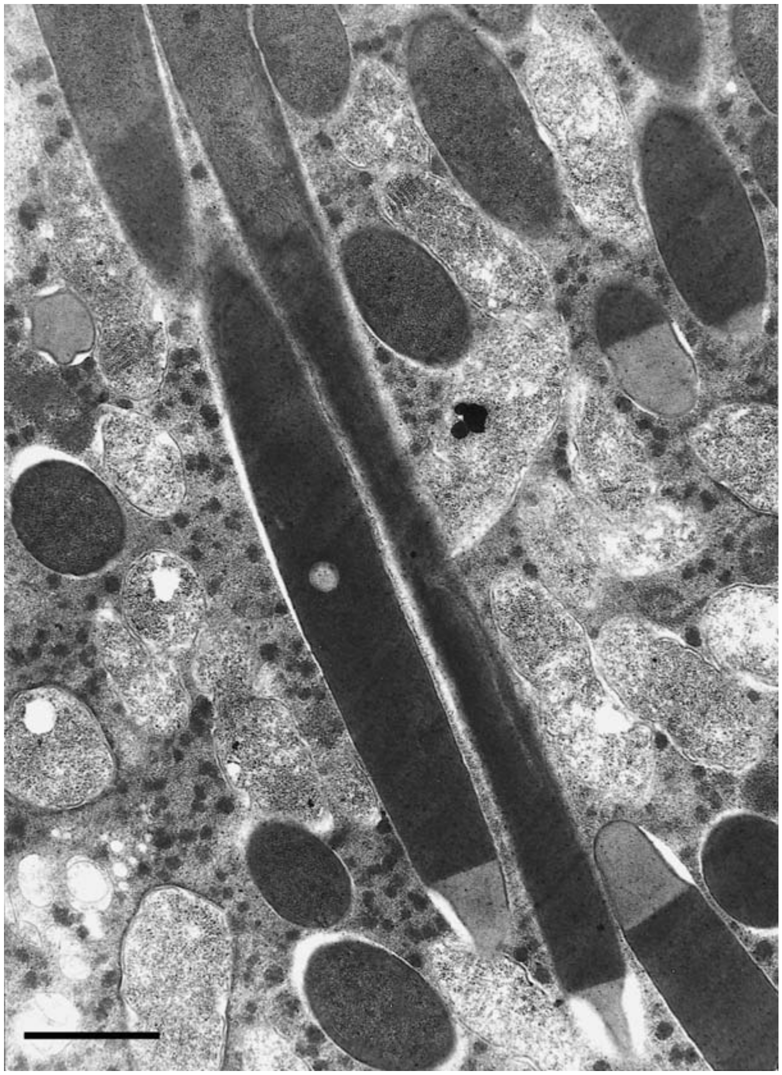

FIGURE BXII.α.58. *Holospora obtusa*, macronuclear symbiont of *Paramecium caudatum*. Infectious form stains darkly; the noninfectious form is light. Bar = 4.3 μm (Reproduced with permission from H.-D. Görtz, 1980. *In* Schwemmler and Schenk (Editors), Endocytobiology: Endosymbiosis and Cell Biology, Vol. 1, ©Walter deGruyter and Co, pp. 381–392.)

2. *"Holospora curvata"* Fokin and Sabaneyeva 1993, 393.

Lives in the macronucleus of *Paramecium calkinsi* (Fokin and Sabaneyeva, 1993). Infectious form 12–20 × 0.7–0.9 μm, curved, both ends rounded. Diagnostic characteristics as given in Table BXII.α.45.

The mol% G + C of the DNA is: not determined.

3. *"Holospora curviuscula"* Borchsenius, Skoblo and Ossipov 1983, 96.

Lives in the macronucleus (sometimes also micronucleus) of *P. bursaria.* Reproductive form short, spindle shaped; infectious form 4.0–10.0 × 0.4–0.5 μm, slightly curved rod with tapered ends. Diagnostic characteristics as given in Table BXII.α.45.

The mol% G + C of the DNA is: not determined.

4. *"Holospora recta"* Fokin 1991, 139.

rec.ta. L. adj. *rectus* straight; M.L. fem. adj. *recta* straight.

Lives in the micronucleus of *Paramecium caudatum* (Fokin, 1991). Infectious form 10–15 × 0.7–1.0 μm, straight, one end rounded, one end tapered. Diagnostic characteristics as given in Table BXII.α.45. Whereas all other species listed in this chapter appear to be taxonomically sound, this has been questioned for *"H. recta"* by Rautian and Ossipov (personal communication), who found a strain of *H. elegans* with a number of individuals exhibiting *"H. recta"*-like features. The question may finally be resolved after molecular data have been obtained from the different strains.

The mol% G + C of the DNA is: not determined.

Genus Incertae Sedis II. **Caedibacter** *(ex Preer, Preer and Jurand 1974) Preer and Preer 1982, 140[VP]**

HANS-DIETER GÖRTZ AND HELMUT J. SCHMIDT

Cae′di.bac.ter. L. n. *caedes* act of killing; M.L. masc. n. *bacter* the masculine equivalent of the Gr. neut. n. *bactrum* a rod; masc. n. *caedibacter* the bacterium which kills.

Straight rods or coccobacilli 0.4–1.0 × 1.0–4.0 µm. Gram negative, nonflagellated, nonmotile. Intracellular (endosymbiotic) bacteria in *Paramecium.* Culture free of *Paramecium* impossible or exceedingly difficult. The ability to produce refractile inclusion (R) bodies was seen as a unique feature of the genus. R bodies are proteinaceous ribbons, approximately 10 µm long, coiled inside the bacterial cell (Figs. BXII.α.59, BXII.α.60, and BXII.α.61). The hollow cylindrical structure formed may be 0.4–0.8 µm long and about 0.4 µm in diameter. R bodies unroll when ingested into a phagosome and under certain *in vitro* conditions (for details see Preer et al., 1974; Quackenbush, 1988; Pond et al., 1989). R bodies are associated with spherical phage-like structures or covalently closed circular DNA plasmids. All species are toxic to certain sensitive strains of paramecia; bacteria confer killer-trait or mate killer-trait upon their host cells. An exception is *"C. macronucleorum"* from *Paramecium duboscqui*, where no toxic effects were observed. Cells containing R bodies are usually larger than cells that do not contain R bodies, and contain many spherical phage-like structures of covalently closed, circular, DNA plasmids. Recently, a symbiotic bacterium from *Acanthamoeba* was included in the genus *Caedibacter* because of its sequence similarity to *Caedibacter caryophilus* (Horn et al., 1999). This new *Caedibacter* species, *Candidatus* Caedibacter acanthamoebae, does not establish R bodies. Also interesting is the relatively close relationship of *Caedibacter* to the genus *Holospora* and to the "NHP bacterium", etiologic agent of necrotizing hepatopancreatitis in shrimp (Loy et al., 1996; Horn et al., 1999).

The mol% G + C of the DNA is: 34–44.

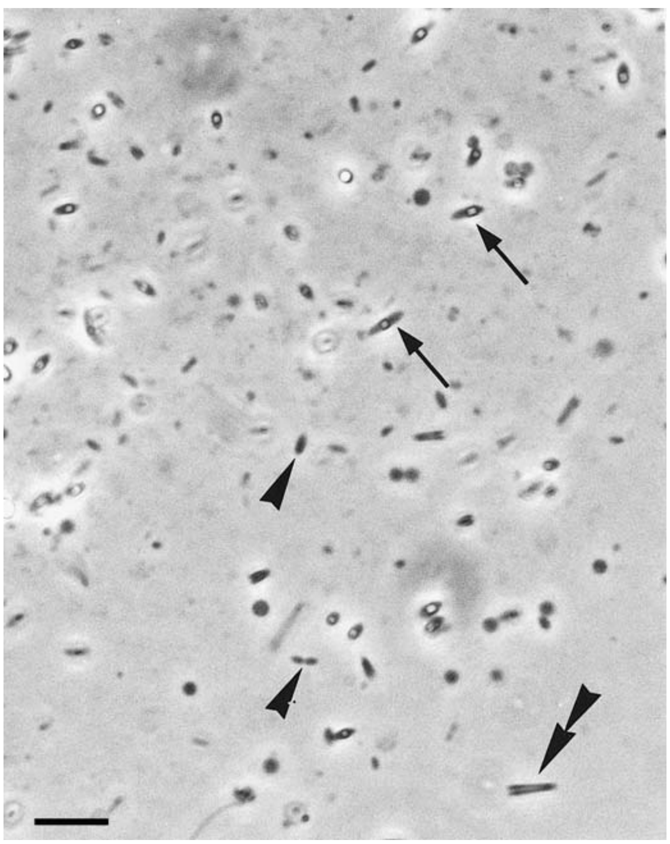

FIGURE BXII.α.59. Fresh squash of *Paramecium novaurelia*, washed free of bacteria, viewed by bright phase-contrast. Note *Caedibacter caryophilus* present in two forms: small rods (*arrowheads*) and large spindle-shaped cells containing refractile bodies (*arrows*) characteristic of the genus. Free R bodies, partly stretched, (*double arrowhead*) are also visible. Bar = 2.4 µm.

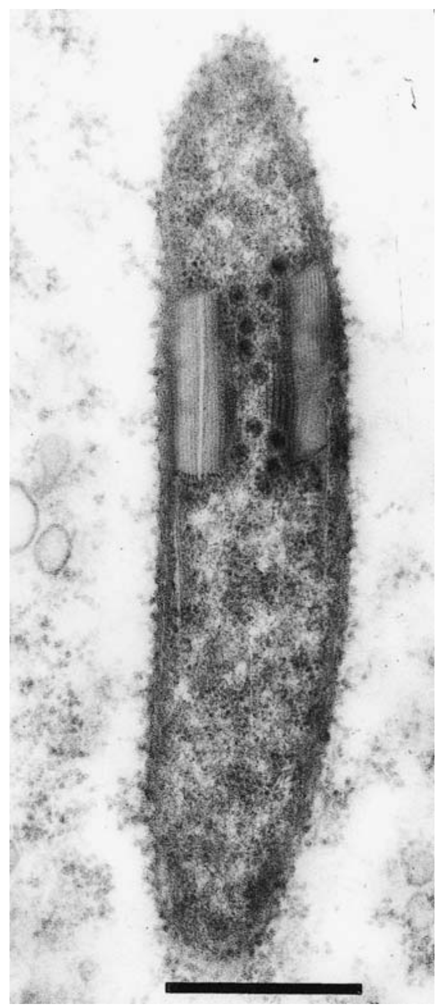

FIGURE BXII.α.60. *Caedibacter varicaedens*, endosymbiont of *Paramecium biaurelia* stock 7. Note spherical phages inside the coiled R body. Longitudinal section. Bar = 0.5 µm. (Reproduced with permission from J.R. Preer, Jr. and A. Jurand, Genetical Research *12:* 331–340, 1968, ©Cambridge University Press.)

**Editorial Note:* This genus was described by J.R. Preer, Jr. and L.B. Preer (1984) in the first edition of *Bergey's Manual of Systematic Bacteriology*. The authors have used their descriptions and added new information.

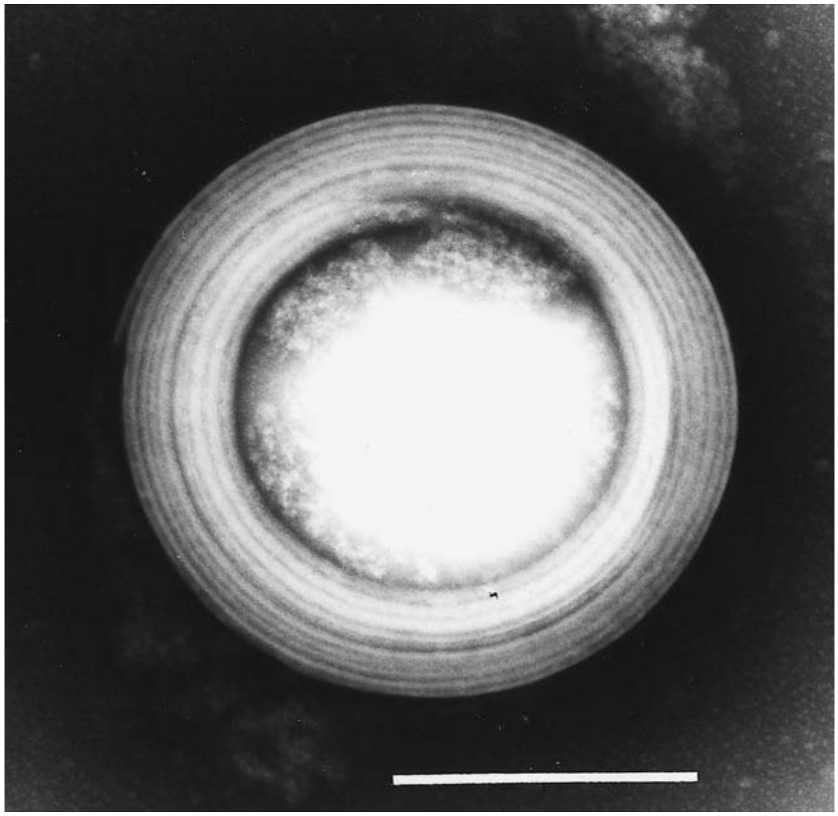

FIGURE BXII.α.61. Intact R body from *Caedibacter varicaedens* of *Paramecium biaurelia* stock 511. Phosphotungstic acid. Bar = 2.5 µm. (Reproduced with permission from J.R. Preer, Jr. et al., Bacteriological Reviews *38:* 113–163, 1974, ©American Society for Microbiology.)

Type species: **Caedibacter taeniospiralis** (ex Preer, Preer and Jurand 1974) Preer and Preer 1982, 140 (*Caedobacter taeniospiralis* [sic] Preer, Preer and Jurand 1974, 157.)

Further descriptive information

The distinguishing characteristic of *Caedibacter* species is the presence of refractile (R) bodies. Between less than 10% and up to 50% of the bacteria in a host cell contain R bodies. Cells containing R bodies are called "brights"; cells without R bodies are called "non-brights". Only a very weak infectivity, if any, is observed for non-brights. The coiled R body, a distinctive structure, is seen with bright phase-contrast microscopy either as doughnut-shaped or as a pair of parallel rods, depending upon its orientation (Fig. BXII.α.62). Although the structure is readily resolved in bright phase-contrast, it is often obscure in dark phase-contrast, because dark phase-contrast optics are usually of such high contrast that phase reversal occurs in most aqueous media. R bodies themselves appear to result from the induction of phage-like or plasmid-like extrachromosomal DNAs (Quackenbush, 1988; Pond et al., 1989). The induction appears to be lethal: R body-containing cells do not have the capacity to reproduce. It is interesting that R bodies have been observed in free-living bacteria belonging to the genus *Pseudomonas* (Lalucat et al., 1979). The toxicity of *C. taeniospiralis* and *C. pseudomutans*, formerly known as kappa, is produced by the ingestion of R body-containing kappas by sensitive strains of paramecia.

R bodies can be induced to unroll (Fig. BXII.α.63) and in some cases, reroll; they have been shown to unroll in the food vacuoles of sensitive paramecia. In some species of *Caedibacter*, the R body unrolls from the inside (Fig. BXII.α.64); in others, from the outside. Rupture of the membrane of the food vacuole occurs, and the contents of the food vacuole, including the R bodies, pass into the cytoplasm of the paramecium. The toxins themselves have never been obtained in soluble form and their nature is unknown. Ingestion of the fourth species, *C. paraconjugatus*, does not produce toxic effects on sensitives. Instead it is a mate-killer, and sensitive paramecia die only after contact with paramecia bearing *C. paraconjugatus* during conjugation. The endosymbiont discovered by Estève (1978) in the macronucleus of a strain of *Paramecium caudatum* was later found again and described as *C. caryophilus* (Schmidt et al., 1987a; Euzéby, 1997).

Note added in proof: According to an analysis of 16S rRNA sequences, *C. taeniospiralis* (isolated from stock 51k of *Paramecium tetraurelia*) belongs to the *Gammaproteobacteria*, whereas *C. caryophilus* belongs to the *Alphaproteobacteria* (Beier et al., 2002).

List of species of the genus Caedibacter

1. **Caedibacter taeniospiralis** (ex Preer, Preer and Jurand 1974) Preer and Preer 1982, 140[VP]
taen.i.o.spi.ral'is. L. n. *taenia* ribbon; L. adj. *spiralis* coiled; M.L. masc. adj. *taeniospiralis* coiled ribbon.

Description of the species as for the genus. Rods, 0.4–0.7 × 1.0–2.5 µm. Found exclusively in the cytoplasm of *Paramecium tetraurelia*. Contain plasmids (Dilts, 1976). R bodies unroll from the inside and contain plasmids. Ingestion of R body-containing symbionts by sensitive paramecia causes development of small blisters or humps on their surface within 2–3 hours preceding the death of the paramecium.

The mol% G + C of the DNA is: 41 (Bd).

Type strain: ATCC 30632.

Additional Remarks: The type strain of *Caedibacter taeniospiralis* was isolated from stock 51 of *Paramecium tetraurelia* (ATCC 30632) (Preer et al., 1974)

2. **Caedibacter caryophilus** Schmidt, Görtz and Quackenbush 1987a, 461[VP]
ca.ry.o'phi.lus. Gr. n. *caryum* nucleus; Gr. adj. *philus* loving; M.L. adj. *caryophilus* nucleus loving.

In macronucleus of *P. caudatum*. Cells without R bodies 1–1.5 × 0.4 µm, cells with R bodies 1.5–2.5 × 0.7 µm. R bodies unrolling from the inside. Outer terminus of unrolled R bodies blunt, inner terminus acute. R bodies associated with phages. Width of R bodies 0.8 µm. Sensitive strains of *Paramecium* are killed by paralysis. Co-infections with *Holospora* species in natural populations.

The mol% G + C of the DNA is: 35 (T_m).

Type strain: ATCC 50168.

GenBank accession number (16S rRNA): X71837.

Additional Remarks: The type strain of *Caedibacter caryophilus* was isolated from stock C221 of *P. caudatum* (ATCC 50168) (Schmidt et al., 1987a).

3. **Caedibacter paraconjugatus** Quackenbush 1982, 266[VP] (Effective publication: Quackenbush 1978, 186.)
par.a.con.ju.ga'tus. Gr. prep. *para* alike; L. part. adj. *conjugatus* conjugated; also the specific epithet of a mate killer (*Pseudocaedibacter conjugatus*); M.L. masc. part. adj. *paraconjugatus* similar to mate killers.

Small rods. Fewer than 1% of the cells contain R bodies, which are smaller than those found in the other species of

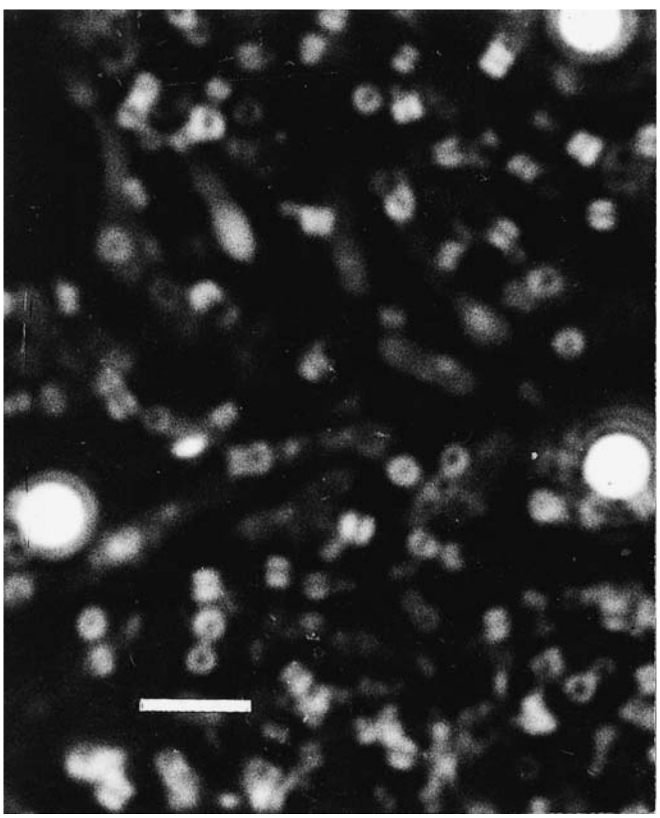

FIGURE BXII.α.62. Isolated R bodies from *Caedibacter varicaedens* of *Paramecium biaurelia* stock 7, viewed with bright phase-contrast. R bodies appear doughnut-shaped when viewed on end, and as two parallel rods when viewed from the side. The large bright spheres are latex particles. Bar = 2 µm.

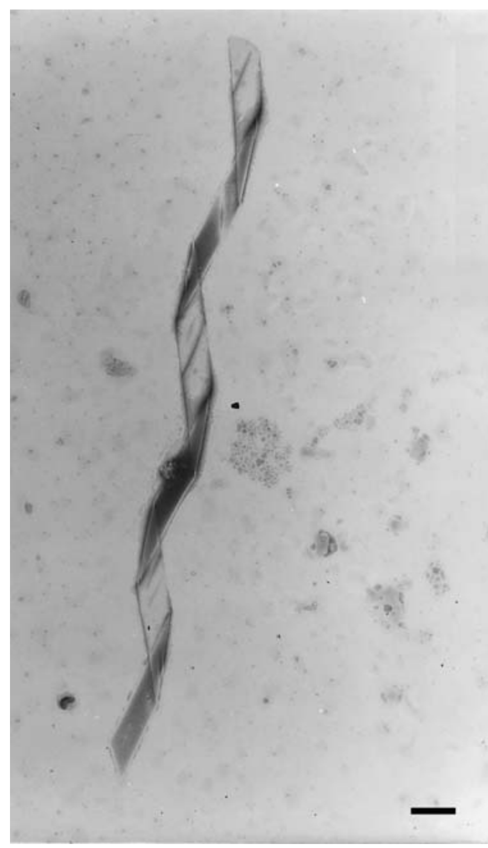

FIGURE BXII.α.63. Unrolled R body isolated from *Caedibacter varicaedens* of *Paramecium biaurelia* stock 1039. Phosphotungstic acid. Bar = 1 µm. (Reproduced with permission from J.R. Preer Jr. et al., Bacteriological Reviews *38:* 113–163, 1974, ©American Society for Microbiology.)

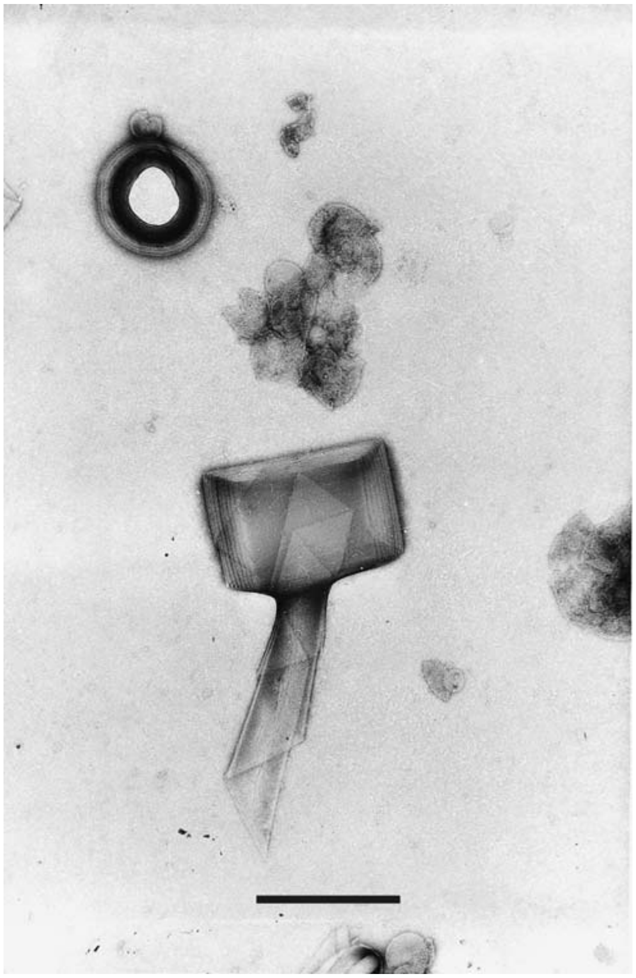

FIGURE BXII.α.64. R bodies isolated from *Caedibacter taeniospiralis* of *Paramecium tetraurelia* stock 51. Note intact doughnut-shaped R body and, below, an R body unrolling from inside. Phosphotungstic acid. Bar = 0.5 µm. (Reproduced with permission from L.B. Preer, Journal of Cell Science, *11:* 581–600, 1972, ©Company of Biologists, Ltd.)

Caedibacter. Ingestion of cells by sensitive paramecia does not cause any observable effects. Cell-to-cell contact between host and sensitive paramecia is required for toxic effects (mate killing) to be observed in the sensitive paramecia. Found in *P. biaurelia*. Contain phage-like structures.

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 30638.

Additional Remarks: The type strain of *Caedibacter paraconjugatus* was isolated from stock 570 of *Paramecium biaurelia* (ATCC 30638) (Preer et al., 1974).

4. **Caedibacter pseudomutans** Quackenbush 1982, 266[VP] (Effective publication: Quackenbush 1978, 186.)
pseu.do.mu′tans. Gr. adj. *pseudo* false; L. part. adj. *mutans* changing; M.L. part. adj. *pseudomutans* false changing, referring to the fact that it was once thought to be a mutant of *C. taeniospiralis* (Dippell, 1950).

Cigar-shaped rods approximately 0.5 × 1.5 µm. Found in *P. tetraurelia*.

The mol% G + C of the DNA is: 44 (Bd).

Type strain: ATCC 30633.

Additional Remarks: The type strain of *Caedibacter pseudomutans* was isolated from stock 51ml of *Paramecium tetraurelia* (ATCC 30633) (Preer et al., 1974).

5. **Caedibacter varicaedens** Quackenbush 1982, 266[VP] (Effective publication: Quackenbush 1978, 186.)
var.i.cae′dens. L. adj. *varis* different; L. v. *caedo* to kill; M.L. part. adj. *varicaedens* killing in different ways.

Rods 0.4–1.9 × 2–4 µm. Different strains cause either vacuolization or paralysis or rapid reverse rotation while swimming (spin killing) in sensitive paramecia. R bodies unroll from the outside. One of the commonest killers of *P. biaurelia*. Most strains contain spherical phage-like structures (Fig. BXII.α.60).

The mol% G + C of the DNA is: 40–41 (Bd).

Type strain: ATCC 30637.

Additional Remarks: The type strain of *Caedibacter varicaedens* was isolated from stock 7 of *Paramecium biaurelia* (ATCC 30637) (Preer et al., 1974).

6. *Candidatus* Caedibacter acanthamoebae Horn, Fritsche, Gautom, Schleifer and Wagner 1999, 364.
a′canth.a.moe.bae. L. gen. sing. n. *acanthamoebae* of *Acanthamoeba*, genus name of host protozoa.

Phylogenetic position, *Alphaproteobacteria*; not cultivated on cell-free media; Gram reaction, negative; rod-shaped ~0.7–3.3 µm in length, 0.22–0.33 µm in diameter; basis of assignment, 16S rDNA sequence (accession number AF1321138) and nucleotide S-S-CaeAc-998-a-A-18 (5′-TCTTGTCTCCGCGATCCC-3′); association and host, intracellular symbiont of *Acanthamoeba polyphaga* HN-3; mesophilic (Horn et al., 1999).

Other Organisms

1. *"Caedibacter macronucleorum"* Fokin and Görtz 1993, 322.
ma.cro.nu.cle.o′rum. Gr. adj. *macro* big; L. n. *nucleus* nucleus; *macronucleorum* of the macronucleus.

In macronucleus of *Paramecium duboscqui*. Cells without R bodies 1–1.5 × 0.4 µm, cells with R bodies 1.5–2.5 × 0.7 µm). R bodies unrolling from the inside. Outer terminus of unrolled R bodies blunt, inner terminus acute. R bodies associated with phages. Width of R bodies 0.8 µm. Sensitive strains of *Paramecium* are killed by paralysis. Co-infections with *Holospora* species in natural populations. As was the rule for intracellular bacteria in protozoa before the advent of molecular sequencing, this organism was named according to morphology and biological behavior. *"Caedibacter macronucleorum"* had been grouped into the genus *Caedibacter*, because it was found as an intracellular bacterium in a protozoon and because of its ability to form R bodies like the valid species of the genus. Since no molecular data have been obtained to date, the true phylogenetic position of the bacterium is not known.

Genus Incertae Sedis III. **Lyticum** *(ex Preer, Preer and Jurand 1974) Preer and Preer 1982, 141*[VP]*

HANS-DIETER GÖRTZ AND HELMUT J. SCHMIDT

Ly′ ti.cum. L. adj. *lyticus* dissolving; M.L. neut. n. *Lyticum* dissolver.

Large rods 0.6–0.8 μm in diameter, straight, curved, or spiral. Length of single forms 3.0–5.0 μm. Numerous **peritrichous flagella**. Although cultivation independently from *Paramecium* has been reported, it has not been confirmed. Produce labile **toxins which kill** sensitive strains of paramecia **very quickly by lysis**. Gram negative. Nonmotile or almost so, in spite of numerous, well-developed flagella (Fig. BXII.α.65). Occurs in *Paramecium biaurelia*, *P. tetraurelia*, and *P. octaurelia* (Fig. BXII.α.66).

The mol% G + C of the DNA is: 27–49.

Type species: **Lyticum flagellatum** (ex Preer, Preer and Jurand 1974) Preer and Preer 1982, 140.

FURTHER DESCRIPTIVE INFORMATION

These very large endosymbionts are unique due to their conspicuous flagella and rapidly acting toxins (less than 30 minutes at room temperature). The nature of the toxin has not been revealed. *Paramecium triaurelia*, *P. pentaurelia*, and *P. novaurelia* are particularly sensitive to the toxins. The substantially different values for mol% G + C of DNA reported by Behme and by Soldo (see Preer et al., 1974 for a discussion) are unresolved.

DIFFERENTIATION OF THE GENUS *LYTICUM* FROM OTHER GENERA

Lyticum flagellatum is a straight rod found in *Paramecium tetraurelia* and *P. octaurelia*, while *L. sinuosum* is a strikingly curved rod found in *Paramecium biaurelia*.

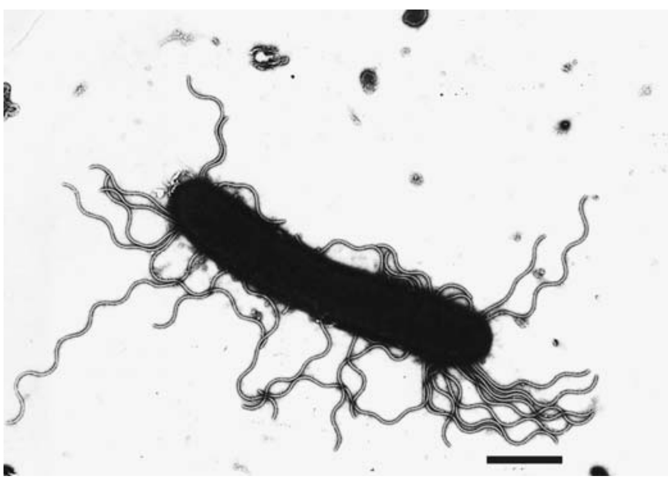

FIGURE BXII.α.65. *Lyticum flagellatum* isolated from *Paramecium octaurelia* stock 327. Phosphotungstic acid. Bar = 1 μm. (Reproduced with permission J. R. Preer, Jr. et al., Bacteriological Reviews *38:* 113–163, 1974, ©American Society for Microbiology.)

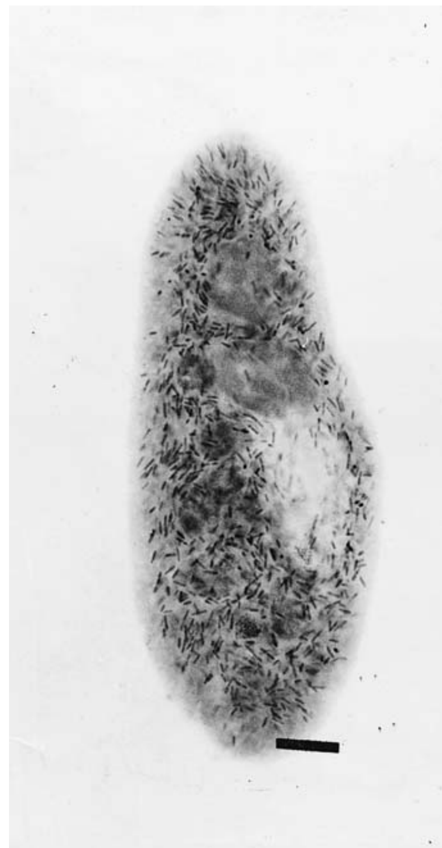

FIGURE BXII.α.66. *Paramecium tetraurelia* stock 239 bearing endosymbiont *Lyticum flagellatum*. The numerous black rods throughout the cytoplasm are the endosymbionts. Osmium–lacto–orcein preparation, whole mount, dark phase-contrast. Bar = 20 μm. (Reproduced with permission J.R. Preer, Jr. et al., Bacteriological Reviews *38:* 113–163, 1974, ©American Society for Microbiology.)

List of species of the genus Lyticum

1. **Lyticum flagellatum** (ex Preer, Preer and Jurand 1974) Preer and Preer 1982, 140[VP]

   fla.gel.la′ tum. L. neut. n. part. adj. *flagellatum* flagellated.

   Straight rods 0.6–0.8 × 2.0–4.0 μm, with many peritrichous flagella (Fig. BXII.α.65). Originally called lambda. Found within the cytoplasm of *Paramecium tetraurelia* and *P. octaurelia*. Stock 299 of *P. octaurelia* containing lambda does not require folic acid, whereas symbiont-free lines of 299 do (Soldo and Godoy, 1973).

   The mol% G + C of the DNA is: 27 (Bd) in one strain (Soldo) and 49 (Bd) in another (Behme; Preer et al. 1974).

   Type strain: 299, ATCC 30700.

**Editorial Note:* This genus was described by J.R. Preer, Jr. and L.B. Preer (1984) in the first edition of *Bergey's Manual of Systematic Bacteriology*. The authors have used their descriptions and figures and have added newer information.

2. **Lyticum sinuosum** (ex Preer, Preer and Jurand 1974) Preer and Preer 1982, 140[VP]
sin'u.o.sum. L. neut. adj. *sinuosum* winding, sinuous.

Curved or spiral rods 0.7–0.9 × 2.0.–10.0 μm, sometimes forming chains of 2–3 cells. Originally called sigma. Found within the cytoplasm of *Paramecium biaurelia*.

The mol% G + C of the DNA is: 45 (Bd).

Type strain: 114, ATCC 30696.

Genus Incertae Sedis IV. ***Candidatus*** **Odyssella** Birtles, Rowbotham, Michel, Pitcher, Lascola, Alexou-Daniel and Raoult 2000, 71

THE EDITORIAL BOARD

Od.ys.sel'la. Gr. dim. fem. n. *Odyssella* pertaining to Odysseus.

Motile, rod-shaped (0.2–0.5 × 0.7–1.0 μm) **intracytoplasmic parasite of** *Acanthamoeba* spp. Does not grow axenically. Most virulent at temperatures above 30°C.

The mol% G + C of the DNA is: 41 ± 1 (T_m).

Type species: *Candidatus* Odyssella thessalonicensis Birtles, Rowbotham, Michel, Pitcher, Lascola, Alexou-Daniel and Raoult 2000, 71.

FURTHER DESCRIPTIVE INFORMATION

Electron micrographs show that the organisms are present in the cytoplasm of infected *Acanthamoeba* cells and that at lower growth temperatures the bacterial cells are sometimes surrounded by a clear zone containing vesicles that appear to have budded from the bacterial cell membrane.

The organism infects the following *Acanthamoeba* species: *A. polyphaga*, *A. lenticulata*, *A. castellanii*, *A. quinaludunensis*, and *A. comandoni*.

Comparisons of 16S rDNA sequences place the organism in the *Alphaproteobacteria*; however, its 16S rDNA sequence was not closely related to those of any of the bacteria to which it was compared. It was most similar to that of two other intracellular parasites: *Holospora obtusa* and *Caedibacter caryophilus*.

ENRICHMENT AND ISOLATION PROCEDURES

Candidatus Odyssella thessalonicensis was first isolated from an *Acanthamoeba* sp. obtained from an air-conditioning system. It was propagated on *A. polyphaga* Linc Ap-1 using the methods of Birtles et al. (1996).

MAINTENANCE PROCEDURES

Suspensions of infected *Acanthamoeba* cells can be stored at −70°C (Birtles et al., 1996).

List of species of the genus Odyssella

1. *Candidatus* Odyssella thessalonicensis *sp. nov.* Birtles, Rowbotham, Michel, Pitcher, Lascola, Alexou-Daniel and Raoult 2000, 71.
thess.al.lon'i.cen'sis. M.L. masc. n. adj. *thessalonicensis* pertaining to the Greek city Thessalonika, where the organism was isolated.

The genus description and the species description are identical.

The mol% G + C of the DNA is: 41 ± 1 (T_m).

Type strain: L13 (only described strain).

GenBank accession number (16S rRNA): AF069496.

Genus Incertae Sedis V. ***Candidatus*** **Paracaedibacter** *Horn, Fritsche, Gautom, Schleifer and Wagner 1999, 364*

HANS-DIETER GÖRTZ AND HELMUT J. SCHMIDT

For a description see the list of species.

TAXONOMIC COMMENTS

A formal description and diagnosis has not yet been published. Because of the relatively low overall 16S rDNA sequence similarities (87–88%) of the two new species *Candidatus* Paracaedibacter acanthamoebae and *Candidatus* Paracaedibacter symbiosus, Horn et al. (1999) propose the provisional classification of these symbionts in the new genus *Candidatus* Paracaedibacter.

List of species of the genus Candidatus Paracaedibacter

1. *Candidatus* Paracaedibacter acanthamoebae Horn, Fritsche, Gautom, Schleifer and Wagner 1999, 364.

Not cultivated on cell-free media; Gram negative; rod shaped, ~1.3–1.7 × 0.22–0.24 μm. Based on 16S rDNA sequence and nucleotide probe S-S-PcaeC9-217-a-A-18 (5′-GGGCTGCTCAATTGGCGA-3′), *Candidatus* Paracaedibacter acanthamoebae is assigned to the *Alphaproteobacteria*. Intracellular symbiont of *Acanthamoeba* sp. UWC9. Mesophilic.

GenBank accession number (16S rRNA): AF132137.

2. *Candidatus* Paracaedibacter symbiosus Horn, Fritsche, Gautom, Schleifer and Wagner 1999, 364.

Not cultivated on cell-free media; Gram negative; rod shaped, ~1.3–1.7 × 0.22–0.24 μm. Based on 16S rDNA sequence and nucleotide probe S-S-PcaeE39-217-a-A-18 (5′-GGGCTGTTCCTTTAGCGA-3′), *Candidatus* Paracaedibacter symbiosus is assigned to the *Alphaproteobacteria*. Intracellular symbiont of *Acanthamoeba* sp. UWE39. Mesophilic.

GenBank accession number (16S rRNA): AF132139.

Genus Incertae Sedis VI. **Pseudocaedibacter** *Quackenbush 1982, 267^VP^ (Effective publication Quackenbush 1978, 186)**

Hans-Dieter Görtz and Helmut J. Schmidt

Pseu.do.cae′di.bac.ter. Gr. adj. *pseudo* false; M.L. n. *Caedibacter* genus of endosymbionts that include organisms commonly known as kappa; M.L. masc. n. *Pseudocaedibacter* false kappa particles.

Rods 0.25–0.7 × 0.5–4 μm. Gram negative. Nonmotile. **Do not produce R-body-containing cells.** May or may not confer a killer trait upon their host paramecia. Occurs in *Paramecium primaurelia*, *P. biaurelia*, *P. pentaurelia*, and *P. octaurelia*. Whether lacking the ability to produce R bodies justifies separation of the genus *Pseudocaedibacter* from the genus *Caedibacter* may be questioned because the newly found endosymbiont from *Acanthamoeba polyphaga*, *Candidatus* Caedibacter acanthamoebae, does not establish R bodies but showed 93% sequence similarity (16S rRNA) to *Caedibacter caryophilus* and was therefore included in the genus *Caedibacter* (Horn et al., 1999).

The mol% G + C of the DNA is: 35–39.

Type species: **Pseudocaedibacter conjugatus** (ex Preer, Preer and Jurand 1974) Quackenbush 1982, 267 (Effective publication: Quackenbush 1978, 187) (*Caedibacter conjugatus* Preer, Preer and Jurand 1974, 157.)

Further descriptive information

Pseudocaedibacter is much like *Caedibacter*, except that no R bodies are found. It includes the typical mate-killing forms (*P. conjugatus*, called mu), the small killing forms of *Paramecium octaurelia* (*Pseudocaedibacter minuta*, gamma), and the nondescript forms with no killing action (*P. falsus*, nu).

Taxonomic Comments

For formal reasons, *"Pseudocaedibacter glomeratus"* is listed under Other Organisms, because the species name has not been validated. However, it should be stated that the validated species, too, were only included in the genus because of a few biological features. As no molecular or physiological data are available for any of the species, the whole genus and its species appear arbitrary.

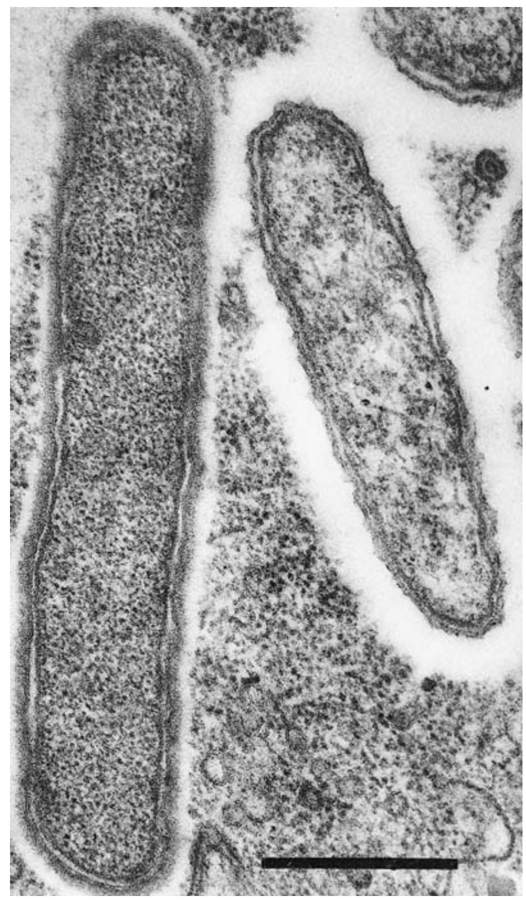

FIGURE BXII.α.67. Two endosymbionts present in a single cell of *Paramecium octaurelia* stock 131. *Left*, *Tectibacter vulgaris* (note electron-dense material surrounding outer membrane); *right*, *Pseudocaedibacter conjugatus*. Longitudinal section. Bar = 0.5 μm. (Reproduced with permission from J.R. Preer, Jr. et al., Bacteriological Reviews *38:* 113–163, 1974, ©American Society for Microbiology.)

**Editorial Note:* This genus was described by J.R. Preer, Jr. and L.B. Preer (1984) in the first edition of *Bergey's Manual of Systematic Bacteriology*. The authors have used their descriptions and figures and have added newer information.

List of species of the genus Pseudocaedibacter

1. **Pseudocaedibacter conjugatus** (ex Preer, Preer and Jurand 1974) Quackenbush 1982, 267^{VP} (Effective publication: Quackenbush 1978, 187) (*Caedibacter conjugatus* Preer, Preer and Jurand 1974, 157.)

con.ju.ga′tus. L. masc. part. adj. *conjugatus* conjugated.

Rods 0.3–0.5 × 1–4 μm. The species is called mu and (except for *Caedibacter paraconjugatus*) is the only symbiont responsible for the mate killer phenotype in the *Paramecium aurelia* complex (Fig. BXII.α.67). It produces the toxin capable of killing sensitive strains of *Paramecium* only after

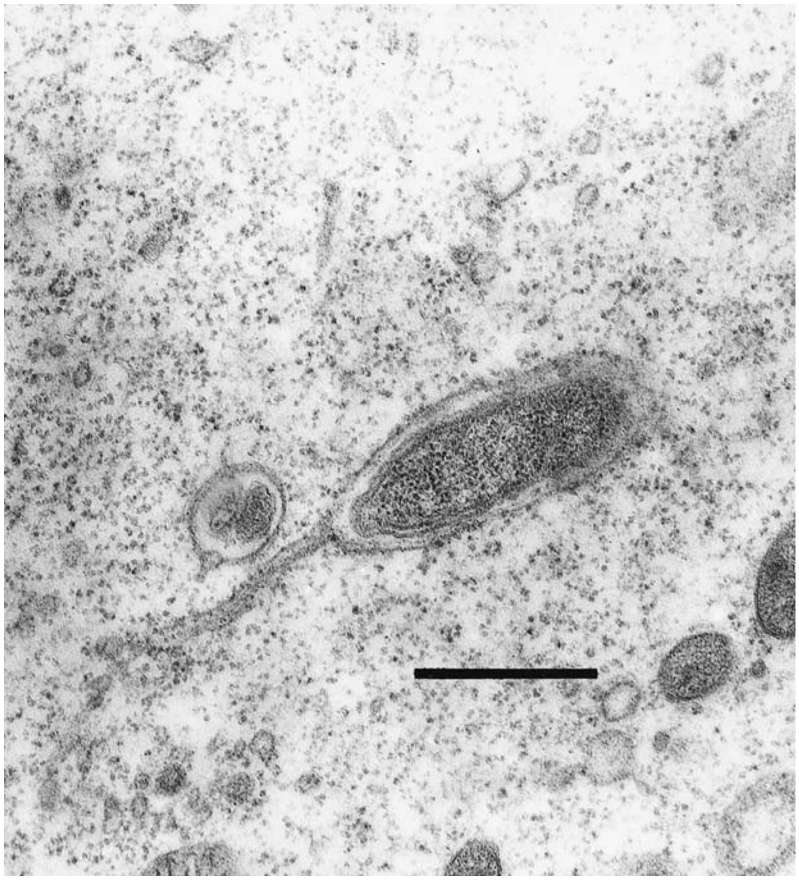

FIGURE BXII.α.68. *Pseudocaedibacter minutus*, endosymbiont of *Paramecium octaurelia* stock 565. No additional outer membrane. Longitudinal section. Bar = 0.5 μm. (Reproduced with permission from A. Jurand.)

cell-to-cell contact between killers and sensitives at conjugation. Cultivation outside the cytoplasm of *Paramecium* has been reported to occur on a very complex medium (Williams, 1971). Found in the cytoplasm of *Paramecium primaurelia* and *P. octaurelia*.

The mol% G + C of the DNA is: 35–37 (Bd).

Type strain: ATCC 30796.

Additional Remarks: The type strain of *P. conjugatus* is isolated from stock 540 of *Paramecium primaurelia* (ATCC 30796) (Preer et al., 1974).

2. **Pseudocaedibacter minutus** (Preer, Preer and Jurand 1974) Quackenbush 1982, 267^VP (Effective publication: Quackenbush 1978, 187) (*Caedibacter minutus* Preer, Preer and Jurand 1974, 157.)
mi.nu′tus. L. masc. adj. *minutus* small.

Rods, often double, 0.25–0.35 × 0.5–1.0 μm (singles). This very small cell is unique among the endosymbionts of *Paramecium* in being surrounded by an extra set of membranes, apparently continuous with the endoplasmic reticulum of its host (Fig. BXII.α.68). Although it never rises to high concentrations in the cytoplasm, the paramecia that bear it are nevertheless very strong killers. Found only in the cytoplasm of *Paramecium octaurelia*. Originally called gamma.

The mol% G + C of the DNA is: 38 (Bd).

Type strain: ATCC 30699.

Additional Remarks: Isolated from stock 214 of *Paramecium octaurelia* (ATCC 30699) (Preer et al., 1974).

3. **Pseudocaedibacter falsus** (Preer, Preer and Jurand 1974) Quackenbush 1982, 267^VP (Effective publication: Quackenbush 1978, 187) (*Caedibacter falsus* Preer, Preer and Jurand 1974, 157.)
fal′sus. L. masc. adj. *falsus* false.

Rods 0.4–0.7 × 1.0–1.5 μm. No toxic action known, although the forms (called nu) found in *Paramecium pentaurelia* are said to increase the resistance of their hosts to the toxin produced by *Lyticum flagellatum* (Holtzman, 1959). The strains found in *Paramecium tetraurelia* were once regarded as mutants of *Caedibacter taeniospiralis* and called pi. Found also in the cytoplasm of *Paramecium biaurelia*.

The mol% G + C of the DNA is: 36 (Bd).

Type strain: ATCC 30640.

Additional Remarks: Isolated from stock 1010 of *P. biaurelia* (ATCC 30640) (Preer et al., 1974).

Other Organisms

1. *"Pseudocaedibacter glomeratus"* Fokin and Ossipov 1986, 1003.
Rods, 1.0–1.2 × 0.3 μm. No flagella. Gram negative, no central nucleoid. Bacteria are encircled by host membranes in a symbiontophoral vacuole. These vacuoles are surrounded by lacunae of endoplasmic reticulum with numerous ribosomes. No killing or toxic actions known.
The mol% G + C of the DNA is: not determined.
The type strain is in *Paramecium pentaurelia* strain Bp171, culture collection of the Laboratory of Protozoan Karyology of the Biological Research Institute of St.Petersburg State University, Russia.

Genus Incertae Sedis VII. "Pseudolyticum" *Boss, Borchsenius and Ossipov 1987, 98**

Hans-Dieter Görtz and Helmut J. Schmidt

pseu' do.ly.ti.cum. Gr. adj. *pseudo* false; L. adj. *lyticus* dissolving; M.L. neut. n. *Lyticum* genus of endosymbionts producing labile toxins which kill sensitive strains of paramecia very quickly by lysis; M.L. n. *Pseudolyticum* false *Lyticum*.

Straight rods, 2.0 × 3.5–14.0 μm. Bacteria are not infective and do not confer a killer trait on their host. Gram negative. Nonmotile in spite of numerous flagella. Occur in *Paramecium caudatum.*

The mol% G + C of the DNA is: not determined.

Type species: **"Pseudolyticum multiflagellatum"** Boss, Borchsenius and Ossipov 1987, 98.

List of species of the genus Pseudolyticum

1. **"Pseudolyticum multiflagellatum"** Boss, Borchsenius and Ossipov 1987, 98.
mul.ti.fla.gel.la' tum. L. neut. adj. *multus* many; L. neut. part. adj. *flagellatum* flagellated; *multiflagellatum* with many flagella.

As the only species, its characteristics are those of the genus. Straight rods 2.0 × 3.5–14.0 μm. Bacteria are not infective and do not confer a killer trait on their host. Occurs in *Paramecium caudatum.* Similar endosymbiotic bacteria in *P. caudatum* have been described by Dieckmann (1977). The bacteria described by Dieckmann were, however, infectious and motile when outside their host cells.

The mol% G + C of the DNA is: not determined.

Deposited strain: in stocks E39-3 and E39-10 (deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, State University of St. Petersburg, Russia).

**Editorial Note:* The genus has not been validly published, due to the custom of Russian protozoologists at the time of its description to publish new symbiont names in Russian journals. However named, species were only included in the genus because of a few biological features. As no molecular or physiological data are available for any of the species, the whole genus and its species appear arbitrary.

Genus Incertae Sedis VIII. Tectibacter *(ex Preer, Preer and Jurand 1974) Preer and Preer 1982, 140^VP^**

Hans-Dieter Görtz and Helmut J. Schmidt

Tec.ti.bac'ter. L. masc. n. *tectum* covering; M.L. masc. n. *bacter* the equivalent of Gr. neut. n. *bactrum* a rod; M.L masc. n. *Tectibacter* the bacterium with a covering.

Straight rods 0.4–0.7 × 1–2 μm. Distinguished by **outer covering around its cell wall**, visible in sections with the transmission electron microscope. Sparsely flagellated, peritrichous. No known strains are toxic to protozoa. Gram negative. Often observed to be motile. Occur widely among strains of *Paramecium primaurelia, P. biaurelia, P. tetraurelia, P. sexaurelia,* and *P. octaurelia*, often with other symbionts (Fig. BXII.α.67).

Type species: **Tectibacter vulgaris** (ex Preer, Preer and Jurand 1974) Preer and Preer 1982, 140.

**Editorial Note:* This genus was described by J.R. Preer, Jr. and L.B. Preer (1984) in the first edition of *Bergey's Manual of Systematic Bacteriology*. We have used their descriptions and figures and have added newer information.

List of species of the genus Tectibacter

1. **Tectibacter vulgaris** (ex Preer, Preer and Jurand 1974) Preer and Preer 1982, 140[VP]
vulgar' is. L. masc. adj. *vulgaris* common.

The characteristics are as described for the genus.
The mol% G + C of the DNA is: not determined.
Type strain: ATCC 30697.
Additional Remarks: The type strain of *Tectibacter vulgaris* was isolated from stock 225 of *Paramecium sexaurelia* (ATCC 30697) (Preer et al., 1974).

Order III. **Rhodobacterales** *ord. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Rho.do.bac.ter.a′les. M.L. masc. n. *Rhodobacter* type genus of the order; *-ales* suffix to denote order; M.L. fem. n. *Rhodobacterales* the *Rhodobacter* order.

The order *Rhodobacterales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the order contains the family *Rhodobacteraceae*.

Description is the same as for the family *Rhodobacteraceae*.

Type genus: **Rhodobacter** Imhoff, Trüper and Pfennig 1984, 342.

Family I. **Rhodobacteraceae** *fam. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Rho.do.bac.ter.a′ce.ae. M.L. masc. n. *Rhodobacter* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Rhodobacteraceae* the *Rhodobacter* family.

The family *Rhodobacteraceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Rhodobacter* (type genus), *Ahrensia*, *Albidovulum*, *Amaricoccus*, *Antarctobacter*, *Gemmobacter*, *Hirschia*, *Hyphomonas*, *Jannaschia*, *Ketogulonicigenium*, *Leisingera*, *Maricaulis*, *Methylarcula*, *Octadecabacter*, *Pannonibacter*, *Paracoccus*, *Pseudorhodobacter*, *Rhodobaca*, *Rhodothalassium*, *Rhodovulum*, *Roseibium*, *Roseinatronobacter*, *Roseivivax*, *Roseobacter*, *Roseovarius*, *Rubrimonas*, *Ruegeria*, *Sagittula*, *Staleya*, *Stappia*, and *Sulfitobacter*. *Albidovulum*, *Leisingera*, *Pseudorhodobacter*, *Pannonibacter*, and *Jannaschia* were proposed after the cut-off date for inclusion in this volume (June 30, 2001) and are not described here (see Albuquerque et al., 2002; Schaefer et al., 2002; Uchino et al., 2002; Borsodi et al., 2003, and Wagner-Döbler et al., 2003, respectively).

Family is phenotypically, metabolically, and ecologically diverse. Includes photoheterotrophs that can also grow photoautotrophically or chemotrophically under appropriate environmental conditions, chemoorganotrophs with either strictly aerobic or facultatively anaerobic respiratory metabolism, facultatively fermentative organisms, and facultative methylotrophs. Some denitrify. Many are aquatic. Many require NaCl for growth.

Type genus: **Rhodobacter** Imhoff, Trüper and Pfennig 1984, 342.

Genus I. **Rhodobacter** *Imhoff, Trüper and Pfennig 1984, 342[VP]*

JOHANNES F. IMHOFF

Rho.do.bac′ter. Gr. n. *rhodon* the rose; M.L. masc. n. *bacter* equivalent of Gr. neut. n. *bakterion* a rod; M.L. masc. n. *Rhodobacter* red rod.

Cells are ovoid or rod-shaped, motile by polar flagella or nonmotile, divide by binary fission or budding, may produce capsules and slime, and may form chains of cells. **Gram negative; belong to the *Alphaproteobacteria*.** Phototrophically grown cells **form vesicular or lamellar internal photosynthetic membranes**. The color of phototrophic cultures is yellow-green to yellow-brown, while aerobic cultures are pink to red. **Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spheroidene series. Ubiquinone 10 is the major quinone. Major fatty acids are C_{18} and C_{16} saturated and monounsaturated fatty acids with $C_{18:1}$ as predominant component.**

Photoheterotrophic growth occurs under anoxic conditions in the light with a variety of organic compounds as carbon and electron sources. **Photoautotrophic growth may be possible with hydrogen, sulfide, or thiosulfate as an electron donor. Chemotrophic growth may occur by aerobic respiration and under anoxic dark conditions, also by denitrification, fermentation, and oxidant-dependent metabolism.** Polysaccharides, poly-β-hydroxybutyric acid and polyphosphates may be present as storage products. Growth factors are required.

Mesophilic freshwater bacteria with optimal growth at neutral pH and in the absence of NaCl.

Habitats: freshwater environments providing organic substrates and reduced oxygen concentrations; sewage ponds, eutrophic lakes and the like.

The mol% G + C of the DNA is: 64.4–73.2.

Type species: **Rhodobacter capsulatus** (Molisch 1907) Imhoff, Trüper and Pfennig 1984, 342 (*Rhodonostoc capsulatum* Molisch 1907, 23; *Rhodopseudomonas capsulata* (Molisch 1907) van Niel 1944, 92.)

FURTHER DESCRIPTIVE INFORMATION

Cells of all *Rhodobacter* species have similar shape and size but different tendencies to form capsules, slime, or chains. Chain formation is also dependent on the growth conditions. Characteristic for *R. capsulatus* is the formation of zigzag chains, which has not been observed in the other species. However, not all strains of this species form zigzag chains, and this phenomenon is best observed in mineral media. Most of the strains that form zigzag chains in mineral media form straight chains in complex media, in which a marked tendency of spheroplast formation was observed, especially if the concentrations of yeast extract were higher than 0.7% (Weaver et al., 1975a).

Physiologically, *Rhodobacter* species are among the most versatile species of the purple nonsulfur bacteria. They can perform a number of different growth modes. Most of the biochemical and genetic research with purple nonsulfur bacteria has been performed with either of the two species, *Rhodobacter capsulatus* and *Rhodobacter sphaeroides*. All species grow well photoheterotrophically under anoxic conditions in the light with a variety of

carbon sources and electron donors. Most species grow photoautotrophically with hydrogen (except *R. veldkampii*). Molecular hydrogen is an excellent electron donor for *R. capsulatus*, while *R. sphaeroides* grows only slowly with hydrogen (Klemme, 1968; Gest et al., 1983). Sulfide is used as a photosynthetic electron donor in all species but *R. blasticus*. The oxidation product of sulfide is elemental sulfur in most species; only in *R. veldkampii* is sulfate the final oxidation product, and elemental sulfur appears as an intermediate outside the cells (Hansen et al., 1975). Thiosulfate and elemental sulfur are used only by *R. veldkampii*. Sulfate is assimilated via 3′-phosphoadenosine-5′-phosphosulfate (PAPS) in those species which are able to use sulfate as sole sulfur source (Imhoff, 1982). *R. veldkampii* lacks this capability and depends on reduced sulfur compounds for growth.

R. capsulatus can grow well under chemoautotrophic conditions aerobically in the dark with molecular hydrogen as electron donor (Madigan and Gest, 1979; Siefert and Pfennig, 1979). Under oxic dark conditions, it can also use sulfide as electron donor (Kompantseva, 1981). Under anoxic dark conditions, pyruvate and sugars can be fermented (Gürgün et al., 1976; Schultz and Weaver, 1982). Sugars, as well as succinate, malate, or acetate, can support anaerobic dark growth of *R. capsulatus* if DMSO or trimethylamine-*N*-oxide is present as electron acceptor (Yen and Marrs, 1977; Madigan and Gest, 1978; Schultz and Weaver, 1982). Molar growth yields from cultures grown anaerobically in the dark with fructose and DMSO were about 60% of that obtained from aerobic respiratory growth with fructose (Schultz and Weaver, 1982) and about 4–5 times higher than those from cultures grown under anoxic dark conditions without DMSO.

Nitrate reductase-linked electron transport and membrane potential generation accompanied by nitrate reduction to nitrite have been found in strains of *R. capsulatus* (McEwan et al., 1983). Nitrite is accumulated and not reduced further. Some strains of *R. sphaeroides* have the ability to denitrify under anoxic dark conditions (Satoh et al., 1974, 1976; Pellerin and Gest, 1983). Denitrification is also found in *R. azotoformans* (Hiraishi et al., 1996).

The abilities to assimilate and dissimilate nitrate are not linked to each other. Denitrifying strains of *R. sphaeroides* are unable to use nitrate as an assimilatory nitrogen source (Satoh et al., 1976) but have the capacity to fix dinitrogen derived from denitrification (Kelley et al., 1982). Nitrate is assimilated under anoxic conditions in the light by strains of *R. capsulatus*, *R. sphaeroides* (Klemme, 1979), and *R. veldkampii* (Hansen et al., 1975).

Ammonia is certainly the preferred nitrogen source. It is assimilated via the glutamine synthetase/glutamate synthase (NADPH-dependent) reactions (Brown and Herbert, 1977) in *R. capsulatus* and *R. sphaeroides*. A nucleotide-unspecific glutamate dehydrogenase is present in *R. sphaeroides* (Engelhardt and Klemme, 1978), but absent in *R. capsulatus*, in which an alanine dehydrogenase, which acts primarily in the catabolism of alanine, was found (Johannson and Gest, 1976; Tolxdorff-Neutzling and Klemme, 1982).

Besides ammonia, dinitrogen is commonly used as a nitrogen source by *Rhodobacter* species (Siefert, 1976; Madigan et al., 1984). Nitrogen fixation is possible not only under anoxic conditions in the light but also under microoxic to oxic conditions in the dark (Madigan et al., 1979; Siefert and Pfennig, 1980) and under anoxic denitrifying conditions in strains of *R. sphaeroides* (Kelley et al., 1982). A number of organic nitrogen compounds also serve as sources for cellular nitrogen, including purines (Aretz et al., 1978) and pyrimidines (Kaspari, 1979).

Most species are sensitive to penicillin (Weaver et al., 1975a; de Bont et al., 1981a; Hansen and Imhoff, 1985). With the exception of *R. sphaeroides*, growth inhibition is almost complete at 0.1 U/ml penicillin. Growth of *R. sphaeroides* is completely inhibited at 1–100 U/ml of penicillin.

Enrichment and Isolation Procedures

Standard media and techniques for enrichment and isolation of PNSB are suitable for *Rhodobacter* species (see Genus *Rhodospirillum*). In enrichment cultures set up for purple nonsulfur bacteria, members of this genus will usually grow faster and outcompete other purple nonsulfur bacteria. Media for the enrichment of *Rhodobacter* species should not contain NaCl in order to specifically exclude *Rhodovulum* species. Media with organic substrates and for most species, the provision of autotrophic conditions with sulfide, thiosulfate, or hydrogen as electron donors are equally effective for enrichment of *Rhodobacter* species (Biebl and Pfennig, 1981; Imhoff, 1988; Imhoff and Trüper, 1992). Photoautotrophic conditions with hydrogen and dinitrogen as electron and nitrogen sources, respectively, appear highly selective for *R. capsulatus*.

Maintenance Procedures

Cultures are well preserved by use of standard techniques with liquid nitrogen, by lyophilization, or storage at −80°C in a mechanical freezer.

Differentiation of the genus *Rhodobacter* from other genera

Characteristic properties of *Rhodobacter* species are the ovoid to rod-shaped cell morphology, the presence of vesicular internal membranes (except in *R. blasticus*), and carotenoids of the spheroidene series. All these properties are shared with *Rhodovulum* species. In addition, *Rubrivivax gelatinosus* (*Betaproteobacteria*) forms carotenoids of the spheroidene series. *Rhodobacter* species can be distinguished from *Rhodovulum* species by the lack of a substantial NaCl requirement for optimal growth, i.e., they show the typical response of freshwater bacteria. This does not exclude, however, very minor requirements for the sodium ion that have been demonstrated e.g., for *R. sphaeroides*, which has a growth optimal at 4 mM sodium chloride (Sistrom, 1960).

Rhodobacter species have a number of characteristic chemotaxonomic properties that enable their distinction from other genera. All investigated species have a large-type cytochrome c_2 (Ambler et al., 1979) and as sole quinone component Q-10 (Imhoff, 1984a). Those species that are able to assimilate sulfate use the pathway via 3′-phosphoadenosine-5′-phosphosulfate (PAPS; Imhoff, 1982). The lipopolysaccharides of investigated species (*R. capsulatus*, *R. sphaeroides*, *R. blasticus*, *R. veldkampii*) contain glucosamine as sole amino sugar in their lipid A moieties, have phosphate, amide-linked 3-OH-14:0 and/or 3-oxo-14:0 and ester-linked 3-OH-10:0 (Weckesser et al., 1995). All of these properties are shared with *Rhodovulum* species. Differentiation of the genera and species of *Rhodobacter*, *Rhodobaca* and *Rhodovulum* is possible based on 16S rDNA sequences (see Fig. 3 [p. 129] in the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A), by phenotypic characteristics (see Tables BXII.α.46, BXII.α.47, and BXII.α.48), and by DNA–DNA hybridization.

Taxonomic Comments

Species of this genus (*R. capsulatus*, *R. sphaeroides*, *R. blasticus*) were formerly included in the genus *Rhodopseudomonas*. The rec-

ognition of morphologically and chemotaxonomically distinct characteristics and early phylogenetic analyses led to their separation from *Rhodopseudomonas* and classification in the genus *Rhodobacter* (Imhoff et al., 1984; Kawasaki et al., 1993a). *Rhodobacter blasticus* is the only species of this genus that forms buds during cell division and contains internal photosynthetic membranes of the lamellar type (Eckersley and Dow, 1980). Because these were characteristic properties of the genus *Rhodopseudomonas* at that time, this bacterium was described as a *Rhodopseudomonas* species (Eckersley and Dow, 1980) and retained within this genus in a

reclassification of the purple nonsulfurbacteria because of insufficient supporting data (Imhoff et al., 1984). With the availability of 16S rDNA sequences and supporting chemotaxonomic data (e.g., lipopolysaccharide analyses; see Weckesser et al., 1995), the great similarity and phylogenetic affiliation of this species to *Rhodobacter* became apparent and led to its reclassification as *Rhodobacter blasticus* (Kawasaki et al., 1993a). These authors correctly proposed *Rhodobacter blasticus* comb. nov. as the new name but did not give a formal description of the new combination. Unfortunately, this name appeared incorrectly in validation list no. 51 of the IJSB as *"Rhodobacter blastica"* and therefore a revision of this name was proposed by Euzéby (1997). As the genus name *Rhodobacter* is masculine, the correct name is *R. blasticus*.

Strains of *R. sphaeroides* that were confirmed as this species by DNA–DNA hybridization studies (de Bont et al., 1981a) are able to denitrify (Satoh et al., 1976; Pellerin and Gest, 1983). The denitrifying *Rhodobacter azotoformans* is clearly distinct from *R. sphaeroides* by DNA–DNA hybridization (Hiraishi et al., 1996).

Differentiation of the species of the genus *Rhodobacter*

The apparent morphological similarity, highly similar pigmentation, and great intraspecies variability regarding the utilization of carbon sources demands careful analyses to identify and differentiate *Rhodobacter* species. Problems in species identification that may arise due to high metabolic versatility and flexibility of the *Rhodobacter* species have been discussed in regard to the differentiation of *R. sphaeroides* and *R. capsulatus* (Imhoff, 1989). Characteristic properties to differentiate species of *Rhodobacter* are summarized in Tables BXII.α.47 and BXII.α.48. The utilization of formate, citrate, tartrate, mannitol, glycerol, ethanol, hydrogen, and thiosulfate is of diagnostic value (Table BXII.α.48).

Rhodobacter species are well characterized and clearly distinct based on 16S rDNA sequence comparison (Fig. 3 (p. 129) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A) and by DNA–DNA hybridization (de Bont et al., 1981a; Ivanova et al., 1988; Hiraishi et al., 1996). In addition, all species of *Rhodobacter* (and *Rhodovulum*) that were included in a study of fatty acid and polar lipid composition can be differentiated on this basis (Imhoff, 1991; Imhoff and Bias-Imhoff, 1995).

List of species of the genus Rhodobacter

1. **Rhodobacter capsulatus** (Molisch 1907) Imhoff, Trüper and Pfennig 1984, 342[VP] (*Rhodonostoc capsulatum* Molisch 1907, 23; *Rhodopseudomonas capsulata* (Molisch 1907) van Niel 1944, 92.)

cap.su.la′ tus. L. dim. n. *capsula* a small chest, capsule; M.L. masc. adj. *capsulatus* capsuled.

Cells are ovoid to rod-shaped, 0.5–1.2 × 2.0–2.5 μm, sometimes even longer. Spherical cells occur in media below pH 7.0 and are often irregularly arranged in chains resembling streptococci. Ovoid and rod-shaped cells are characteristic in media above pH 7.0, but pleomorphic cells appear and media become mucoid above pH 8.0. Chains of cells in zigzag arrangement are typical, but in some strains, these chains may be straight. Most strains that show zigzag arrangement in mineral media form straight chains in complex media. Capsules of varying thickness are formed. Cells are motile by means of polar flagella. Internal photosynthetic membranes appear as vesicles.

Cultures grown anaerobically in the light are yellowish brown or greenish to deep brown. When grown in the presence of oxygen, they are red. Anaerobically grown cells change their color to a distinct red when shaken with air for a few hours; light enhances the color change. Absorption spectra of living cells show maxima at 376–378, 450–455, 478–480, 508–513, 590–592, 802–805, and 860–863 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spheroidene series, including spheroidene and hydroxyspheroidene. These two carotenoids are converted to the corresponding ketocarotenoids under oxic conditions, which causes the color change to red.

Photoautotrophic growth with molecular hydrogen as electron donor is excellent, but is also possible with sulfide, which is oxidized to elemental sulfur only; thiosulfate and elemental sulfur are not used. Photoheterotrophic growth occurs anaerobically in the light with a variety of organic compounds. Chemotrophic growth aerobically in the dark occurs heterotrophically with organic substrates or autotrophically with molecular hydrogen at the full oxygen tension of air. With sugars, anaerobic dark growth occurs in the presence of DMSO or trimethylamine-*N*-oxide as oxidant. Some strains may use nitrate as electron acceptor under similar conditions, reducing it to nitrite. Marginal growth is possible during fermentation of pyruvate or sugars. Carbon sources utilized are listed in Table BXII.α.48.

Ammonia, dinitrogen, and a number of amino acids are used as nitrogen sources; nitrate only by some strains; guanine, xanthine, uric acid, cytidine, uracil, thymine, and adenine only under oxic conditions. Sulfate assimilation occurs. Thiamine is required as a growth factor; some strains also require biotin or biotin and niacin.

All strains of *R. capsulatus* are susceptible to lysis by at least 1 of 16 bacteriophages, which are species specific and do not attack other purple nonsulfur bacteria (Wall et al., 1975).

Mesophilic freshwater bacteria with optimal growth at pH 7.0 (range: 6.5–7.5), 30–35°C (temperature maximum for most strains is above 36°C) and in the absence of added salt (NaCl).

Habitat: stagnant waters exposed to the light and with reduced oxygen concentrations, sewage plants, eutrophic ponds and lakes, and the like.

The mol% G + C of the DNA is: 65.5–66.8 (Bd) and 68.1–69.6 (T_m).

Type strain: ATCC 11166, ATH 2.3.1, DSM 1710, NCIB 8286.

GenBank accession number (16S rRNA): D16428, D134.

2. **Rhodobacter azotoformans** Hiraishi, Muramatsu and Ueda 1997a, 601[VP] (Effective publication: Hiraishi, Muramatsu and Ueda 1996, 175.)
a.zo.to.for′ mans. Fr. n. *azote* nitrogen; L. part. adj. *formans* forming; M.L. adj. *azotoformans* nitrogen forming.

Cells are ovoid to rod-shaped, 0.6–1.0 × 0.9–1.5 μm, motile by means of single polar flagella and divide by binary fission. Pleomorphic and swollen cells occur when growing in the presence of peptone or yeast extract at a concentration of 0.1% or more. Slime is produced under phototrophic growth conditions. Neither zigzag arrangement of cells in chains nor rosette formation is found. Internal photosynthetic membranes appear as vesicles. The color of phototrophic cultures is yellow-green to yellow-brown, while aerobic cultures are pink to red. Phototrophically grown cells have absorption maxima at 376, 449, 476, 510, 589, 800, and 850 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spheroidene series.

Growth occurs under anoxic conditions in the light and under oxic conditions in the dark at full atmospheric oxygen tension. Sulfide at low concentrations (less than 0.5 mM), but not thiosulfate, is utilized under phototrophic conditions and oxidized to elemental sulfur as the final oxidation product. Anaerobic growth in darkness occurs with nitrate (by denitrification) but not with dimethylsulfoxide or trimethylamine *N*-oxide as a terminal electron acceptor. Photoheterotrophy with various organic compounds is the preferred mode of growth. Good carbon sources are acetate, pyruvate, lactate, succinate, fumarate, malate, D-xylose, D-fructose, D-glucose, D-mannose, D-mannitol, L-alanine, L-asparagine, L-glutamate, peptone, Casamino acids, and yeast extract. Growth also occurs with formate, propionate, butyrate, malonate, D-dulcitol, D-sorbitol, glycerol, and L-leucine. Not utilized are caprylate, tartrate, glycolate, benzoate, and methanol. Nitrogen sources are ammonia, dinitrogen, and glutamate. Nitrogenase-dependent photoevolution of hydrogen gas is found under ammonium-limited conditions. Sulfate is assimilated. Biotin, niacin, and thiamine are required as growth factors.

Mesophilic freshwater bacterium with optimal growth at pH 7.0–7.5, 30–35°C and in the absence of sodium chloride. Growth is possible at 3% NaCl.

Habitat: sewage and activated sludge of wastewater treatment plants.

The mol% G + C of the DNA is: 69.5–70.2 (HPLC).

Type strain: KA25, JCM 9340.

GenBank accession number (16S rRNA): D70846.

3. **Rhodobacter blasticus** (Eckersley and Dow 1981) Kawasaki, Hoshino, Hirata and Yamasato 1994a, 852[VP] (Effective publication: Kawasaki, Hoshino, Hirata and Yamasato 1993a, 362.) (*Rhodopseudomonas blastica* Eckersley and Dow 1981, 216.)
blas′ ti.cus. Gr. adj. *blasticos* to bud; M.L. masc. adj. *blasticus* apt to bud.

Cells are ovoid to rod-shaped, 0.6–0.8 × 1.0–2.5 μm, nonmotile, reproduce by budding, and form sessile buds. Although mother and daughter cells appear morphologically similar at cell division, they differ with regard to the

time taken to reach the next division. The mother cell initiates cell growth immediately after division, whereas the daughter cell has to undergo an obligate period of maturation. In media containing yeast extract, abnormally swollen cells and spheroplasts are formed. Internal photosynthetic membranes are present as lamellae underlying and parallel to the cytoplasmic membrane.

Color of cell suspensions is orange-brown if grown under anoxic conditions in the light, but changes to red in the presence of oxygen. Cells grown under oxic conditions in the dark are colorless to faint pink. Absorption spectra of living cells have maxima at 378, 418, 476, 506, 590, 795, and 862 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spheroidene series.

Preferred growth is photoheterotrophically under anoxic conditions in the light. Photoautotrophic growth occurs with hydrogen as electron donor; sulfide and thiosulfate are not used. Chemotrophic growth is possible under oxic conditions in the dark. Ammonia, dinitrogen, glutamate, aspartate, glutamine, alanine, ornithine, tyrosine, thymine, and urea serve as nitrogen sources; nitrate and nitrite are not used. Sulfate is assimilated. In addition to thiamine and niacin, biotin and vitamin B_{12} are required as growth factors (Schmidt and Bowien, 1983).

Mesophilic freshwater bacterium with optimal growth at pH 6.5–7.5, 30–35°C and in the absence of salt (NaCl).

Habitat: stagnant waters exposed to the light and with reduced oxygen concentrations, sewage plants, eutrophic ponds, and lakes.

The mol% G + C of the DNA is: 65.3 (Bd).

Type strain: NCIB 11576, ATCC 33485.

GenBank accession number (16S rRNA): D16429, D138.

4. **Rhodobacter sphaeroides** (van Niel 1944) Imhoff, Trüper and Pfennig 1984, 342^VP (*Rhodopseudomonas sphaeroides* van Niel 1944, 95.)
sphae.ro' i.des. Gr. adj. *sphaeroides* spherical.

Cells have highly variable morphology, especially in media containing complex nutrients; morphology is more uniform in mineral salts media (Fig. BXII.α.69). Cells are spherical to ovoid, 2.0–2.5 × 2.5–3.5 μm in sugar-containing media, 0.7–4.0 μm wide under other conditions. Frequently cells occur in pairs or as a chain of beads which in many instances are connected by a thin filament and slightly unequal in size. As cultures age, they become viscous due to slime production, except when sugars serve as carbon source. Slime formation is enhanced in complex media. In young cultures, cells are motile by polar flagella; motility ceases in alkaline media. Internal photosynthetic membranes appear as vesicles.

Cultures grown under anoxic conditions in the light are greenish brown to dark brown, if grown in the presence of oxygen they are red. The brown color of cells grown anaerobically in the light changes to red if cells are shaken with air; light stimulates this change. Absorption spectra of living cells have maxima at 372–375, 446–450, 474–481, 507–513, 588–590, 800–805, 850–852, and 870–880 nm. The relative absorbances at 850–880 nm vary greatly with the culture conditions. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spheroidene series, including spheroidene and hydroxyspheroidene, which are converted to their corresponding ketocarotenoids under oxic conditions and thereby cause the color change to red.

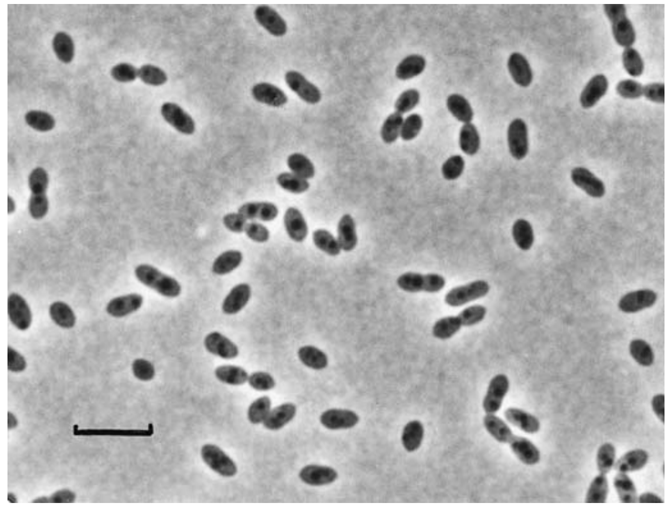

FIGURE BXII.α.69. *Rhodobacter sphaeroides* ATCC 17032 grown in mineral medium with 0.2% succinate and 0.05% yeast extract at pH 6.8. Phase-contrast micrograph. Bar = 5 μm. (Courtesy of N. Pfennig.)

Preferred growth is photoheterotrophically under anoxic conditions. Photoautotrophic growth with molecular hydrogen or sulfide as electron donor is slow; thiosulfate and elemental sulfur are not used; sulfide is oxidized to elemental sulfur only. Good growth is observed under oxic conditions in the dark with a number of organic carbon sources. In addition, oxidant-dependent anaerobic dark growth with DMSO and TMAO as electron acceptors and several organic substrates is possible. Anaerobic dark fermentative growth with pyruvate and sugars is only marginal. Some strains are able to denitrify under anoxic conditions in the dark.

Organic substrates utilized are shown in Table BXII.α.48. Lower fatty acids are used at low concentrations. Higher fatty acids are toxic. Growth with glycerol depends on the presence of CO_2. Acids are produced in sugar-containing media under all conditions but disappear later. Nitrogen sources are ammonia, dinitrogen, alanine, glutamate, and aspartate; dinitrogen is also used under microoxic to oxic growth conditions in the dark. Some strains use uric acid, guanine, xanthine, cytidine, uracil, thymine, adenine (only under oxic conditions), and nitrate. Sulfate is assimilated. Thiamine, biotin, and niacin are required as growth factors.

Mesophilic freshwater bacterium with optimal growth at pH 7.0 (range: 6.0–8.5), 30–34°C, and in the absence of NaCl. Growth is possible at 3% NaCl.

Habitat: stagnant waters exposed to the light and with reduced oxygen concentrations, sewage plants, eutrophic ponds, and lakes.

The mol% G + C of the DNA is: 68.4–69.9 (Bd) and 70.8–73.2 (T_m).

Type strain: ATCC 17023, ATH 2.4.1, DSM 158, NCIB 8253.

GenBank accession number (16S rRNA): X53853, X53854, X53855.

5. **Rhodobacter veldkampii** Hansen and Imhoff 1985, 115^VP

veld.kamp'i.i. M.L. gen. n. *veldkampii* of Veldkamp; named for H. Veldkamp, a Dutch microbiologist.

Cells are ovoid to rod-shaped, 0.6–0.8 × 1.0–1.3 μm, nonmotile, have a pronounced tendency to form chains of cells under certain growth conditions, and do not produce slime. Internal photosynthetic membranes appear as vesicles. Color of photosynthetically grown cells varies from yellowish brown to dark brown and red. Aerobically grown cells are red. Absorption spectra of photosynthetically grown cells have maxima at 373, 448, 477, 510, 589, 803, and 855 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spheroidene series.

Photoheterotrophic growth occurs under anoxic conditions in the light with a variety of carbon compounds, if a reduced sulfur source is provided. Sulfide, thiosulfate, and elemental sulfur, but not hydrogen, serve as electron donors for photoautotrophic growth. Chemotrophic growth occurs aerobically in the dark. During phototrophic growth with sulfide, elemental sulfur is deposited outside the cells and oxidized further to sulfate after sulfide depletion in batch cultures. In sulfide-limited chemostat cultures, sulfate is the major oxidation product. High concentrations of sulfide (5 mM) are tolerated. The carbon compounds utilized are shown in Table BXII.α.48.

Nitrogen sources are ammonia, dinitrogen, and nitrate. Sulfate cannot be assimilated and reduced sulfur sources are required: sulfide, cysteine, and cystine are used, but not sulfite, thiosulfate, and methionine. Biotin, thiamine, and *p*-aminobenzoic acid are required as growth factors; 0.01% yeast extract can replace the vitamin requirement.

Mesophilic freshwater bacterium with optimal growth (with succinate as substrate and in the presence of cysteine) at pH 7.5, 30–35°C, and in the absence of NaCl.

Habitat: stagnant waters exposed to the light and with reduced oxygen concentrations, sewage plants, eutrophic ponds, and lakes.

The mol% G + C of the DNA is: 64.4–67.5 (T_m).

Type strain: Hansen 51, ATCC 35703.

GenBank accession number (16S rRNA): D137, D16421.

Genus II. **Ahrensia** *Uchino, Hirata, Yokota and Sugiyama 1999, 1[VP] (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 208*

Noel R. Krieg

Ahrens.i.a. M.L. dim ending *-ia* ; M.L. fem. n. *Ahrensia* named after R. Ahrens, a German microbiologist, who contributed to the taxonomy of marine species of *Agrobacterium*.

Rods, 0.6–1.0 × 2.0–4.0 μm. Motile. Do not form spores. Gram negative. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. **Na^+ is required for growth.** Optimal growth occurs between 20 and 30°C; growth occurs at 5°C but not at 37°C. **Catalase and oxidase positive.** Nitrate is not reduced to nitrite or to gas. Gelatin, starch, chitin, and alginate are not hydrolyzed. Indole is not produced. The major fatty acid is $C_{18:1}$. The 3-hydroxy fatty acid is $C_{12:0\ 3OH}$. 2-Hydroxy fatty acids are absent. The major quinone is ubiquinone 10. The genus belongs to the class *Alphaproteobacteria.* Isolated from seawater.

The mol% G + C of the DNA is: 48.

Type species: **Ahrensia kieliensis** (ex Ahrens 1968) Uchino, Hirata, Yokota and Sugiyama 1999, 1 (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 208) (*Agrobacterium kieliense* Ahrens 1968, 156.)

Further descriptive information

Some discrepancies regarding the phenotypic characteristics of *Ahrensia* have become evident. Although Uchino et al. (1998) defined the genus *Ahrensia* as having polar flagella, they also indicated in a table that *A. kieliensis* possessed peritrichous flagella. Rüger and Höfle (1992) reported *A. kieliensis* to have peritrichous or degenerately peritrichous flagella.

It is also not clear whether *A. kieliensis* can use carbohydrates. Rüger and Höfle (1992) reported that none of the 34 compounds tested could be used as sole sources of carbon and energy after incubation at 20°C for 4 weeks. These compounds included glucose and 11 other sugars, the salts of eight organic acids, glycerol, mannitol, sorbitol, and 7 amino acids. Acid production, however, was reported from glucose and xylose after 4–6 weeks of incubation at 20°C.

Differentiation of the genus *Ahrensia* from other genera

It is not yet clear how the genus can be readily differentiated phenotypically from other aerobic marine rods such as *Alteromonas*, *Deleya*, *Marinomonas*, *Marinobacter*, *Neptunomonas*, *Oceanospirillum kriegii*, and *Oceanospirillum jannaschii.* It differs from the genus *Stappia* by having $C_{12:0\ 3OH}$ as its major 3-OH fatty acid rather than $C_{14:0\ 3OH}$.

Taxonomic Comments

Ahrens (1968) classified a new marine species in the genus *Agrobacterium* as *Agrobacterium kieliense* but later withdrew this proposal (Allen and Holding, 1974). DNA–rRNA hybridization studies by De Smedt and De Ley (1977) showed that *Agrobacterium kieliense* was not an agrobacterium, although with a $T_{m(e)}$ of 72°C it did belong on the *Agrobacterium–Rhizobium–Phyllobacterium* branch. 16S rDNA sequence analysis by Uchino et al. (1998) showed that *Agrobacterium kieliense* was separated from other genera in the *Proteobacteria*, and the species was assigned to a new genus, *Ahrensia*, as *Ahrensia kieliense* (sic). In this edition of the *Manual*, the species is placed in the class *Alphaproteobacteria*, the order *Rhodobacterales*, and the family *Rhodobacteraceae.*

List of species of the genus Ahrensia

1. **Ahrensia kieliensis** (ex Ahrens 1968) Uchino, Hirata, Yokota and Sugiyama 1999, 1[VP] (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 208) (*Agrobacterium kieliense* Ahrens 1968, 156.)

kiel.i.ensis. M.L. fem. adj. *kieliensis* pertaining to Kiel, Germany.

The characteristics are as described for the genus. Isolated from brackish seawater of the Baltic Sea.

The mol% G + C of the DNA is: 48.

Type strain: B9, ATCC 25656, DSM 5980, IAM 12618, IFO 15762, NCMB 2205.

GenBank accession number (16S rRNA): D88524.

Genus III. **Amaricoccus** *Maszenan, Seviour, Patel, Rees and McDougall 1997, 732*[VP]

Abdul M. Maszenan, Robert J. Seviour and Bharat K.C. Patel

A.ma' ri.coc.cus. Gr. n. *amara* sewage duct; Gr. n. *coccus* grain; L. n. *Amaricoccus* spherical cells from sewage ducts.

Cocci, 1.3–1.8 μm in diameter, usually arranged in tetrads. Gram negative. Nonmotile. Do not form spores or store polyphosphate granules. Oxidase positive. Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Growth occurs at 20–37°C and at pH 5.5–9.0. Chemoheterotrophic. A variety of organic compounds can be used as carbon sources, including D-fructose, glucose, mannitol, L-glutamic acid, D-mannose, D-sorbitol, sucrose, L-rhamnose, L-arabinose, L-leucine, and L-histidine. Isolated from activated sludge and sewage.

The mol% G + C of the DNA is: 51–63.

Type species: **Amaricoccus kaplicensis** Maszenan, Seviour, Patel, Rees and McDougall 1997, 733.

Further descriptive information

The following enzymes are produced: alkaline phosphatase, esterase, esterase-lipase, lipase, leucine arylamidase, valine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and α-glucosidase. Do not produce cystine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, lysine decarboxylase, ornithine decarboxylase, and arginine dihydrolase.

The following compounds are used as carbon sources: dextrin, L-arabinose, D-arabitol, cellobiose, D-fructose, L-fucose, D-galactose, α-D-glucose, *m*-inositol, maltose, D-mannitol, D-mannose, D-psicose, L-rhamnose, D-sorbitol, sucrose, D-trehalose, turanose, xylitol, methyl pyruvate, monomethyl succinate, α-hydroxybutyric acid, β-hydroxybutyric acid, α-ketobutyric acid, DL-lactic acid, succinic acid, succinamic acid, D-alanine, L-alanine, L-asparagine, L-glutamic acid, maltotriose, palatinose, D-ribose, salicin, D-tagatose, D-xylose, D-lactic acid methyl ester, L-lactic acid, D-malic acid, methyl succinate, pyruvic acid, *N*-acetyl-L-glutamic acid, and adenosine. The following compounds are not used: α-cyclodextrin, *N*-acetyl-D-galactosamine, *i*-erythritol, α-D-lactose, lactulose, D-raffinose, D-glucosaminic acid, D-saccharic acid, sebacic acid, L-alanyl-glycine, glycyl-L-aspartic acid, L-histidine, L-leucine, L-ornithine, L-pyroglutamic acid, uridine, inulin, amygdalin, α-methyl-D-galactoside, β-methyl-D-mannoside, sedoheptulosan, stachyose, and UMP.

Cech and Hartman (1993) suggested that "G-Bacteria" (*Amaricoccus* species) grew well in activated sludge systems operating with alternating aerobic/anaerobic zones, and were dominant when glucose was the carbon source rather than acetate. They hypothesized that "G-Bacteria" were detrimental to the process of biological phosphate removal as they outcompeted polyphosphate-accumulating bacteria (PAB) by anaerobic assimilation of glucose to the storage compound poly-β-hydroxybutyrate, which was subsequently used under aerobic conditions to form glycogen instead of polyphosphate. However, pure cultures of *Amaricoccus* have failed to demonstrate any ability for anaerobic substrate utilization (Seviour et al., 2000).

Amaricoccus species have so far been isolated only from activated sludge. Data from whole-cell hybridization studies with a fluorescently labeled rRNA-targeted oligonucleotide probe suggest that *Amaricoccus* is widespread in the activated sludge environment (Maszenan et al., 2000).

Enrichment and Isolation Procedures

Cech and Hartman (1990, 1993) initially isolated a pure culture of a bacterium described as "G-Bacteria" from a laboratory-scale activated sludge reactor sample. The isolate was subsequently shown to belong to a new genus *Amaricoccus* and described as *Amaricoccus kaplicensis* (Maszenan et al., 1997). A pure culture of "G-Bacteria" was also isolated using a Skerman micromanipulator and called *"Tetracoccus cechi"*, but because its 16S rRNA gene sequence was identical to that of *A. kaplicensis*, it was not taxonomically validated (Blackall et al., 1997). Maszenan et al. (1997, 1998) used a micromanipulator to isolate additional strains from activated sludge biomass samples onto a range of different media and found the Glucose Sulfide (GS) agar medium of Williams and Unz (1985)[1] to be the best for isolation purposes. Once isolated, pure culture cells were able to grow well on a range of media (Maszenan et al., 1997).

Differentiation of the genus *Amaricoccus* from other genera

Members of the order *Rhodobacterales* are heterogenous, comprising different morphologies and physiologies and varying in the mol% G + C value of the DNA. The genus *Amaricoccus* can be differentiated from phylogenetically closely related members of *Rhodobacterales* by the phenotypic criteria listed in Table BXII.α.49.

Taxonomic Comments

Phylogenetic analyses based on 16S rDNA sequencing indicate that *Amaricoccus* species belong to the order *Rhodobacterales* in the class *Alphaproteobacteria* within the phylum *Proteobacteria* (Fig. BXII.α.70). The genus appears to be almost equidistant from *Paracoccus*, *Rhodobacter*, and *Rhodovulum* (91% similarity), and less closely related to *Roseobacter* (88% similarity).

The type strains of the four *Amaricoccus* species exhibit a high

1. The medium contains (g/l distilled water): glucose, 0.15; $(NH_4)_2SO_4$, 0.50; $CaCO_3$, 0.10; $Ca(NO_3)_2$, 0.10; KCl, 0.05; K_2HPO_4, 0.05; $MgSO_4 \cdot 7H_2O$, 0.05; $Na_2S \cdot 9H_2O$, 0.187; 1.0 ml of vitamin solution (Eikelboom, 1975); agar technical No. 3 (Oxoid), 15; pH adjusted to 7.3 (± 0.2). The vitamin solution contains (μg/l): biotin, 5; calcium pantothenate, 100; cocarboxylase, 100; cyanocobalamin (vitamin B_{12}), 5; folic acid, 5; inositol, 100; niacin, 100; *p*-aminobenzoic acid, 100; pyridoxine, 100; riboflavin, 100; thiamine, 100.

Differentiation of the species of the genus *Amaricoccus*

Table BXII.α.50 lists the features that differentiate the four species of *Amaricoccus*.

List of species of the genus Amaricoccus

1. **Amaricoccus kaplicensis** Maszenan, Seviour, Patel, Rees and McDougall 1997, 733[VP]

ka.pli.cen′ sis. M.L. adj. *kaplicensis* referring to Kaplice, Czech Republic, the source of the type strain.

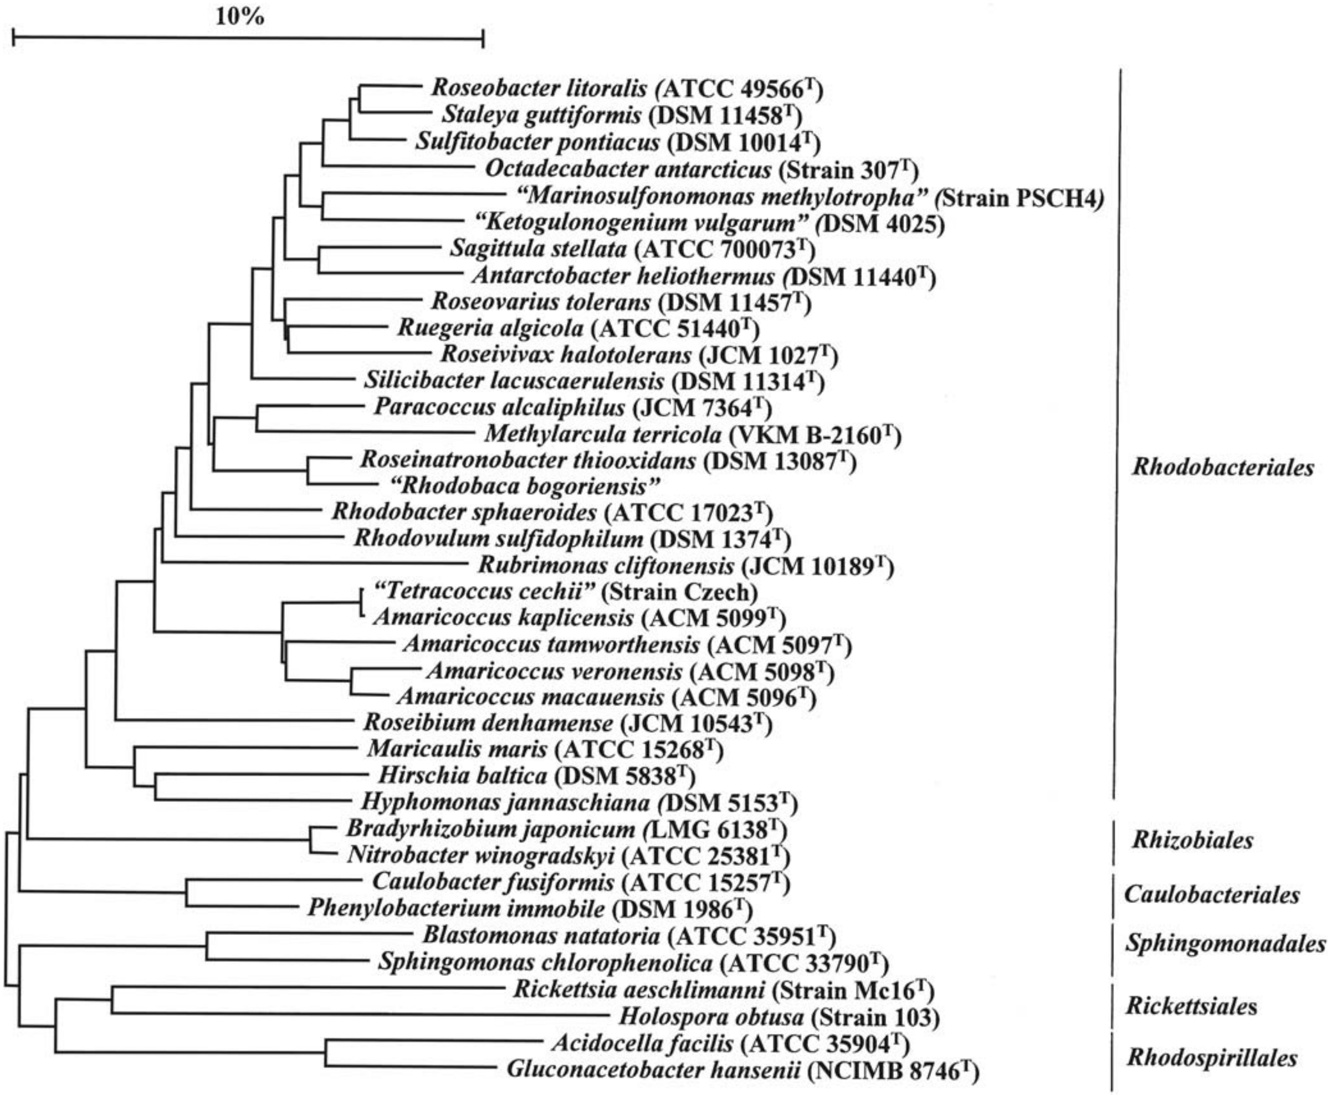

FIGURE BXII.α.70. The phylogenetic position of genus *Amaricoccus* as a member of the order *Rhodobacterales* is shown. The order *Rhodobacterales*, together with the orders *Rhizobiales*, *Caulobacteriales*, *Sphingomonadales*, *Rickettsiales*, and *Rhodospirillales*, constitute the class *Alphaproteobacteria*. The strains used in the analysis, their culture collection numbers and corresponding 16S rRNA gene sequences extracted from GenBank/EMBL are listed below. *Roseobacter litoralis* (X78312, ATCC 49566^{T}), *Staleya guttiformis* (SY16427, DSM 11458^{T}), *Sulfitobacter pontiacus* (Y13155, DSM 10014^{T}), *Octadecabacter antarcticus* (U14583, strain 307^{T}), *"Marinosulfonomonas methylotrophus"* (U62894, strain PSCH4), *"Ketogulonogenium vulgare"* (AF136849, DSM 4025), *Sagittula stellata* (U58356, ATCC 700073^{T}), *Antarctobacter heliothermus* (Y11552, DSM 11445^{T}), *Roseovarius tolerans* (Y11551, DSM 11457^{T}), *Ruegeria algicola* (X78315, ATCC 51440^{T}), *Roseivivax halotolerans* (D85831, JCM 1027^{T}), *Silicibacter lacuscaerulensis* (U77644, DSM 11314^{T}), *Paracoccus alcaliphilus* (Y17512, JCM 7364^{T}), *Methylarcula terricola* (AF030437, VKM B-2160^{T}), *Roseinatronobacter thiooxidans* (AF249749, DSM 13087^{T}), *Rhodobaca bogoriensis* (AF248638^{T}), *Rhodobacter sphaeroides* (X53854, ATCC 17023^{T}), *Rhodovulum sulfidophilum* (U55277, DSM 1374^{T}), *Rubrimonas cliftonensis* (D85834, JCM 10189^{T}), *"Tetracoccus cechi"* (Y09610^{T}, strain Czech), *Amaricoccus kaplicensis* (U88041, ACM 5099^{T}), *Amaricoccus tamworthensis* (U88044, ACM 5097^{T}), *Amaricoccus veronensis* (U88043, ACM 5098^{T}), *Amaricoccus macauensis* (U88042, ACM 5096^{T}), *Roseibium denhamense* (D85832, JCM 10543^{T}), *Maricaulis maris* (AJ227802, ATCC 15268^{T}), *Hirschia baltica* (X52909, DSM 5838^{T}), *Hyphomonas jannaschiana* (AF082789, DSM 5153^{T}), *Bradyrhizobium japonicum* (S46916, LMG 6138^{T}), *Nitrobacter winogradskyi* (L35506, ATCC 25381^{T}), *Caulobacter fusiformis* (AJ007803, ATCC 15257^{T}), *Phenylobacterium immobile* (Y18216, DSM 1986^{T}), *Blastomonas natatoria* (X73043, ATCC 35951^{T}), *Sphingomonas chlorophenolica* (X87161, ATCC 33790^{T}), *Rickettsia aeschlimannii* (U74757, Strain Mc16^{T}), *Holospora obtusa* (endosymbiont), *Acidocella facilis* (D30774, ATCC 35904^{T}) and *Gluconacetobacter hansenii* (X75620, NCIMB 8746^{T}). Phylogenetic analysis was performed on 1230 unambiguous nucleotides using dnadist and neighbor-joining programs which form part of the PHYLIP suite of software. Bar = 10 nucleotide changes per 100 nucleotides. The following abbreviations have been used: ^{T}, Type culture; ATCC, American Type Culture Collection; DSM, Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH; ACM, Australian Collection of Microorganisms; JCM, Japan Collection of Microorganisms; NCIMB, National Collection of Industrial and Marine Bacteria; VKM, All-Russian Collection of Microorganisms.

Pleomorphic cells, 1.6 μm in diameter. Colonies are mucoid on GS agar. D-galactosidic acid, lactone, and α-ketovaleric acid can be used as carbon sources. Does not utilize gentiobiose, β-methyl-D-glucoside, inositol, or lactamide. Nitrate reduced to nitrite.

The mol% G + C of the DNA is: 56 (T_m).
Type strain: Ben 101, ACM 5099.
GenBank accession number (16S rRNA): U88041.

[a]Symbols: see standard definitions.

2. **Amaricoccus macauensis** Maszenan, Seviour, Patel, Rees and McDougall 1997, 733[VP]
ma.cau.en′sis. M.L. adj. *macauensis* referring to Macau, the source of the type strain.

Cells are 1.3 μm in diameter. D-Glucuronic acid, citrate, *p*-hydroxyphenylacetate, itaconate, malonate, quinic acid, glucuronamide, β-methyl-D-galactoside, hydroxy-L-proline, L-phenylalanine, γ-aminobutyric acid, putrescine, 2-ami-

noethanol, and DL-α-glycerol phosphate are used as carbon sources. Lysine decarboxylase activity is present.

The mol% G + C of the DNA is: 63 (T_m).

Type strain: BEN 104, ACM 5096.

GenBank accession number (16S rRNA): U88042.

3. **Amaricoccus tamworthensis** Maszenan, Seviour, Patel, Rees and McDougall 1997, 733^VP

tam.worth.en'sis. M.L. adj. *tamworthensis* referring to Tamworth, Australia, the source of the type strain.

Cells are 1.3 μm in diameter. Individual tetrad cells are joined by an interconnecting fibril network. Tween 40, D-melibiose, D-galacturonic acid, and α-ketoglutaric acid can be used as carbon sources. Glycogen, acetic acid, formic acid, bromosuccinic acid, alaninamide, L-aspartic acid, inosine, thymidine, phenylethylamine, arbutin, and 2-deoxyadenosine are not used.

The mol% G + C of the DNA is: 51 (T_m).

Type strain: BEN 103, ACM 5097.

GenBank accession number (16S rRNA): U88044.

4. **Amaricoccus veronensis** Maszenan, Seviour, Patel, Rees and McDougall 1997, 733^VP

ve.ron.en'sis. M.L. adj. *veronensis* referring to Verona, Italy, the source of the type strain.

Cells are 1.8 μm in diameter. Adonitol, glycyl-L-glutamic acid, 2,3-butanediol, *N*-acetylmannosamine, and α-methyl-D-glucoside can be used as carbon sources. *N*-Acetyl-D-galactosamine, D-gluconic acid, γ-hydroxybutyric acid, and glycerol are not used.

The mol% G + C of the DNA is: 58 (T_m).

Type strain: Ben 102, ACM 5098.

GenBank accession number (16S rRNA): U88043.

Genus IV. **Antarctobacter** *Labrenz, Collins, Lawson, Tindall, Braker and Hirsch 1998, 1369^VP*

MATTHIAS LABRENZ AND PETER HIRSCH

Ant.arc'to.bac.ter. M.L. *Antarctica* name of the South Pole continent; derived from Gr. pref. *anti* against (on the other side); Gr. adj. *arcticos* northern; M.L. masc. n. *bacter* Gr. n. *baktron* a rod or staff; *Antarctobacter* a rod-shaped bacterium from Antarctica.

Rods, one or both cell poles narrower, sizes vary due to age and growth conditions: 0.8–1.2 × 2.0–33.6 μm. Rosettes are formed. Gram negative. **Daughter cells may be motile.** No resting stages are known. **Aerobic**, with a strictly respiratory type of metabolism. **Intracellular granules of poly-β-hydroxybutyrate are present.** Cells have an absolute requirement for Na^+. Temperature range <3–43.5°C, salinity range <1.0 to <10.0% NaCl and <10 to >150‰ of artificial seawater (ASW), pH range 5.3 to >9. **Oxidase and catalase positive.** Do not grow photoautotrophically with H_2/CO_2 (80:20) or photoorganotrophically with acetate or glutamate. Do not contain bacteriochlorophyll *a* (bchl *a*). Occur in marine habitats.

The mol% G + C of the DNA is: 62–63.

Type species: **Antarctobacter heliothermus** Labrenz, Collins, Lawson, Tindall, Braker and Hirsch 1998, 1371.

FURTHER DESCRIPTIVE INFORMATION

Visible aerobic growth of *A. heliothermus* appears after 3–5 d on medium PYGV (Staley, 1968) + 25‰ (or 40‰) artificial seawater (ASW; Lyman and Fleming, 1940) at 20°C. Colonies are circular, smooth, convex, 1–4 mm in diameter and brownish yellow. On R2A agar (Difco, Detroit, USA) + ASW the colonies are brownish red. Cell growth of *A. heliothermus* appears to be monopolar since one cell end is usually narrower and shorter, possibly indicating a budding process. In such cases, the "daughter cell" is often positioned at an angle to the "mother cell". The cell sizes of the strains EL-54, EL-165, EL-185, and EL-219^T are very similar; a peculiar characteristic of laboratory-cultured cells, as well as those from the source (Ekho Lake, Vestfold Hills, East Antarctica), is the frequent formation of elongated cells up to 33 μm in length. Motility is observed in some strains. Electron microscopy reveals 1–3 subpolar flagella in strains EL-54 and EL-185.

A. heliothermus has an absolute requirement for Na^+, but none for K^+, Mg^{2+}, Ca^{2+}, Cl^- or SO_4^{2-}. This species is susceptible to chloramphenicol, penicillin G, streptomycin, tetracycline, and polymyxin B. Nitrate is reduced to nitrite. Nitrite is not reduced aerobically, anaerobic reduction to N_2 is variable. Poly-β-hydroxybutyrate is formed intracellularly.

In the presence of available nitrogen, *A. heliothermus* uses succinate, butyrate, glutamate, acetate, pyruvate, malate, citrate, and α-D-glucose, but not methanol or methanesulfonic acid. In the absence of other N-sources, glutamate is utilized as a C- and N-source. Without any added nitrogen source, there occurs a slight growth with acetate, butyrate, pyruvate, malate, or succinate. Metabolism of carbon sources tested with the Biolog system was described by Labrenz et al. (1998).

Two strains of *A. heliothermus* (EL-54 and EL-165) grow microaerophilically, but they do not grow anaerobically in a photolithoautotrophic mode with H_2/CO_2 (80:20) in the gas phase or photoorganotrophically. Bacteriochlorophyll *a* is never found in cell suspensions nor in methanolic extracts. Absorption spectra of methanolic extracts are very similar to those of *Ruegeria algicola* (Lafay et al., 1995; Uchino et al., 1998) when grown on PYGV + 25‰ ASW.

The peptidoglycan of *A. heliothermus* contains *m*-diaminopimelic acid, and the peptidoglycan of strain EL-185 is of the directly cross-linked type A1γ (Schleifer and Kandler, 1972). Respiratory quinone is Q-10. Phosphatidylglycerol and phosphatidylcholine are present as well as unknown phospholipids and an aminolipid. The dominant fatty acid is $C_{18:1}$ (81.4–84.0%); other fatty acids are $C_{12:1\ 3OH}$ (3.0–3.6%), $C_{16:0}$ (0.6–1.1%), $C_{16:1}$ (2.3–2.7%), $C_{18:0}$ (0.7–1.4%), and $C_{19:0\ cyclo}$ (1.9–2.7%).

Comparative 16S rDNA sequence analysis shows that *A. heliothermus* is a member of the *Alphaproteobacteria*, specifically associated with the *Roseobacter* cluster of organisms, which includes *Sagittula*, *Octadecabacter*, *Silicibacter*, *Prionitis lanceolata* gall symbiont, *Roseobacter*, *Roseovarius*, *Ruegeria*, *Staleya*, and *Sulfitobacter*.

Enrichment and Isolation Procedures

For *A. heliothermus*, three enrichment procedures may be used: (1) 5 ml of the original water sample are inoculated into 10 ml of sterile medium "398" (Labrenz et al., 1998) and incubated for four weeks at 15°C under dim light (4.1 mmol photons $m^{-2} s^{-1}$). (2) Original water samples (50 ml) are amended with 1 ml of a filter-sterilized solution of 12.5 mg/ml Bacto Yeast Extract in original sample water and incubated at 15°C and at 4.1 mmol photons $m^{-2} s^{-1}$. (3) Original water samples (0.5 ml) are spread directly on agar plates of medium PYGV that have been prepared with original water of 10‰ salinity. Incubation at 15°C and in the dark yields the best results. Pure cultures are isolated by several dilution transfers on the corresponding agar media.

Maintenance Procedures

Strains of *A. heliothermus* are initially cultured on PYGV or R2A agar with 25 or 40‰ ASW. After incubation at 16–26°C to allow abundant growth, the cultures may be maintained in a refrigerator (4°C) for 6 months. They can be preserved indefinitely by lyophilization or in 15% glycerol (frozen at −72°C).

Procedures for Testing Special Characters

For the study of 16S rRNA gene fragments, PCR amplification as described by Hudson et al. (1993) and Labrenz et al. (1998) is recommended.

Differentiation of the genus *Antarctobacter* from other genera

Table BXII.α.51 indicates those characteristics of *Antarctobacter* that differentiate it from other morphologically, physiologically, or chemotaxonomically similar organisms. Fig. BXII.α.71 presents an unrooted tree showing phylogenetic relationships of *Antarctobacter heliothermus* and closely related *Alphaproteobacteria*.

Taxonomic Comments

The sum of respiratory lipoquinones, fatty acids, and polar lipid data indicates that *A. heliothermus* belongs to a group of organisms (at the genus or family rank) within the *Proteobacteria*.

Comparative 16S rDNA sequence analysis also shows that it is a member of the *Alphaproteobacteria* and specifically associated with the *Roseobacter* supercluster of organisms, which includes *Sagittula*, *Octadecabacter*, *Silicibacter*, *Prionitis lanceolata* gall symbiont, *Roseovarius*, *Ruegeria*, *Staleya*, and *Sulfitobacter*. Sequence divergence values of >5% show this genus is genetically distinct from all currently recognized members of the *Proteobacteria*. Furthermore, bootstrap resampling shows that *A. heliothermus* does not possess a particularly significant phylogenetic affinity with any individual species within the above-mentioned genera.

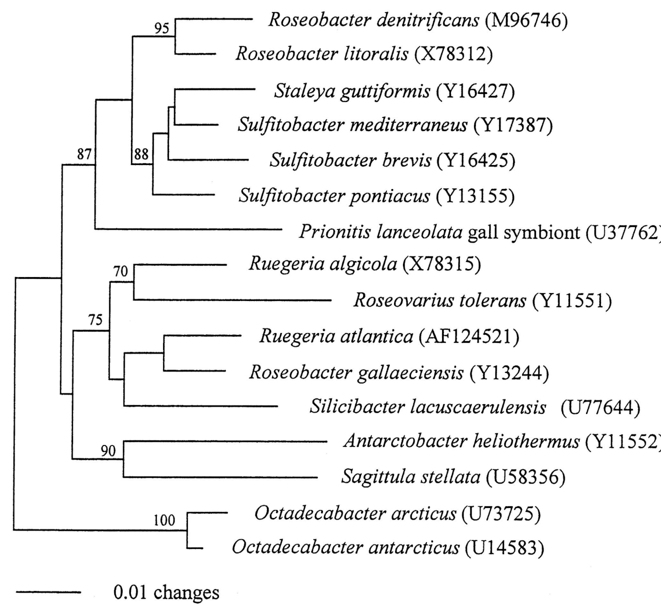

FIGURE BXII.α.71. Unrooted tree showing phylogenetic relationships of *Antarctobacter heliothermus* and closely related *Proteobacteria*. The tree was constructed using the neighbor-joining method; it was based on a comparison of approximately 1300 nucleotides. Bootstrap values, expressed as a percentage of 500 replications, are given at branching points; only those above 70% are shown.

List of species of the genus Antarctobacter

1. **Antarctobacter heliothermus** Labrenz, Collins, Lawson, Tindall, Braker and Hirsch 1998, 1371[VP]
he.li.o.ther'mus. Gr. n. *helios* sun; Gr. adj. *thermos* hot; M.L. masc. n. *heliothermus* heated by the sun, referring to the heliothermal water layers of Ekho Lake, the source.

Rods with an average length of 3.8–7.7 μm. Further morphological description as for the genus. Physiological and nutritional characteristics of the species are presented in Table BXII.α.52. Optimal growth occurs at 16–26°C with salt concentrations of 20–60‰ NaCl or 10–70‰ ASW. Optimal pH for growth is 6.9–7.8. Colonies on medium PYGV + 25‰ (or 40‰) ASW are circular, smooth, convex, 1–4 mm in diameter and brownish yellow. Isolated from hypersaline, meromictic, and heliothermal Ekho Lake, East Antarctica.

The mol% G + C of the DNA is: 62–63 (HPLC).

Type strain: EL-219, DSM 11445.

GenBank accession number (16S rRNA): Y11552.

Additional Remarks: Reference strain: EL-165, DSM 11440.

TABLE BXII.α.52. Other characteristics of *Antarctobacter heliothermus*

Characteristic	*A. heliothermus*
Oxidase and catalase activity	+
NO_3^- reduced to NO_2^-	+
NO_2^- reduced to N_2	v
Requirement of thiamine or nicotinic acid	+
Requirement of pantothenate or vitamin B_{12}	−

Susceptible to chloramphenicol, penicillin G, streptomycin, polymyxin B or tetracycline	+

Genus V. Gemmobacter *Rothe, Fischer, Hirsch, Sittig and Stackebrandt 1988, 328*[VP] *(Effective publication: Rothe, Fischer, Hirsch, Sittig and Stackebrandt 1987, 97)*

PETER HIRSCH AND HEINZ SCHLESNER

Gem.mo.bac'ter. L. n. *gemma* a bud; M.L. masc. n. *bacter* equivalent; Gr. neut. n. *bactrum* a rod; M.L. masc. n. *Gemmobacter* a budding rod.

Rod-shaped cells with rounded poles or ovoid, 1.0–1.2 × 1.25–2.7 μm. New cell formation by budding from one cell pole or laterally (Fig. BXII.α.72). Daughter cells may stay connected with the mother cell resulting in formation of short chains. Not acid-fast, do not form spores or cysts; without prosthecae or other appendages. Nonmotile. **Gram negative.** Colonies colorless, round with entire margins. Temperature range 17–39°C, optimal temperature for growth 31°C.

Aerobic or facultatively anaerobic, chemoorganotrophic. **Sugars and ethanol are fermented.** Do not produce gas, D- or L-lactate, acetate or ethanol. **Dissimilatory nitrate reduction positive.** The respiratory ubiquinone is **Q-10**.

The mol% G + C of the DNA is: 63.4.

Type species: **Gemmobacter aquatilis** Rothe, Fischer, Hirsch, Sittig and Stackebrandt 1988, 328 (Effective publication: Rothe, Fischer, Hirsch, Sittig and Stackebrandt 1987, 98.)

FURTHER DESCRIPTIVE INFORMATION

Cells of *Gemmobacter* are morphologically and physiologically similar to those of members of the *Blastobacter* genus and *Sphingomonas natatoria* (Table BXII.α.53). Analysis by the 16S rRNA cataloging approach indicated that *Gemmobacter* is a member of the *Alphaproteobacteria* (Rothe et al., 1987).

ENRICHMENT AND ISOLATION PROCEDURES

The strain was isolated from water of a forest pond near Augusta (Michigan, USA). A 100-ml water sample was placed in a 250-ml Erlenmeyer flask and Bacto-peptone (Difco) was added to a final concentration of 0.005%. After plugging the flask with cotton,

[b]Data from Sittig and Hirsch (1992).

the enrichment was incubated for 12 d in the dark at 20–25°C. Subsamples were then streaked onto medium PYGV[1] (Staley, 1968). Single colonies were further purified on the same medium.

Maintenance Procedures

The strain can be kept on slants at 4–5°C; it should be subcultured every three months. The strain is easily revived from lyophilized cultures.

Procedures for Testing Special Characters

Light microscopy with phase contrast and agar-coated glass slides (Pfennig and Wagener, 1986).

Differentiation of the genus *Gemmobacter* from other genera

Table BXII.α.53 lists the major features that differentiate *Gemmobacter aquatilis* from closely related taxa.

List of species of the genus Gemmobacter

1. **Gemmobacter aquatilis** Rothe, Fischer, Hirsch, Sittig and Stackebrandt 1988, 328[VP] (Effective publication: Rothe, Fischer, Hirsch, Sittig and Stackebrandt 1987, 98.)
a.qua'ti.lis. L. neut. adj. *aquatilis* belonging to the water, describing its biotope.

Genus VI. **Hirschia** Schlesner, Bartels, Sittig, Dorsch and Stackebrandt 1990, 449[VP]

HEINZ SCHLESNER

Hirsch′i.a. M.L. fem. n. *Hirschia* honoring Peter Hirsch, a German microbiologist, who is an expert on budding and hyphal bacteria.

Rod-shaped or oval cells, 0.5–1.0 × 0.5–6.0 µm with one or two polar hyphae (prosthecae) with a diameter of 0.2 µm. Buds are formed at the tips of the hyphae. Daughter cells are motile by a single polar flagellum. **Gram negative. Aerobic** and **chemoorganotrophic**. **PHB is not stored.** Utilize various sugars and organic acids. **C_1-compounds are not used as a carbon source.** Ammonia and amino acids are nitrogen sources for growth. The ubiquinone system is a **Q-10** system. Hydroxy fatty acids are of the **3-OH** type.

The mol% G + C of the DNA is: 45–47 (T_m).

Type species: **Hirschia baltica** Schlesner, Bartels, Sittig, Dorsch and Stackebrandt 1990, 449.

FURTHER DESCRIPTIVE INFORMATION

Cells of *Hirschia* spp. are morphologically very similar to members of the genera *Hyphomicrobium* and *Hyphomonas* (Fig. BXII.α.73). Even the life cycle resembles that of the above genera, i.e., a motile swarmer cell loses the flagellum, the cell produces a hypha at one pole and a bud is formed at the tip of the hypha. A flagellum is produced at the distal pole of the bud. The mature bud separates from the mother cell by fission of the hyphal tip. Additional daughter cells may be produced by the mother cell.

Analysis of the 16S rRNA gene sequence of the type strain indicated that the genus *Hirschia* is a member of the *Alphaproteobacteria* and is distinctly but remotely related to members of the genera *Hyphomicrobium*, *Filomicrobium*, *Pedomicrobium*, and *Dichotomicrobium*. The 23S rRNA is not nicked (Schlesner et al., 1990).

ENRICHMENT AND ISOLATION PROCEDURES

The strains were obtained from brackish surface water (Kiel Fjord) after either enrichment or direct plating of sample on medium 13 (M13): peptone, 0.25 g/l; yeast extract, 0.25 g/l; glucose, 0.25 g/l; artificial seawater, 250 ml/l; vitamin solution, 10 ml/l; Hutners basal salts medium, 20 ml/l; 100 mM Tris/HCl (pH 7.5), 50 ml/l; agar, 18 g/l (Schlesner, 1986).

Three enrichment procedures are described by Schlesner et al., 1990:

1. Add glucose (0.05% final concentration) to the sample and incubate in a cotton stoppered Erlenmeyer flask at room temperature.
2. Add *N*-acetylglucosamine (0.1% final concentration) to the sample and incubate in a cotton-stoppered Erlenmeyer flask at room temperature.
3. The Petri dish procedure: A layer (about 1 cm) of water agar (1.8% agar in distilled water) on the bottom of a Petri dish (diameter, 25 cm) is covered with the sample to a depth of about 2 cm. The Petri dish is incubated at room temperature.

The cultures are examined by phase-contrast microscopy for the presence of hyphal bacteria. Samples are then streaked on M13 agar. After three weeks of incubation at 25°C, colonies are screened by phase-contrast microscopy. Pure cultures are obtained by repeatedly streaking on M13 agar.

MAINTENANCE PROCEDURES

Hirschia strains grown on slants can be kept at 4–5°C. They should be subcultured every three months. They are easily revived from lyophilized cultures and can be stored at −70°C in a solution of 50% glycerol in M13.

PROCEDURES FOR TESTING SPECIAL CHARACTERS

This genus is easily distinguished from other hyphal bacteria by the yellow colonies formed on M13 agar.

DIFFERENTIATION OF THE GENUS *HIRSCHIA* FROM OTHER GENERA

Table BXII.α.55 lists the major features that differentiate *Hirschia* from other genera of budding prosthecate bacteria.

List of species of the genus Hirschia

1. **Hirschia baltica** Schlesner, Bartels, Sittig, Dorsch and Stackebrandt 1990, 449

bal′ ti.ca. M.L. fem. adj. *baltica* pertaining to the Baltic Sea.

Cells are rods, 0.5–1.0 × 0.5–6.0 μm, elliptical or ovoid. Colonies are mucoid or dry and yellow. Optimal growth occurs between 22 and 28°C. Seawater is required for growth. Further characteristics are listed in Table BXII.α.56.

The habitat is brackish water. The isolates were obtained from the Baltic Sea (Kiel Fjord).

The mol% G + C of the DNA is: 45–47 (T_m); type strain 46 (T_m).

Type strain: SH 149, ATCC 49814, DSM 5838, IFAM 1418.

GenBank accession number (16S rRNA): X52909.

Additional Remarks: The 16S rRNA gene sequence of *Hirschia baltica* IFAM 1418 has been deposited at the European Molecular Biology Laboratory (EMBL), Heidelberg, Germany.

Other Organisms

Besides the three strains of *H. baltica* (IFAM 1408, 1415, and 1418[T]), a fourth strain (IFAM 1538) was isolated and investigated. Morphological characteristics are similar to *H. baltica*, the base composition of the DNA is 47 mol% G + C (T_m). Differences are found in the utilization of carbon sources, i.e., the ability to utilize lactose and glycerol and the inability to utilize acetate, propionate, pyruvate, lactate, or alanine. Furthermore, with the LRA ZYM Osidase System (API bioMérieux, Montalieu, France) the enzymes α-D-galactosidase, β-D-galactosidase, phospho-β-D-galactosidase, β-D-fucosidase, and β-D-lactosidase were found in IFAM 1538, but not in the strains of *H. baltica*, while only the strains of *H. baltica* tested positive for α-D-arabinosidase.

Genus VII. **Hyphomonas** *(ex Pongratz 1957) Moore, Weiner and Gebers 1984, 71^{VP} emend. Weiner, Melick, O'Neill and Quintero 2000, 466*

RONALD M. WEINER

Hy.pho.mo′ nas. Gr. n. *hyphos* filament; Gr. n. *monas* a unit, monad; M.L. fem. n. *Hyphomonas* hypha-bearing unit.

Rod-shaped to oval mature cells measure 0.5–1.0 × 1.0–3.0 μm and may become larger and rounder just prior to bud formation. Unicellular. Cell division occurs by budding. **Buds are produced at tips of single polar prosthecae**, which are 0.2–0.3 μm in diameter and 1–5 times the length of the cell body. Prosthecae are nonseptate and rarely branch under normal growth conditions. Pleomorphic. *Hyphomonas* spp. have a **biphasic life cycle** and normally generate only a single polar prostheca (hypha). Young daughter cells (i.e., newly formed buds) are oval to pear shaped, lack prosthecae, and are smaller than the mother cell. Motile by means of a **single polar to lateral flagellum located on developing buds** or young daughter cells. **Gram negative**. Not acid-fast. Aerobic. Nonsporeforming. Chemooganotrophic. *Hyphomonas* spp. **catabolize amino acids or tricarboxylic acid cycle intermediates** for energy and growth. All strains investigated thus far are catalase positive, oxidase positive, nonproteolytic, nonsaccharolytic, and nonpathogenic. Gelatin and starch not hydrolyzed; no indole from tryptophan; no DNase, ornithine decarboxylase, lysine decarboxylase, or coagulase activity. With one exception, all species denitrify. Amino acids are required for heterotrophic growth. Optimal temperature for growth ranges from 22 to 37°C at one atmosphere of pressure. Prefer slightly alkaline conditions for growth. **All strains were isolated from marine sources**.

The mol% G + C of the DNA is: 57–64.

Type species: **Hyphomonas polymorpha** (ex Pongratz 1957) Moore, Weiner and Gebers 1984, 71.

FURTHER DESCRIPTIVE INFORMATION

Normal-appearing cells of the type strain of *Hyphomonas polymorpha* (ATCC 33881, IFAM PS 728) are shown in Fig. BXII.α.74. All species include strains that have capsules and/or holdfasts (Langille and Weiner, 1998; Quintero, et al., 1998). Old cultures or poor growth conditions produce a large number of aberrant cell forms. These include giant cells, spindle-shaped or triangular cells, cells with unusually long or branched prosthecae, cells with intercalary buds and cells with hyphae originating from locations other than the poles. Daughter cells may be half their normal dimensions. Polyphosphate and poly-β-hydroxybutyrate granules, which are normally present (Weiner et al., 1985), may become especially pronounced under poor growth conditions. A number of traits set *Hyphomonas* spp. apart from other bacteria that bud through a prostheca (Table BXII.α.57).

The appearance of the cell wall in thin sections is typical of other Gram-negative bacteria. The cytoplasmic membrane is continuous with the cell wall, and no organized membrane structures are observed. The composition of the cell wall of *Hyphomonas*

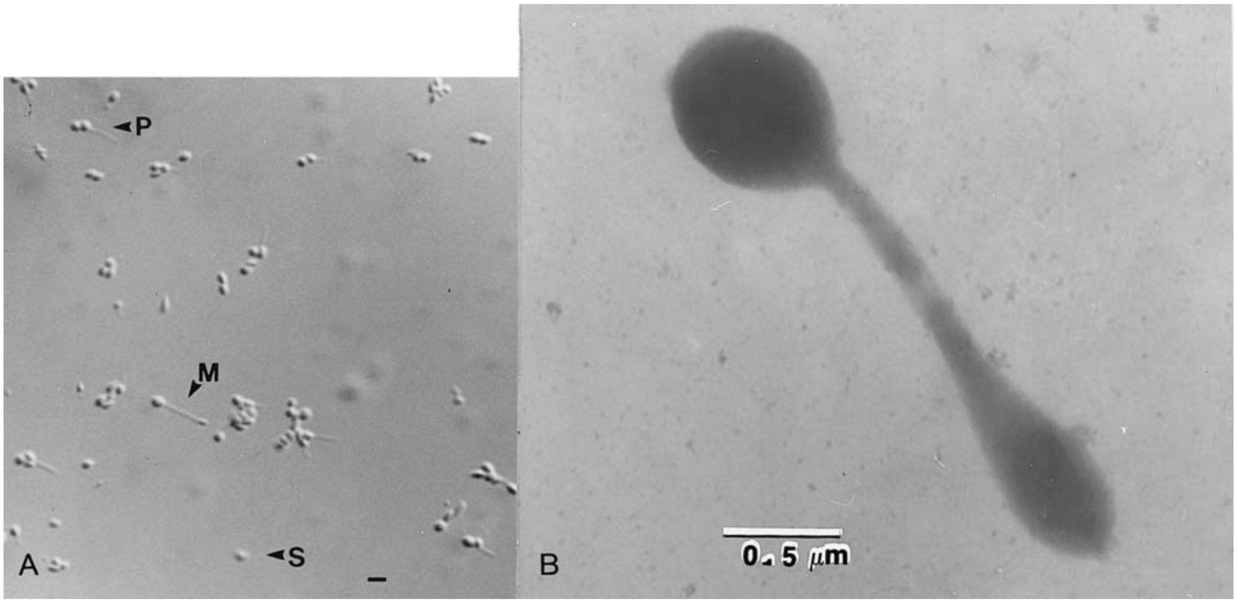

FIGURE BXII.α.74. *H. polymorpha*, type species. *A*, type strain S (ATCC 33881; IFAM PS 728). [a]Symbols: +, 90% or more of strains are positive; −, 90% or more of strains are negative; D, differs, depending on species of genus; G, gray; b, brown; B, dark brown; R, red; Y, yellow (Moore et al., 1984).

[b]Schlesner et al., 1990.

[c]Occasionally two hyphae are present.

neptunium was found to be much more similar to that of *Escherichia coli* than to a strain of *Hyphomicrobium* (Jones and Hirsch, 1968). The cells are sensitive to detergents (see Table BXII.α.58) and are readily lysed in a solution of ethylenediaminetetraacetate with 1% sodium lauryl sulfate. Cells stain well with aniline dyes. The use of Lugol's iodine as a mordant facilitates the staining of the narrow hyphae. Best results are obtained with silver impregnation.

The life cycle of these organisms is generally similar to those of other prosthecate, budding bacteria (Hirsch, 1974a) and has been investigated in some detail (Wali et al., 1980; Moore, 1981a; Quintero, et al., 1998; Weiner, 1998). At 36°C, *Hyphomonas neptunium* requires about 265 min to complete a full cycle. During the first 85 min, the cell exists as a motile swarmer cell. The flagellum becomes detached, and the cell produces a prostheca at one, usually the narrower, of the cell poles. Some species produce polar fimbriae at the other pole (Quintero et al., 1998). The major outer membrane protein profile undergoes a marked change (Shen et al., 1989). This prosthecal growth stage requires approximately 95 min of the total cycle. At the end of this stage, the size of the main cell body may increase by up to 2–4 times. The bud development stage occupies the remaining 85 min of the life cycle. The bud is produced at the very tip of the prostheca and synthesizes a single flagellum (Quintero et al., 1998). The

[e]Sensitivities were assessed on 50% concentrations of marine broth (Zobell, 1941). Sensitivity on other medium may be different (Hirsch, 1974a).

mother cell is pushed through the medium by the motile bud, in contrast to *Hyphomicrobium* species, which are pulled by the motile bud (Moore, 1981a). Whether this constitutes a serious diagnostic feature, however, is uncertain. The mature bud eventually separates from the mother cell by fission of the prosthecal tip. After a short period of prosthecal growth, further daughter cells may be produced by the mother cell. Altering the temperature of growth not only influences the time course of the life cycle but also results in a shift in the relative proportion of the various cell types present in a given culture. DNA synthesis is discontinuous and occurs just prior to bud formation. Membrane structures are involved in DNA segregation (Zerfas et al., 1997).

Good growth occurs on Casamino acids, blood agar, and other rich media. The addition of sea salts is required by nearly all strains and is stimulatory to the others (Havenner et al., 1979; Weiner et al., 2000). Growth in a defined medium supplemented with a mixture of glutamic acid, aspartic acid, methionine, and serine as substrates has been reported for *Hyphomonas neptunium* (Havenner et al., 1979). *H. hirschiana* and *H. polymorpha* have the same requirements as *H. neptunium*; *H. jannaschiana* requires biotin but not methionine; *H. oceanitis* requires the four amino acids plus biotin, folic acid, pyridoxine, riboflavin, and *p*-aminobenzoic acid. *H. johnsonii* differs from the other species of *Hyphomonas*, being able to utilize glucose as a carbon source in the presence of amino acids. *H. adhaerens* does not have auxotrophic requirements for amino acids but requires them (or peptone or protein) for carbon and energy.

CO_2 is the primary end product of metabolism, and the medium becomes alkaline, probably due to the evolution of ammonia (Leifson, 1964; Havenner et al., 1979). Deamination and tricarboxylic acid cycle oxidation of amino acids is the major catabolic pathway (Havenner et al., 1979).

No growth on mineral salts media with $CaCO_3$, acetate, propionate, lactate, ethanol, glycerol, glycine, or C_1 compounds as the sole source of carbon. Growth is not influenced by light.

Under certain conditions, some strains may produce a dark brown, acid-insoluble, base-soluble pigment (see Table BXII.α.58), identified as a pyomelanin, the product of *p*-hydroxyphenylpyruvate hydroxylase via homogentisic acid (Kotob et al., 1995).

H. neptunium, *H. polymorpha*, *H. oceanitis*, and *H. hirschiana* have a Q-11 ubiquinone type along with a significant amount of Q-10 (approximately 10% of total ubiquinones) and minor amounts of Q-9 and Q-12. *H. jannaschiana* has Q-10 as its major quinone with trace amounts of Q-9 and Q-11 (Urakami and Komagata, 1987b).

Hyphomonas spp. synthesize high percentages of octadecenoic acid, ($C_{18:1}$; Table BXII.α.59), albeit in varying amounts. These range from 11% in *H. jannaschiana* to 80% in MHS-3, a value exceeding that found in all extant *Hyphomonas* spp. but correlating well with most other budding/prosthecate bacteria (i.e., *Rhodomicrobium*, *Pedomicrobium*, and *Hyphomicrobium*) (Urakami and Komagata, 1987b; Sittig and Hirsch, 1992). *Hyphomonas* also contains novel lipids (Batrakov et al., 1996).

The membrane protein profile similarities of the eight species range from 30 to 80% (Dagasan and Weiner, 1986; Weiner et al., 2000), and all but one species, *H. johnsonii*, synthesize large amounts of a 47 kDa protein. All species are serologically related, based upon exposed determinants (Weiner et al., 2000).

Proteases (Shi et al., 1997) and S-layer proteins (Shen and Weiner, 1998) have been identified and characterized.

Table BXII.α.60 shows the % overall DNA–DNA homologies among the eight extant *Hyphomonas* species.

Enrichment and Isolation Procedures

Most of the currently available isolates have been obtained by direct plating of samples onto commonly used media such as blood agar, medium 383 (casitone, 2 g/l; yeast extract, 1 g/l; $MgCl_2$, 1 g/l; [Leifson, 1964]) and marine agar (Difco 2216; [Zobell, 1941]). However, a simple procedure has been reported for their isolation from water samples (Moore, 1981b). The sample is brought to 0.005% (w/v) peptone and 0.005% (w/v) yeast extract. The cultures are incubated aerobically, and after times ranging from about one day to a week or more, are plated onto solid medium. The colonies, which arise relatively slowly, are screened microscopically for cells with the typical morphology of *Hyphomonas* species and are replated for purification and identification. Three of the eight species have been isolated from warm water hydrothermal vents, either from shellfish beds near the Galapagos Islands, at a depth of 2600 m (Jannasch and Wir-

sen, 1981), or from the Guyamas Basin at a depth of 2000 m. Members of the genus have been identified as primary colonizers of submerged surfaces in marine waters (Baier et al.,1983; Frolund et al., 1996). Due to their relatively slow growth, they are not readily isolated, though they can be well represented on submerged surfaces in marine waters (Weidner et al., 1996).

Maintenance Procedures

The members of this genus are generally quite hardy and will survive up to several months in liquid or solid growth medium at 4°C. They are easily revived from lyophilized cultures and can be stored at −20°C over a period of several years, or for a longer period of time at −70°C, in a solution of 60% glycerol in 0.05 M KH_2PO_4 at pH 7.

Differentiation of the genus *Hyphomonas* from other genera

The eight species have signature 16S rDNA sequences (Weiner et al., 2000) that place them in the *Alphaproteobacteria* (Stackebrandt et al., 1988a). Each is related to the other above the 96% similarity level. A member of the most closely related genus, *Hirschia*, (Schlesner et al., 1990), is related to each of the strains of *Hyphomonas* at the 90 ± 1% level. 16S rDNA sequence analyses support the notion that *Hyphomonas*, a genus of marine bacteria, is more closely related to the marine line of *Caulobacter* (Stahl et al., 1992) than to terrestrial, budding, prosthecate genera (e.g., *Hyphomicrobium*; Fig. BXII.α.75).

Table BXII.α.57 lists other major features which differentiate *Hyphomonas* from other genera of prosthecate, budding bacteria. Support for the separation of this genus is also indicated by the low level of intergeneric cross-reactions seen in serological studies (Powell et al., 1980; Weiner et al., 2000), DNA–DNA homology studies (Moore and Hirsch, 1972; Moore and Staley, 1976; Gebers et al., 1984, Weiner et al., 2000), rRNA–DNA studies (Moore, 1977), fatty acid analyses (Urakami and Komagata, 1987b; Sittig and Hirsch, 1992; Weiner, et al., 2000), rRNA cistron similarities (Roggentin and Hirsch, 1989), comparisons of membrane protein profiles (Dagasan and Weiner, 1986; Weiner et al., 2000), and other criteria (Gebers et al., 1985; Köbel-Boelke et al., 1985; Nikitin et al., 1990).

Differentiation of the species of the genus *Hyphomonas*

Most criteria, other than 16S rDNA sequence analysis, support the placement of *Hyphomonas* as a discrete genus but do not clearly establish relationships between all species. These criteria include serological identity based upon surface antigen (Powell

et al., 1980; Weiner et al., 2000), some DNA–DNA homology results (Moore and Hirsch, 1972; Moore and Staley, 1976; Gebers et al., 1986, Weiner et al., 2000), rRNA–DNA studies (Moore, 1977), fatty acid analyses (Weiner et al., 2000), and comparisons of membrane protein profiles (Dagasan and Weiner, 1986; Weiner et al., 2000).

The best criterion to ascertain the interrelationship of *Hyphomonas* species is genetic similarity. The phylogenetic tree (Fig. BXII.α.75) shows the relatedness of each of the species of *Hyphomonas* according to 16S rDNA sequence analysis. *H. rosenbergii* (nov.), *H. hirschiana*, *H. polymorpha*, and *H. neptunium* cluster at the 99.4% similarity level. *H. adhaerens* (nov.) and *H. jannaschiana* share sequence similarities of 99.3% and, as expected, each of the strains of *H. jannaschiana* is related at a high level (99.3%) as well. *H. johnsonii* (nov.) is most closely related to *H. oceanitis* at the 98.7% level, and neither of these species is closely related to other species of *Hyphomonas*.

Thus, 16S rDNA sequence analyses divide the eight species of *Hyphomonas* into: 1) a tight group of four species, *H. rosenbergii*, *H. hirschiana*, *H. polymorpha*, and *H. neptunium*; 2) a group with two species, *H. adhaerens* and *H. jannaschiana*; and 3) a less tight group of two species, *H. johnsonii* and *H. oceanitis*. Likewise, the DNA–DNA hybridization data (Table BXII.α.60) show *H. neptunium* to be closely related to *H. hirschiana* and supports both of the two species groupings, i.e., *H. adhaerens* and *H. jannaschiana* plus *H. johnsonii* and *H. oceanitis*. (DNA–DNA hybridization data also suggest that *H. neptunium* forms a tighter relationship with *H. adhaerens* based upon DNA–DNA reassociation values (Table BXII.α.60) than by 16S rDNA sequence comparisons. However, DNA–DNA reassociation values can be inflated by shared plasmids and other horizontal genetic exchange).

Phenotypic characteristics tend to support these placements, as can be ascertained from an examination of Table BXII.α.58. Rosette formation is a result of holdfast (polar adhesive capsule) production. *H. rosenbergii* synthesizes both a capsule that surrounds the entire cell, including main body, prostheca and bud, and a holdfast (Langille and Weiner, 1998). *H. adhaerens* produces a capsule that surrounds only the main body of the mother cell, mediating side/side adhesion as well as pole/pole adhesion (Quintero and Weiner, 1995; Quintero et al., 1998). The holdfast of *H. rosenbergii* and capsule of *H. adhaerens* are chemically different, while sharing certain properties such as an abundance of amino sugars (Quintero and Weiner, 1995). The LPS of *H. adhaerens* is antigenically unique from that of any other surface antigen of any other *Hyphomonas* species (Weiner et al., 2000).

H. johnsonii is clearly the outlier species of *Hyphomonas* based on almost all criteria. So far, it is the only species shown to be able to utilize sugars for carbon and energy. Additionally, it has little DNA–DNA hybridization similarity with other *Hyphomonas* species (Table BXII.α.60) and lacks some genus-specific phenotypic characteristics (Jones and Krieg, 1984), including outer membrane proteins (Weiner et al., 2000), Furthermore, it has the lowest serological identity with any of the other *Hyphomonas* species (Weiner et al., 2000).

The site of isolation (e.g., hydrothermal vent, benthos, coastal) does not appear to have a bearing on the relationships between *Hyphomonas* species.

List of species of the genus Hyphomonas

1. **Hyphomonas polymorpha** (ex Pongratz 1957) Moore, Weiner and Gebers 1984, 71[VP]

po.ly.mor′pha. Gr. adj. *poly* many; Gr. n. *morphe* shape, body; M.L. adj. *polymorpha* many shapes.

Pongratz (1957) reported that upon isolation on solid media, colonies appear as smooth or rough types. The smooth colonies are round, convex, watery, and translucent and can be emulsified easily. A capsule covers the main body of the reproductive cell (not prostheca). Rough colonies are rare. They are smaller and dry and form a central crater after several days. The colonies are not readily emulsified, and suspensions remain granular. They lack capsules.

No growth on inulin, dextrin, glycogen, esculin, glycerol, erythritol, mannitol, sorbitol, or urea. Reduces neutral red, methylene blue and Janus green. Produces H_2S. Other characteristics are given in Table BXII.α.58.

Contrary to the original description (Pongratz, 1957), NO_3^- and NO_2^- are not reduced, indole is not formed from tryptophan, and the rough strain, PR 727, is motile. It is not known whether these differences are due to the continuous subculturing of these strains.

Not virulent for mice (5 ml), rats (1 ml), guinea pigs (1 ml), or rabbits (1 ml) if a suspension which contains 5×10^9 cells/ml is injected subcutaneously or intraperitoneally. The organisms cannot be recovered from treated animals. The major fatty acids are $C_{17:0}$, $C_{17:1}$, and octadecanoate ($C_{18:1}$) at 24, 19, and 14%, respectively, of the total fatty acids (Table BXII.α.59). Isolated only once from a patient (deep sea diver) with infectious sinusitis. The overall DNA–DNA similarities with other *Hyphomonas* species are reported in Table BXII.α.60.

The mol% G + C of the DNA is: 60 (Bd) (Mandel et al., 1972); rough strain (IFAM PR 727, ATCC 33880), 61 (Bd).

Type strain: PS728, ATCC 33881; IFAM PS728.

GenBank accession number (16S rRNA): AJ227813.

2. **Hyphomonas adhaerens** Weiner, Melick, O' Neill and Quintero 2000,467[VP]

ad.hae′rens. L. part. adj. *adhaerens* hanging on, sticking to.

Main body of the mother cell is prolate spheroid, ~1–2 μm in diameter, and has one prostheca, 0.2 × 1–5 μm. Buds are motile by a single flagellum. The main body of the reproductive cell, but not the prostheca, is surrounded by capsular polysaccharide. Gram negative. Not acid fast. No endospores. Aerobic. Additional phenotypic characteristics are reported in Table BXII.α.58.

Colonies are round, undulate, about 1.5 mm in diameter after 3 days at 30°C on marine agar. In liquid media, there is granular turbidity due to adhering cell masses, and thick biofilm forms on the surface of the growth vessel. Does not form rosettes. The optimal temperature range for growth is 25–37°C. The ocean salts growth range is 1.5–12%. The optimal pH growth range is 5.7–8.7. Nitrate is reduced. Sheep erythrocytes are not hemolyzed. Susceptible to novobiocin, streptomycin, tellurite, crystal violet, brilliant green, and methylene blue, and resistant to 1.0% Tween 80, penicillin, and ampicillin.

The major fatty acid is octadecanoate ($C_{18:1}$) at 80% of the total fatty acids (Table BXII.α.59). Isolated in 1982 by J. Smit from an inshore slough in Puget Sound, Pacific Ocean. The overall DNA–DNA similarities with other *Hyphomonas* species are reported in Table BXII.α.60.

The mol% G + C of the DNA is: 60 (Bd).
Type strain: MHS-3, ATCC 43965.
GenBank accession number (16S rRNA): AF082790.

3. **Hyphomonas hirschiana** Weiner, Devine, Powell, Dagasan and Moore 1985, 242[VP]
hir' schi.an.a. L. fem. adj. *hirschiana* pertaining to Hirsch; named for P. Hirsch for his contributions to the study of prosthecate, budding bacteria.

Cellular morphology is like that of *H. polymorpha*. Colonies are small (1.0 mm in diameter after 48 h), dull gray, dry, and circular to irregular, with dimpled elevations and lobate margins. Growth in broth produces a pellicle at the surface and a light film of growth on the sides and bottom of the culture vessel.

A mixture of L-glutamic acid, L-aspartic acid, L-serine, and L-methionine is required for growth. The temperature range for optimal growth is 25–31°C. The NaCl concentration for growth is 2.0–15.0%. Optimal pH for growth: 7.6.

Nitrate is reduced. Sheep erythrocytes are not hemolyzed. Susceptible to 0.01% NP-40, novobiocin, and ampicillin. Resistant to 1.0% Tween 80. Intermediate susceptibility to penicillin and streptomycin. Treatment for 9 min or more with a Brownwill Biosonik IV sonicator (low probe at full power) is required to produce 99% lysis of cells.

A major fatty acid is octadecanoate ($C_{18:1}$) at up to 67% of the total fatty acids (Table BXII.α.59). The type strain was isolated in 1979 from shellfish beds near hydrothermal vents on the floor of the mid-Pacific Ocean by H. Jannasch. The overall DNA–DNA similarities with other *Hyphomonas* species are reported in Table BXII.α.60.

The mol% G + C of the DNA is: 57 (Bd).
Type strain: VP5, ATCC 33886.
GenBank accession number (16S rRNA): AF082794.

4. **Hyphomonas jannaschiana** Weiner, Devine, Powell, Dagasan and Moore 1985, 240[VP]
jan' nasch.i.an.a. L. fem. adj. *jannaschiana* pertaining to Jannasch; named for H. Jannasch for his contributions to marine microbiology.

Mature mother cells are 0.5–0.8 × 1.0–3.0 μm, and the main body of the cell tends to be elongated and bullet- or spindle-shaped. Young swarmer cells are motile and pear-shaped and resemble those of other members of the genus. On Zobell marine agar supplemented with 5% sheep blood, colonies are small, dull gray, dry, and circular to irregular with dimpled elevations and lobate margins (strains VP1 and VP3) or gray, circular, convex, entire, glistening, and mucoid (strains VP2^T and VP4), resembling *H. neptunium* colonies, which have similar shape and are off-white. In broth, growth appears granular, and a film of tan cells covers the sides and bottom of the culture vessel (strains VP1 and VP3), or growth may appear ropy and produce only a slight film (strains VP2^T and VP4). Strains VP1 and VP3 tend to form rosette-like cell aggregates.

A brown pigment, identified as a pyomelanin, is produced in type 2216 marine broth at 31–37°C. A mixture containing glutamic acid, aspartic acid, and serine as substrates and the cofactor biotin is required for chemoorganotrophic growth. The temperature for optimal growth is 37°C. The NaCl concentration for optimal growth is 3.5–7.5%. Optimal pH for growth: 7.6.

Nitrate is reduced. Produces α-hemolysis on Zobell marine medium supplemented with 5% sheep blood. Susceptible to NP-40 (0.01%), novobiocin, penicillin, ampicillin, and streptomycin. Resistant to Tween 80 (1.0%). Very resistant to breakage by sonication.

A major fatty acid is octadecanoate ($C_{18:1}$) at up to 65% of the total fatty acids (Table BXII.α.59). Four strains, ATCC 33882 (VP1), ATCC 33883^T (VP2^T), ATCC 33884 (VP3), and ATCC 33885 (VP4), of *H. jannaschiana* were isolated in 1979 from shellfish beds near hydrothermal vents on the floor of the mid-Pacific Ocean. The appearance is typical of Gram-negative bacteria. The only notable fine-structural difference among the strains is the consistent presence of large dark granules in strains VP1 and VP3. The occurrence of these granules is independent of the medium used for culturing. Strains cannot be differentiated on the basis of morphological, serological, nutritional or biochemical tests. The overall DNA–DNA similarities with other *Hyphomonas* species are reported in Table BXII.α.60.

The mol% G + C of the DNA is: 60 (Bd).
Type strain: VP2, ATCC 33883.
GenBank accession number (16S rRNA): AF082789.

5. **Hyphomonas johnsonii** Weiner, Melick, O'Neill and Quintero 2000, 467[VP]
john.so' ni.i. M.L. gen. n. *johnsonii* of Johnson, named after the (American) molecular taxonomist John Johnson.

Main body of the mother cell is prolate spheroid, ~1 μm in diameter and has one prostheca, 0.2 × 1 μm. Buds are motile by a single flagellum. Gram negative. Not acid fast. No endospores. Aerobic. Additional phenotypic characteristics are reported in Table BXII.α.58.

Colonies are round, convex, about 1.5 mm in diameter after 3 days at 30°C on marine agar. In liquid medium, growth is granular and/or ropy. May form thin film on growth vessel. Can utilize sugars, in the presence of amino acids, for carbon and energy. The optimal temperature range for growth is 25–37°C. The ocean salts growth range is 1.5–6.0. The pH growth range is 5.7–8.0. Nitrate is reduced. α-Hemolysis in the presence of sheep erythrocytes. Susceptible to novobiocin, penicillin, ampicillin, streptomycin, tellurite, crystal violet, brilliant green; resistant to 1.0% Tween 80, methylene blue, and neutral red.

The major fatty acid is octadecanoate ($C_{18:1}$) at 64% total fatty acids (Table BXII.α.59). The outer membrane protein profiles, DNA homology, and serology have low but significant similarity to other strains of *Hyphomonas*. Isolated in 1982 by J. Smit from an inshore slough in Puget Sound, Pacific Ocean. The overall DNA–DNA similarities with other *Hyphomonas* species are reported in Table BXII.α.60.

The mol% G + C of the DNA is: 64 (Bd).
Type strain: MHS-2, ATCC 43964.
GenBank accession number (16S rRNA): AF082791.

6. **Hyphomonas neptunium** (Leifson 1964) Moore, Weiner and Gebers 1984, 71[VP] (*Hyphomicrobium neptunium* Leifson 1964, 249.)
nep.tu' ni.um. L. n. *neptunus* god of the sea, probably should be L. gen. n. *neptuni.*

See Table BXII.α.58 for characteristics. A major fatty acid is octadecanoate ($C_{18:1}$) at up to 37% of the total fatty acids (Table BXII.α.59). Isolated from a sample of stored seawater or obtained from the harbor at Barcelona, Spain. The

overall DNA–DNA similarities with other *Hyphomonas* species are reported in Table BXII.α.60.

The mol% G + C of the DNA is: 61.7 (Bd).

Type strain: LE 670, IFAM LE 670, ATCC 15444.

GenBank accession number (16S rRNA): AF082798.

7. **Hyphomonas oceanitis** Weiner, Devine, Powell, Dagasan and Moore 1985, 240^{VP}

o.cean.i'tis. N.L. fem. n. *oceanitis* daughter of the ocean.

Cells are round to oval and ~0.9 μm in diameter and usually have one hypha, which is up to 3 times the length of the mother cell. Under favorable growth conditions, a small proportion of cells produce two hyphae, one at each of the poles. Both hyphae are capable of producing buds concurrently. Buds (daughter cells) are pear-shaped and become larger and rounder when they are mature (mother cells) and producing buds. Intercalary buds (i.e., two or more daughter cells remaining attached to the distal pole(s) of the stalk(s) of the mother cell) are common. Buds are motile until hyphae form. Gram negative. Not acid-fast. No endospores. Aerobic or microaerophilic.

On agar, the colonies are colorless, raised, semitranslucent or opaque and, after 3 days, up to 1.5 mm in diameter. In liquid media, growth produces uniform turbidity without a pellicle or sediment. The best growth occurs in media containing sea salts. Does not grow on the mineral salts medium used for *Hyphomicrobium vulgare*. A mixture of L-glutamic acid, L-aspartic acid, L-serine, and L-methionine is required for growth. Requires biotin.

The temperature range for optimal growth is 20–30°C. The NaCl concentration for optimal growth is 1.0–7.5%. Optimal pH for growth is: 7.6. Nitrate is reduced. Sheep erythrocytes are not hemolyzed. Under optimal conditions in marine broth, growth is slower than the growth of other species of *Hyphomonas*. Susceptible to NP-40 (0.01%) and Tween 80 (0.1–1.0%). Resistant to novobiocin, penicillin, ampicillin, and streptomycin. Requires 6–8 min of treatment with a Brownwill Biosonik IV sonicator (low probe at full power) to produce 99% lysis of cells.

A major fatty acid is octadecanoate ($C_{18:1}$) at up to 60% of the total fatty acids (Table BXII.α.59). Isolated from the Baltic Sea in 1979 by H. Schlesner. The overall DNA–DNA similarities with other *Hyphomonas* species are reported in Table BXII.α.60.

The mol% G + C of the DNA is: 59 (Bd).

Type strain: SCH 1325, IFAM 1325, ATCC 33879.

GenBank accession number (16S rRNA): AF082797.

8. **Hyphomonas rosenbergii** Weiner, Melick, O'Neill and Qintero 2000, 467^{VP}

ro.sen.ber'gi.i. M.L. gen. n. *rosenbergii* of Rosenberg, named after the (Israeli) microbial ecologist Eugene Rosenberg.

Main body of the mother cell is prolate spheroid, ~1 μm in diameter and has one prostheca, 0.2 × 1 μm. Buds are motile by a single flagellum. Synthesizes a capsule, which surrounds the entire cell at all growth stages, and a polar holdfast, which is temporally synthesized. Gram negative. Not acid fast. No endospores. Aerobic. Additional phenotypic characteristics are reported in Table BXII.α.58.

Colonies are round, convex, about 1.5 mm in diameter after 3 days at 37°C on marine agar. In liquid medium, growth is granular and/or ropy. Biofilm forms on walls of growth vessel. Cells form rosettes. The optimal temperature range is 25–45°C. The ocean salts growth range is 1.0–12.0. The pH growth range is 5.7–8.9. Nitrate is reduced. Sheep erythrocytes are not hemolyzed.

Susceptible to novobiocin, penicillin, ampicillin, streptomycin, tellurite, crystal violet, brilliant green, and methylene blue; resistant to 1.0% Tween 80 and neutral red. The major fatty acid is octadecanoate ($C_{18:1}$) at 43% total fatty acids. The outer membrane protein profiles, DNA homology, and serology have low but significant similarity to other strains of *Hyphomonas*. Isolated in 1985 from the Guaymas Basin thermal vent region (2000 m deep), Gulf of Mexico by H. Jannasch. The overall DNA–DNA similarities with other *Hyphomonas* species are reported in Table BXII.α.60.

The mol% G + C of the DNA is: 61 (Bd).

Type strain: VP-6, ATCC 43869.

GenBank accession number (16S rRNA): AF082795.

Genus VIII. **Ketogulonicigenium** *corrig.* Urbance, Bratina, Stoddard and Schmidt 2001, 1068^{VP} *(Ketogulonigenium (sic) Urbance, Bratina, Stoddard and Schmidt 2001, 1068)*

THE EDITORIAL BOARD

Ke.to.gu.lo.ni.ci.ge'ni.um. N.L. n. *acidum ketogulonicum* ketogulonic acid; N.L. neut. suff. *genium* genium that which produces; L. neut. n. *Ketogulonicigenium* that which produces ketogulonic acid.

Gram-negative chemoorganotrophic facultative anaerobes. Cells ovoid or rod-shaped (0.5–0.7 × 0.8–1.3 μm). Oxidase and catalase positive. **Convert L-sorbose to 2-keto-L-gulonic acid. Major fatty acids $C_{16:0}$, and $C_{18:1\ \omega7c/\omega9t/\omega12t}$.** Temperature optimal 27–31°C; pH optimal 7.2–8.5. Grow best on arabinose, glycerol, inositol, lactose, mannitol, and sorbitol.

The mol% G + C of the DNA is: 52.1–54.

Type species: **Ketogulonicigenium vulgare** Urbance, Bratina, Stoddard and Schmidt 2001, 1069 (*Ketogulonigenium vulgare* (sic) Urbance, Bratina, Stoddard and Schmidt 2001, 1069.)

FURTHER DESCRIPTIVE INFORMATION

Analysis of 16S rDNA sequences placed the two species of the genus *Ketogulonicigenium* in the family *Rhodobacteraceae* of the *Alphaproteobacteria*, distinct from a cluster containing the genera *Gluconobacter* and *Acetobacter*. The five strains of *Ketogulonicigenium* were phenotypically similar but could be separated into two species on the basis of DNA/DNA hybridization; the five strains include four new isolates and DSM 4025, which was previously classified as *Gluconobacter oxydans* (Urbance et al., 2001).

Enrichment and Isolation Procedures

Enrichments were carried out in liquid medium with L-sorbose as the predominant carbon source and with $CaCO_3$ (6 g/l) added to buffer the medium against acidic metabolic products (Urbance et al., 2001). Culture supernatants were examined for 2-keto-L-gulonic acid production by TLC and HPLC; positive cultures were serially diluted and spread on agar of the same composition as the enrichment medium. Individual colonies were purified by streaking and then tested for the ability to produce 2-keto-L-gulonic acid by TLC and HPLC (Urbance et al., 2001).

Maintenance Procedures

Isolates were maintained on trypticase soy agar or another complex medium, SYM agar, described in Urbance et al. (2001). Long-term storage was achieved by freezing at −70°C in peptone-yeast extract-mannitol medium amended with 20% glycerol (Urbance et al., 2001).

Differentiation of the species of the genus *Ketogulonicigenium*

Ketogulonicigenium vulgare is nonmotile, does not grow at 37°C, has a pH optimum of 7.2–8.0, and grows best at a sodium ion concentration of 31.2 mM. *Ketogulonicigenium robustum* is motile, grows at 37°C, has a pH optimum of 8.0–8.5, and grows best at sodium ion concentrations between 117–459 mM (Urbance et al., 2001).

List of species of the genus Ketogulonicigenium

1. **Ketogulonicigenium vulgare** Urbance, Bratina, Stoddard and Schmidt 2001, 1069^{VP} (*Ketogulonigenium vulgare* (sic) Urbance, Bratina, Stoddard and Schmidt 2001, 1069.)
vul.ga′ re. L. neut. adj. *vulgare* common.

Description as for the genus with the following additional characteristics. Nonmotile. No growth at 37°C. pH optimum 7.2–8.0. Optimum Na^+ concentration for growth 31.2 mM.
The mol% G + C of the DNA is: 53.4–54.0 (T_m).
Type strain: : DSM 4025 (patent strain).
GenBank accession number (16S rRNA): AF136849.

2. **Ketogulonicigenium robustum** Urbance, Bratina, Stoddard and Schmidt 2001, 1069^{VP} (*Ketogulonigenium robustum* (sic) Urbance, Bratina, Stoddard and Schmidt 2001, 1069.)
ro.bus′ tum. L. adj. *robustum* strong.

Description as for the genus with the following additional characteristics. Motile. Grow at 37°C. pH optimum 8.0–8.5. Optimum Na^+ concentration for growth 117–459 mM.
The mol% G + C of the DNA is: 52.1 (T_m).
Type strain: X6L, KCTC 0858BP, NRRL B-21267.
GenBank accession number (16S rRNA): AF136850.

Genus IX. **Maricaulis** *Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1071*^{VP}

Jeanne S. Poindexter

Ma′ ri.cau′ lis. L. neut. n. *mare* the sea; L. masc. n. *caulis* stalk; M.L. masc. n. *Maricaulis* stalk from the sea.

Cells single, unbranched, with poles gently rounded or slightly tapered; long axis typically straight and cell shape **bacteroid**, but may be slightly curved in some cells and some isolates and cell shape **subvibrioid**; 0.4–0.6 × 1–2 μm during growth in most media. The younger pole of the dividing cell bears a **single flagellum**, and the older pole bears a prostheca (the **stalk**) developed by outgrowth of the cell envelope. Stalk diameter is constant along its length, varying from 0.11 to 0.18 μm among isolates. Binary **fission is asymmetric**: prior to fission, one pole bears a stalk and the other a single flagellum, and fission results in the separation of a non-motile stalked cell and a motile, monoflagellate swarmer cell. At the base of the flagellum and at the outer tip of the stalk is a small mass of adhesive material, the **holdfast**, which confers adhesiveness on each of the progeny.

Gram negative. All isolates grow aerobically with O_2 as terminal electron acceptor; principal respiratory quinone is ubiquinone-10. Nitrate may be reduced to nitrite anaerobically; N_2 is not produced. Some isolates (12 of 25 tested) can grow anaerobically on peptone-yeast extract medium without additional carbohydrates. Colonies are circular, convex and glistening, with a smooth margin, butyrous in texture, and colorless. In unagitated liquid cultures, cells accumulate as a **surface film** or pellicle and develop as a ring of growth on the vessel wall at or just below the air-liquid interface. Growth in agitated liquid cultures is evenly dispersed.

Chemoorganotrophic and **oligotrophic**; grow optimally in media such as peptone-yeast extract containing 0.05–0.3% (w/v) organic solutes prepared in sea water or artificial sea salts solution, but not in undiluted standard marine broth such as Zobell' s medium 2216, in which growth is inhibited or cells are deformed and viability is low. Optimal temperature range for growth 20–25°C; tolerated range for growth 10–35°C. Optimal pH for growth near neutrality; pH 6–8 tolerated. Growth in peptone or Casamino acids media requires the addition of sea salts or NaCl; optimal NaCl concentration for growth 2–6% (w/v); tolerated range 0.5–8% (w/v). Maximum specific rates of exponential growth 0.17–0.23 h^{-1}. Do not grow in defined media, and growth is not stimulated by B vitamins; almost all isolates require unidentified growth factors available in peptone. Do not use alcohols as sole sources of carbon.

Comparative analysis of 16S rDNA sequences is consistent with placement of *Maricaulis* among the *Alphaproteobacteria*. The positions of the 15 sequences grouped as *Maricaulis* in Fig. BXII.α.111 of the chapter describing the genus *Caulobacter* (see the family *Caulobacteraceae*) are represented here in Fig. BXII.α.76 by the seven nonredundant sequences with their strain identities and GenBank accession numbers shown. These seven sequences were determined for isolates known to exhibit *Maricaulis* phenotypes. The positions of the sequences for *Hirschia baltica*, "marine caulobacter" isolate MCS23, and the six nonredundant se-

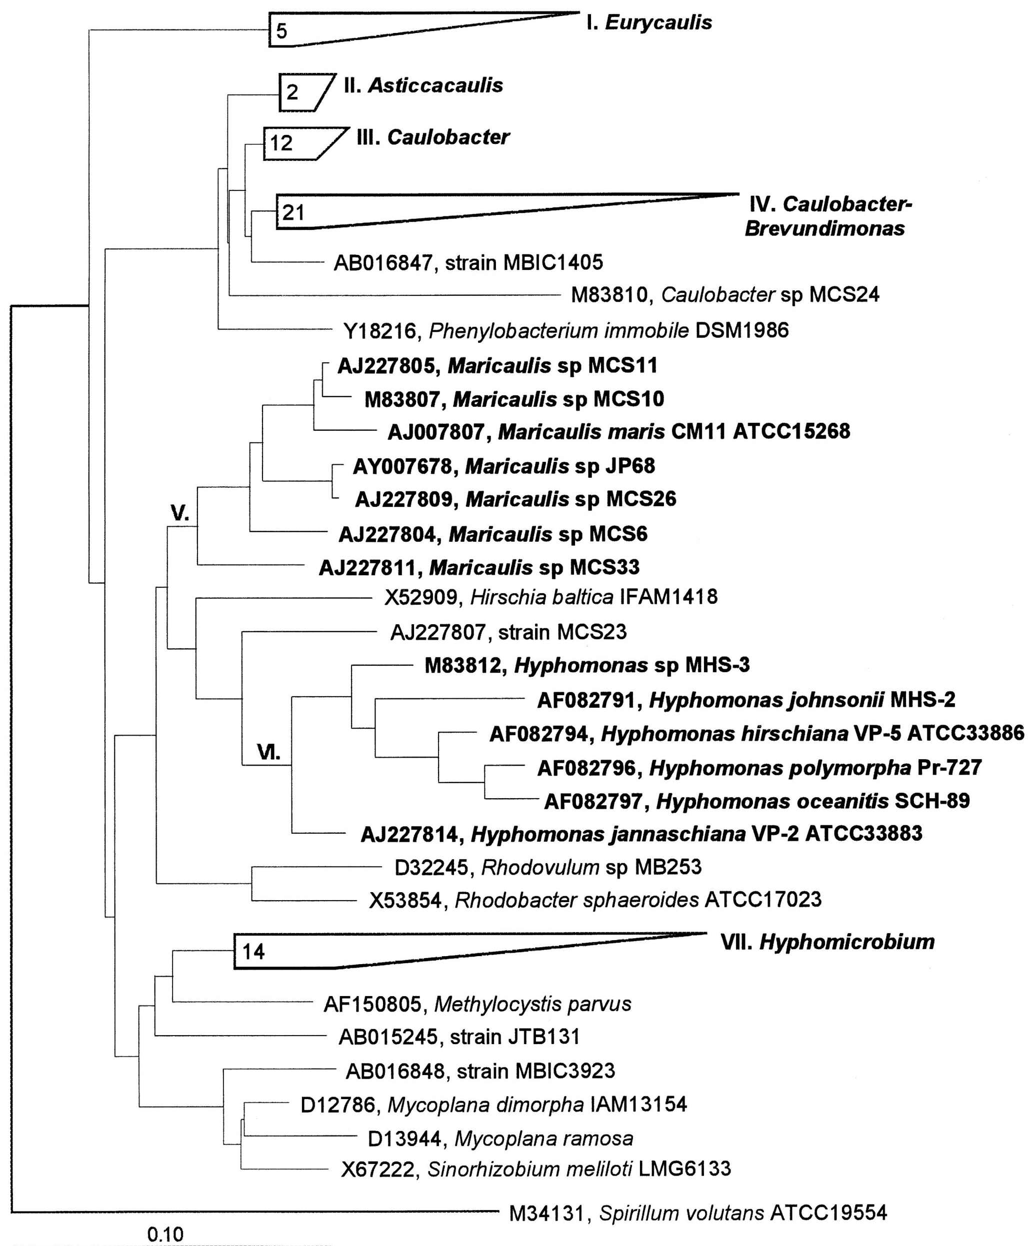

FIGURE BXII.α.76. Phylogenetic tree of 81 16S rDNA sequences, with group V. *Maricaulis* and group VI. *Hyphomonas* expanded to display GenBank accession numbers and strain identities (see Fig. BXII.α.114 in the chapter on the genus *Caulobacter*). Also represented are the positions of *Maricaulis* sequences AJ227810 (by AJ227805); AJ007804, AJ227802, and AJ227803 (by AJ007807); AJ227808 (by AJ227809); and AJ227806, M83809, and M83811 (by AJ227811). Represented *Hyphomonas* sequences are AF082795 and AF082798 (by AF082794); AJ227813 (by AF082796); AF082789, AF082790, AF082792, AF082793, and AF082799 (by AJ227814); and M83806 (by M83812). Bar indicates evolutionary distance.

quences among the 15 reported for *Hyphomonas* spp. are also displayed to illustrate their similarity to *Maricaulis* sequences. (See "Taxonomic Comments" in the chapter in which the genus *Caulobacter* is described.)

Sources: isolated from filtered, stored seawater and from natural bodies of seawater. Not encountered as clinical isolates, and not known to be pathogenic for plants or animals.

The mol% G + C of the DNA is: 62.5–64.0.

Type species: **Maricaulis maris** (Poindexter 1964) Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1071 (*Caulobacter maris* Poindexter 1964, 289.)

Further descriptive information

Morphology and fine structure Known isolates of *Maricaulis* are either bacteroid or subvibrioid, i.e., cell poles are gently rounded or tapered, and the long axis is not strongly curved. However, vibrioid caulobacters are seen in samples and enrichment cultures of seawater, and the present description should not prevent an isolate from being identified provisionally as *Mari-*

caulis. Vibrioid marine isolates have been obtained from deep-sea vent communities (Poindexter, unpublished), but further characterizations are required to determine whether they are otherwise significantly different from isolates on which the present description is based.

As in freshwater caulobacters, a holdfast is present at the distal tip of the *Maricaulis* stalk; the holdfasts of all adhesive marine strains tested bound Wheat Germ Agglutinin (Merker and Smit, 1988; Abraham et al., 1999; 2001) and so must contain some *N*-acetylglucosamine. This is a higher proportion of WGA-binding strains than was found for freshwater caulobacters, suggesting that the composition of holdfast material may be constrained by the ionic environment of the marine habitat.

Maricaulis isolates have not been examined in ultrathin sections to determine the ultrastructure of the stalk. Although these marine bacteria are susceptible to disintegration during preparation for electron microscopy of whole cells, the slenderness of the stalks on the cells that do remain intact during specimen preparation and the absence of budding from the tip of the prostheca are features consistent with an internal structure comparable to that of freshwater caulobacters (see Morphology in the chapter on the genus *Caulobacter*). In contrast to freshwater caulobacters, however, the stalks of *Maricaulis* isolates do not contain stalk bands. An S-layer coat has not been discerned in *Maricaulis* cells, but their cell surface is poorly preserved by the procedures that have been used to study this feature in *Caulobacter* cells.

Cellular composition The principal phospholipid in *Maricaulis* cells is phosphatidylglycerol, and the most abundant fatty acid species are $C_{18:1}$ and $C_{16:0}$. All isolates tested also contain lower, but significant, amounts of $C_{18:1\ \omega 7c\ 11CH_3}$ and species of $C_{17:1}$ and $C_{16:1}$, $C_{17:0}$, and—in contrast to freshwater caulobacters—$C_{18:0}$ and $C_{11:0\ iso\ 3OH}$ (Abraham et al., 1999; Abraham et al., 2001). Phospholipids are significantly less abundant than in freshwater caulobacters and most other bacteria, and phosphoglucolipids are not detectable. All seven isolates so far analyzed possess sulfoquinovosyl diacylglycerols, one of which was identified as 1-O-(α-6′,6-deoxy-aldohexopyranosyl-6′-sulfonic acid)-3-O-diacylglycerol, and four also formed at least small amounts of taurineamide diacylglycerols (Abraham et al., 1999). This pattern of cellular lipids is similar to that found by the same laboratory for *Hyphomonas* isolates, but differs noticeably by the absence of sulfoquinovosyl diacylglycerides from the cells of these budding, hyphal bacteria and of one isolate (MCS23) regarded as a caulobacter throughout its isolation. This is lipid pattern "M" of Abraham et al. (1997).

Genome structure Native plasmids were detected in two marine isolates by Anast and Smit (1988), but not in the majority of strains. More significantly for potential employment of these organisms in marine habitats, every isolate tested was able to propagate and express genes (for antibiotic resistance) carried on plasmids transferred to the marine caulobacters by conjugation with *Escherichia coli* donors. Ribosomal DNA sequences have been determined for a large number of *Maricaulis* and *Maricaulis*-like isolates. *Maricaulis* sequences constitute one of five coherent groups among caulobacterial sequences. The minimum similarity value among sequences grouped within V. *Maricaulis* in Fig. BXII.α.76 is 92.2%. The highest similarities outside the genus are to sequences for organisms identified as *Hyphomonas jannaschiana* (90.6–92.0%). Two sequences are similar to *Maricaulis* and *H. jannaschiana* sequences: the sequence for *Hirschia baltica* is up to 89.8% similar to *Maricaulis* sequences, and the sequence for isolate MCS23, described as a caulobacter, is up to 89.5% similar. Bacteriophages lytic for *Maricaulis* isolates have not been reported. (See "Taxonomic Comments" below and the chapter on the genus *Caulobacter* for further discussion of 16S rDNA sequences and other bacteriophages.)

Antibiotic and metal susceptibilities *Maricaulis* isolates are typically susceptible to most antibiotics tested. However, nine of 20 isolates tested were found resistant to 10 μg/ml or more of $HgCl_2$. Mercury resistance was not correlated with the presence of plasmids, and a probe could not detect the mercury reductase gene.

Enrichment and Isolation Procedures

Maricaulis isolates are obtained by the basic procedure described for *Caulobacter* (see the chapter on the genus *Caulobacter*), beginning with a sample of estuarine or seawater. Deep-sea *Maricaulis* isolates were obtained by allowing glass cover slips to reside in an open box for several weeks near a deep-sea vent; caulobacters attached to the glass surfaces, which were used as inocula for enrichment cultures in dilute peptone-seawater medium (Poindexter, unpublished). Once isolated, *Maricaulis* strains can be maintained on slants of dilute peptone (0.05%, w/v)–Casamino acids (0.05%, w/v) media prepared with 75–80% seawater or artificial sea salts solution, transferred every two months, incubated for 2–3 d at room temperature, then refrigerated. Lyophilization is not a suitable means of preservation.

Procedures for Testing Special Characters

The distinctive features of these bacteria are morphological—the asymmetry of the dividing cell, the single polar flagellum, the holdfast, and the absence of bands in the stalks. However, intact cells are difficult to preserve for the electron microscopical examinations needed for close examination of these features. Aldehyde preservation is effective with some isolates, and acetic acid (2%, v/v) for others, but many disintegrate during specimen preparation. Close observation by phase-contrast microscopy of wet cells is, however, adequate to determine the asymmetry of dividing cells, the presence of stalks, and adhesiveness and motility of cells.

Differentiation of the genus *Maricaulis* from other genera

Four groups of bacteria other than caulobacters produce long cellular appendages of the envelope that are of constant diameter; these bacteria also tend to occur in habitats with caulobacters. They are distinguishable from caulobacters, and from each other, by the morphology of their reproductive stages. The five groups are distinguished as in Table BXII.α.101, and the five species groups of caulobacters are distinguished as shown in Table BXII.α.102, both in the chapter in which the *Caulobacter* is described. Relationships to nonprosthecate bacteria implied by 16S rDNA sequence analysis are illustrated and discussed further in "Taxonomic Comments" in the chapter describing the genus *Caulobacter*.

Taxonomic Comments

Among the 16S rDNA sequences that were found similar to those of *Maricaulis* isolates, the entire set determined for *Hyphomonas* isolates is clearly the most similar (more than 90% similarity), while the sequences of freshwater caulobacters are less similar to *Maricaulis* sequences than are those of phototrophic bacteria such as *Rhodobacter* and *Rhodopseudomonas*. This phylogenetic re-

lationship could reflect a common marine ancestry of *Maricaulis* and *Hyphomonas* in the ocean, an ancestry further implied by the similarity of lipid composition of these two groups. In each morphological type, the marine isolates are more like their co-habitants than like their freshwater/soil morphological twins. It is not so easy to distinguish these two kinds of dimorphic, prosthecate bacteria upon first observing them, even in pure cultures. For example, the "VP" designation on several *Hyphomonas* strains was used to label deep-sea Vent Prosthecate bacteria until morphology could be established unequivocally for pure populations (Poindexter, unpublished). Among the marine caulobacters collected by Anast and Smit (1988), one isolate (MCS23) appears closer, by several criteria, to *Hyphomonas* than to any isolates within the coherent *Maricaulis* group. This isolate might reflect a shift in reproductive function between prostheca and cell, but the direction in which it might be evolving cannot be inferred.

Two species are recognized, distinguished by physiological traits as shown in Tables BXII.α.61 and BXII.α62..

TABLE BXII.α.61. Differential characteristics of the species of the genus *Maricaulis*[a]

Characteristic	*M. maris*	"*M. halobacteroides*"
Growth with 4% NaCl	+	−
Carbon sources generally used:		
Carbohydrates	+	+
Amino acids	−	+
Other organic acids	−	+
Starch hydrolyzed	−	+
Nitrate reduced to nitrite anaerobically	+	−

[a]Symbols: +, 90% or more of strains are positive; −, 90% or more of strains are negative.

TABLE BXII.α.62. Other characteristics of the species of the genus *Maricaulis*[a]

Characteristic	*M. maris*	"*M. halobacteroides*"
Carbon-source utilization:[b]		
Arabinose	−	+
Ribose	−	+
Xylose	+	+
Glucose	+	+
Galactose	−	+
Mannose	−	+
Lactose	−	+
Maltose	+	+
Sucrose	+	+
Proline	−	+
Acetate	−	+
Butyrate	−	+
Pyruvate	−	+
Starch hydrolysis	−	+

[a]Symbols: +, 90% or more of strains are positive; −, 90% or more of strains are negative. Neither species utilizes any of fructose, alanine, aspartate, glutamate, tyrosine, pimelate, malate, fumarate, or succinate when provided as sole source of carbon in dilute (0.005%, w/v, of each of peptone and yeast extract) media prepared with mineral nutrients and 3% NaCl.

[b]Carbon-source utilizations were determined with D-isomers of sugars, with L-isomers of amino acids, or (when single isomers were not available) with racemic mixtures.

List of species of the genus Maricaulis

1. **Maricaulis maris** (Poindexter 1964) Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1071[VP] (*Caulobacter maris* Poindexter 1964, 289.)
ma'ris. L. gen. n. *maris* of the sea.

Rod-shaped cells slender. Colonies colorless. Organic growth factor requirements not satisfied by mixtures of B vitamins and amino acids. Growth requires NaCl (1–4%, w/v). Known isolates utilize few sugars and do not hydrolyze starch; they do not utilize individual amino acids as carbon sources, but grow on peptone-Casamino acids media.

Strain CM11 was isolated from filtered, stored seawater in Pacific Grove, CA.

The mol% G + C of the DNA is: 62.5 (HPLC).

Type strain: CM11, ACM 5106, ATCC 15268, DSM 4734.

GenBank accession number (16S rRNA): AJ227802.

Additional Remarks: One of two marine species included in this list. Vibrioid marine and estuarine isolates, also dependent on NaCl supplementation for growth in complex organic media, are known; their characteristics have not been reported. At least some of the isolates of marine caulobacters reported by Anast and Smit (1988) could be assigned here, but others may require accommodation in another species. Some of those isolates appear more subvibrioid than bacteroid, but whether cell morphology will serve as a suitable subgeneric criterion among *Maricaulis* isolates has yet to be determined.

Other Organisms

1. *"Maricaulis halobacteroides"* (*Caulobacter maris* Poindexter 1964, 289.)

hal.o.bac.ter.oi'des. Gr. n. *hals* salt; M.L. masc. *bacter* Gr. neut. n. *bactrum* rod; Gr. n. *eidus* form, shape; M.L. adj. *halobacteroides* salt (-needing) and rod shaped.

Rod-shaped cells slender. Colonies colorless. Organic growth factor requirements not satisfied by mixtures of B vitamins and amino acids. Starch is hydrolyzed, and most sugars, but few individual amino acids, can be utilized as sole sources of carbon for growth. Growth requires NaCl (0.5–3%, w/v) and is inhibited at 4% (w/v) NaCl.

Strain CM13 was isolated from filtered, stored seawater in Pacific Grove, CA.

The mol% G + C of the DNA is: not determined.

Deposited strain: CM13, ATCC 15269.

GenBank accession number (16S rRNA): AJ007804.

Additional Remarks: The original type strain deposited with the ATCC appears to have been, very early, overgrown by strain CM11 (*M. maris*), resulting in identity of the 16S rDNA sequences that have been determined for the two strains (see Fig. BXII.α.76) and DNA–DNA hybridization >90% (Moore et al., 1978; Abraham et al., 1997). Other copies of the ATCC strain (DSM 4734 and ACM 5106) may also be strain CM11. The problem probably arose from attempts to maintain the strains as lyophilized suspensions, a state from which it is difficult to revive these marine bacteria. At present, it seems wiser to continue to recognize the species and thereby possibly provide a taxon suitable for recent isolates of this type of marine caulobacter.

Genus X. **Methylarcula** *Doronina, Trotsenko, and Tourova 2000a, 1857*[VP]

Nina V. Doronina and Yuri A. Trotsenko

Me.thyl.ar.cu′ la. Fr. *méthyle* the methyl radical; L. fem. n. *arcula* small box; M.L. fem. n. *Methylarcula* methyl-using small box.

Rods 0.5–0.8 × 0.8–2.0 µm. Nonmotile. Gram negative. **Poly-β-hydroxybutyrate granules are formed.** Endospores and prosthecae are not formed. Colonies are white or pale pink. Do not produce pyocyanin and fluorescein. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. **Moderately halophilic**; NaCl is required for growth. Ectoine is accumulated intracellularly as the main osmoprotectant. Growth does not occur on peptone/yeast extract medium, with or without NaCl. Nitrate is not reduced to nitrite. Chemoorganotrophic. **Facultatively methylotrophic. Assimilate C_1 compounds via the isocitrate lyase-negative (icl^-) serine pathway. Methylamine, sugars, and some organic acids are used as carbon and energy sources.** Ammonium salts, some amino acids, and methylamine are used as nitrogen sources. Growth factors are not required. **Oxidase positive.** Acids are produced from sugars oxidatively. Acetoin, hydrogen sulfide, and ammonium are not formed. Indole is formed from L-tryptophan. The major ubiquinone is Q-10. The dominant phospholipids are phosphatidylethanolamine and phosphatidylcholine. The predominant cellular fatty acids are straight-chain unsaturated ($C_{18:1}$), saturated ($C_{18:0}$), and cyclopropane ($C_{19:0}$) acids. Belongs to the *Alphaproteobacteria*.

The mol% G + C of the DNA is: 57–60.

Type species: **Methylarcula marina** Doronina, Trotsenko and Tourova 2000a, 1858.

Further descriptive information

Cells are lysed when transferred into distilled water after NaCl treatment. The divalent cations Mg^{2+} and Ca^{2+} added to the 0.5 M NaCl washing solution at concentrations as low as 50 mM prevent cell lysis. The ectoine pool increases when the NaCl concentration in the growth medium is increased.

Methylamine dehydrogenase and amine oxidase are absent in methylamine-grown cells. Alternatively, they contain an inducible γ-glutamylmethylamide synthetase/lyase and *N*-methylglutamate synthase/lyase. Both enzyme systems produce formaldehyde, which is further oxidized by glutathione-independent formaldehyde dehydrogenase to formate. The latter is ultimately oxidized to CO_2 by phenazine methosulfate-linked and NAD-dependent formate dehydrogenases. Formaldehyde assimilation occurs via the serine pathway as confirmed by the presence of the appropriate specific enzymes: hydroxypyruvate reductase, serine-glyoxylate aminotransferase, and malate lyase. *Methylarcula* strains either lack or have very low isocitrate lyase (icl^-) activity and during growth on C_1 compounds consequently implement the icl^- variant of the serine pathway. Primary assimilation of ammonia occurs both by reductive amination of α-ketoglutarate and via the glutamate cycle.

Enrichment and Isolation Procedures

Successful enrichment has been achieved by inoculating water or soil samples with a salinity of 6–11% (pH 6.5–7.5) into mineral medium MK[1]. Enrichment cultures were grown for 1 week at 29°C in 750-ml Erlenmeyer flasks containing 100 ml of the medium, with shaking at 120 rpm; they were then diluted 1:10^3 and plated on solidified MK medium containing 2.0% Bacto agar (Difco).

Maintenance Procedures

Methylarcula cultures can be stored for 2 months on MK agar slants at 4°C. For long-term preservation, *Methylarcula* strains can be lyophilized in skim milk by using common procedures for aerobes.

Differentiation of the genus *Methylarcula* from other genera

The major characteristics differentiating the genus *Methylarcula* from other related genera are summarized in Table BXII.α.63.

Taxonomic Comments

In the phylogenetic tree derived from 16S rRNA sequences, *Methylarcula* is located in the order *Rhodobacterales* in the class *Alphaproteobacteria*, whereas most other genera of methylobacteria having the serine pathway belong to the order *Rhizobiales* in the class *Alphaproteobacteria*. The moderately halophilic marine genus *Methylophaga*, which uses the ribulose monophosphate pathway, belongs to the class *Gammaproteobacteria*. The similarity values for species *Methylarcula* and other members of the order *Rhodobacterales* in the class *Alphaproteobacteria*, including the marine methylotroph *"Marinosulfonomonas"* (Holmes et al., 1997), fell into the range 87.1–92.6%.

Methylarcula has less than 10% DNA–DNA similarity with members of *Methylorhabdus*, *Methylobacterium*, *Aminobacter*, and *Methylopila*.

1. MK medium contains (g/l of distilled water): $(NH_4)_2SO_4$, 2.0; KH_2PO_4, 2.0; NaCl, 60.0; $MgSO_4 \cdot 7H_2O$, 0.2 g; $FeSO_4 \cdot 7H_2O$, 0.002 (Doronina et al., 2000a). The pH of the medium was adjusted to 7.2 prior to autoclaving. Methylamine was added to a final concentration of 3.0 g/l.

List of species of the genus Methylarcula

1. **Methylarcula marina** Doronina, Trotsenko and Tourova 2000a, 1858[VP]

ma.ri′ na. L. fem. n. *mare* sea; L. fem. adj. *marina* of the sea.

Fig. BXII.α.77 illustrates the morphological features. Colonies on methylamine agar medium are white or pale pink, round, convex, 1–2 mm in diameter. Oxidase positive. Urease, lipase, and catalase negative. Nitrate is not utilized. Able to grow at 10–42°C, at pH 5.0–10.5, and in the presence of 0.05–12% NaCl. Optimal conditions for growth are 29–35°C, pH 7.5–8.5, and 3–8% NaCl. Utilizable carbon sources are methylamine, fructose, glucose, maltose, lactose, mannose, ribose, trehalose, galactose, xylose, sucrose, succinate, pyruvate, and acetate. Methylamine is oxidized to formaldehyde by the *N*-methylglutamate pathway enzymes γ-glutamylmethylamide synthetase/lyase and *N*-methylglutamate synthase/lyase.

The type strain was isolated from Azov Sea estuary water.

The mol% G + C of the DNA is: 60.4 (T_m).

Type strain: h1, VKM B-2159.

GenBank accession number (16S rRNA): AF030437.

2. **Methylarcula terricola** Doronina, Trotsenko and Tourova 2000a, 1858[VP]

ter.ri′ co.la. Gr. adj. *terricola* of the soil.

Fig. BXII.α.77 illustrates the morphological features. Colonies on methylamine agar medium are white, 2 mm in diameter. Oxidase and catalase positive. Urease and lipase negative. Nitrate is not utilized. Able to grow at 10–40°C, pH 5.5–10.0, and in the presence of 0.05–14% NaCl. Optimal conditions for growth are 29–32°C, pH 7.5–8.5, and 3–6% NaCl. Utilizable carbon sources are mono- and dimethylamine, fructose, glucose, maltose, lactose, mannose, ribose, trehalose, galactose, xylose, sucrose, succinate, pyruvate, and acetate. Methylamine is oxidized to formaldehyde by the *N*-methylglutamate pathway enzymes γ-glutamylmethylamide synthetase/lyase and *N*-methylglutamate synthase/lyase.

The level of DNA–DNA similarity with the type species *Methylarcula marina* is ~25–30% (membrane method).

The type strain was isolated from coastal salty soil of the Black Sea (Crimea).

The mol% G + C of the DNA is: 57.1 (T_m).

Type strain: h37, VKM B-2160.

GenBank accession number (16S rRNA): AF030436.

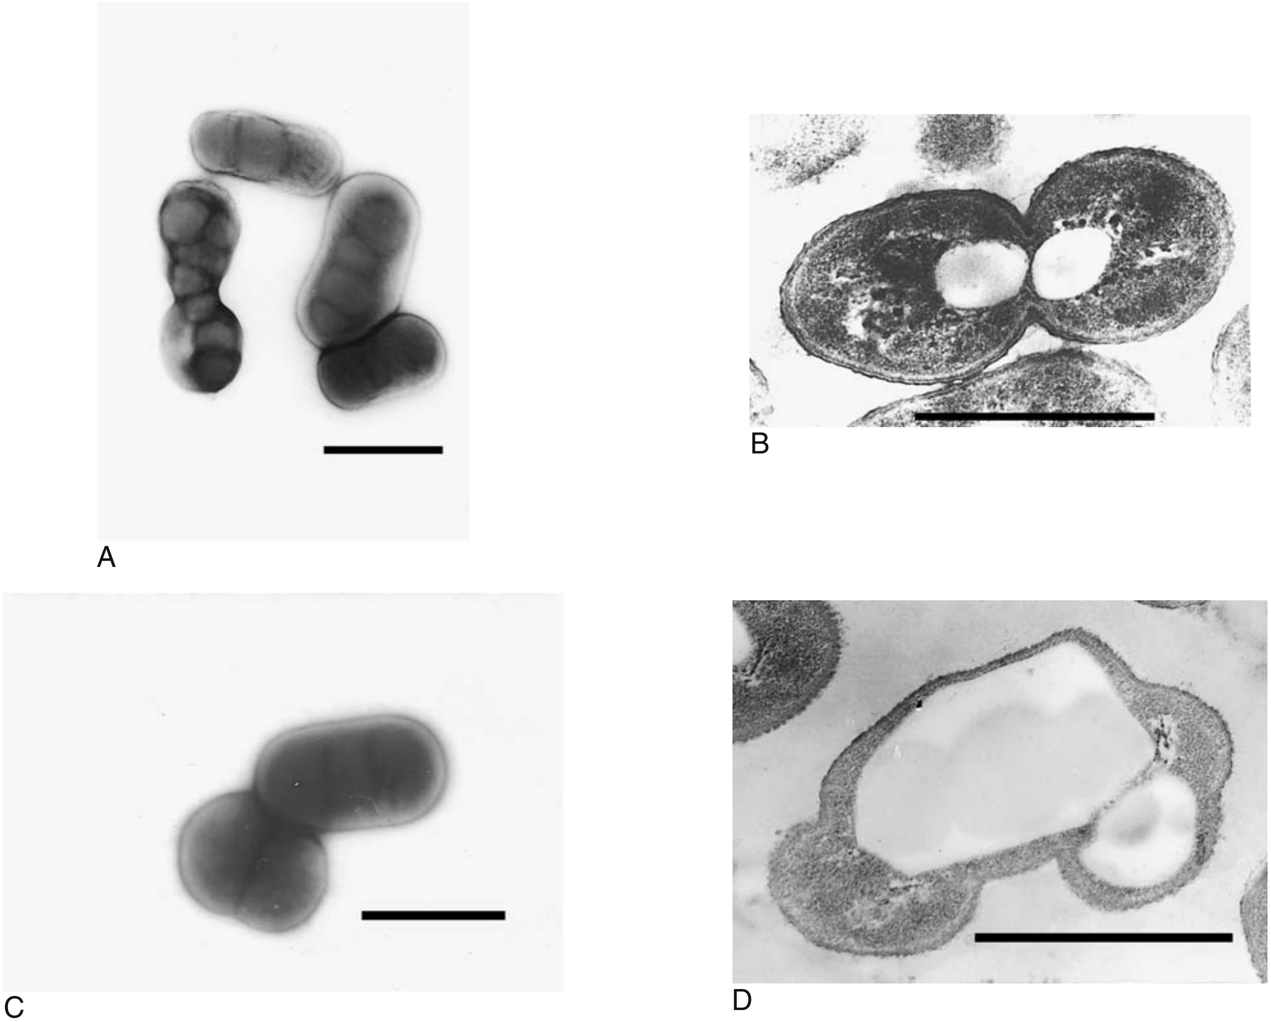

FIGURE BXII.α.77. *Methylarcula marina* (*A*, *B*) and *Methylarcula terricola* (*C*, *D*). *A* and *C*, negatively stained cells; *B* and *D*, ultrathin sections showing cell wall structure and granules of poly-β-hydroxybutyrate. Bars = 1 µm.

Genus XI. **Octadecabacter** *Gosink, Herwig and Staley 1998, 327[VP] (Effective publication: Gosink, Herwig and Staley 1997, 363)*

JOHN J. GOSINK

Oc.ta.dec' a.bac.ter. Gr. pref. *okto* eight; Gr. pref. *deca* ten; Gr. neut. n. *bakterion* a rod; M.L. masc. n. *Octadecabacter* an 18-carbon fatty acid–containing rod.

Straight or pleomorphic rods 0.6–0.8 × 1.6–4.8 µm. Nonmotile. All known strains produce gas vesicles. Gram negative. Aerobic or microaerophilic, possessing a strictly respiratory type of metabolism, with oxygen as the terminal electron acceptor. Do not reduce NO_3^- to NO_2^-. Do not grow anaerobically. Do not produce bacteriochlorophyll *a*. Form white, circular, convex, entire colonies on SWCm agar.[1] Growth occurs at pH 6.5–8.5 and at temperatures as low as 4°C in media having 17–70‰ salinity (4.8% NaCl). **Catalase positive. Oxidase negative.** Growth occurs on few (if any) organic compounds as sole carbon sources at 0.2% concentration. Growth occurs sparingly on selected carbon sources, including L-glutamate, glycerol, and mixed amino acids in dilute yeast extract. **Octadecenoic acid ($C_{18:1}$) is the major fatty acid.** Member of the class *Alphaproteobacteria*. Isolated from polar marine sea ice.

The mol% G + C of the DNA is: 56–57 (HPLC).

Type species: **Octadecabacter arcticus** Gosink, Herwig and

1. SWCm agar (Irgens et al., 1989) has the following composition (g per l of distilled water): NaCl, 12.0; $MgS0_4{\cdot}7H_20$, 7.0; $MgCl_2{\cdot}6H_20$, 5.2; $CaCl_2{\cdot}2H_20$, 1.1; KCl, 0.7; KH_2P0_4, 0.01; ferric citrate, 0.001; NH_4Cl, 0.4; yeast extract, 0.4; beef extract, 0.4; tryptone, 0.4; vitamins (mg per l of distilled water): pyridoxine·HCl, 10; calcium pantothentate, 5; nicotinamide, 5; *p*-aminobenzoic acid, 5; riboflavin, 5; thiamine·HCl, 5; biotin, 2; folic acid, 2; cyanocobalamine(B_{12}), 0.1), 10 ml; trace elements solution ((g per l of distilled water): H_3BO_3, 0.2; $CaCl_2{\cdot}2H_2O$, 0.2; $ZnSO_4{\cdot}7H_2O$, 0.1; $MnCl{\cdot}4H_2O$, 0.03; $Na_2MoO_4{\cdot}2H_2O$, 0.03; $NiCl_2{\cdot}6H_2O$, 0.02; $CuCl_2{\cdot}2H_2O$, 0.01; adjust pH to 3.5.), 2.0 ml; agar, 15; adjust pH to 7.0 before sterilizing.

Staley 1998, 327 (Effective publication: Gosink, Herwig and Staley 1997, 363.)

Further descriptive information

Octadecabacter strains appear as rods or pleomorphic rods that form small, white, circular, convex, entire colonies when grown on SWCm agar plates at 4°C for several weeks. These strains do not produce bacteriochlorophyll *a* or any associated pigments.

All known *Octadecabacter* strains produce gas vesicles. The role of gas vesicles in this genus is unknown. Gas vesicles may serve to buoy cells in the water column up to the sea ice microbial community. Alternatively, gas vesicles may serve as a mechanism for cell dispersal during spring breakup of the sea ice.

Octadecabacter (and some related genera) are distinguished by a high level of octadecenoic acid: 70–80% of the total cellular fatty acids (Gosink and Staley, 1995). The location and *cis* or *trans* nature of the double bond in the octadecenoic acid (either $C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, or $C_{18:1\ \omega12t}$) of *Octadecabacter* has not been determined. The remainder of the fatty acids are mostly $C_{16:1\ \omega7c}$, $C_{16:0}$, and $C_{10:0\ 3OH}$ and several other fatty acids, each of which constitutes 3% or less of the total.

The strains grow on few (if any) organic compounds as sole carbon sources at 0.2% concentration. However, limited growth occurs when 0.2 g/l yeast extract is added to the basal medium. All of the polar gas vacuolate strains grow on L-glutamate, glycerol, and mixed amino acids in the presence of 0.2 g/l yeast extract.

Phylogenetically closely related taxa have been isolated from a number of marine environments around the world. The physiological capabilities and ecological roles of these bacteria are quite diverse (Sorokin, 1995; Bowman et al., 1997a; Gonzáles and Moran, 1997; Labrenz et al., 1999).

Enrichment and Isolation Procedures

All currently known strains have been obtained from polar marine sea ice. Strains can be collected by melting ice fragments at room temperature several hours to overnight. The meltwater is then plated on suitable media and incubated at 4°C. *Octadecabacter* has only been cultivated from natural environments by plating on SWCm medium; however, media using several other carbon sources may also work. In general, only dilute carbon sources should be used. *Octadecabacter* colonies are usually only seen as small white colonies after several weeks of growth. The presence of gas vesicles gives the colonies a chalky opaque coloration. The occurrence of gas vesicles can be confirmed by phase and electron microscopy. *Octadecabacter* strains are readily distinguished from other gas vacuolate strains by their color, slow growth, and fatty acid composition.

Maintenance Procedures

Stocks are maintained for general work on SWCm at 4°C. Care must be taken when transferring or working with the strains to keep them and the growth media at 4°C. Cultures can be killed by leaving them out at room temperature for several hours or overnight. Long-term storage is best done by transferring cells to SWCm broth with 25% glycerol or 10% DMSO and freezing at −80°C.

Differentiation of the genus *Octadecabacter* from other genera

In terms of phenotypic characteristics, *Octadecabacter* can be differentiated from *Roseobacter* and *Sulfitobacter* primarily on the basis of fatty acid composition, lack of pigmentation, lack of bacteriochlorophyll *a*, and gas vesicles (Table BXII.α.64).

Octadecenoic acid ($C_{18:1}$) comprises a reproducibly high proportion (70–80%) of the total cellular fatty acids of *Octadecabacter* (Gosink and Staley, 1995). However, this fatty acid is found in relative abundance in both pigmented and nonpigmented, bacteriochlorophyll *a*–producing and nonbacteriochlorophyll *a*–producing, psychrotrophic, and mesophilic, acidophilic and nonacidophilic species of the *Alphaproteobacteria* (Fuerst et al., 1993; Kishimoto et al., 1995b).

The known members of *Octadecabacter*, unlike *Roseobacter*, do not produce bacteriochlorophyll *a* or pigments.

Another difference between *Octadecabacter* vs. *Roseobacter* and *Sulfitobacter* is the presence of gas vesicles. Phase contrast microscopy of cultures of *R. denitrificans* and *Ruegeria algicola* under different growth conditions at different stages of growth never reveals the presence of gas vesicles (Gosink et al., 1997). Likewise, there are no reports of closely related genera, including *Sulfitobacter*, that produce gas vesicles.

TABLE BXII.α.64. Features that differentiate *Octadecabacter* from *Roseobacter* and *Sulfitobacter*[a,b]

[b]Data from Shiba, 1991a; Sorokin and Lysenko, 1993; Sorokin, 1995; Gosink et al., 1997.

Taxonomic Comments

Eighteen strains of bacteria have been associated with the genus *Octadecabacter*. Of these, four strains (238, 307, 308, and 309) have been examined closely, and two strains (238 and 307) have been officially recognized (Gosink et al., 1997).

Phylogenetic analysis of the 16S rDNA of strains 238 and 307 shows that *Octadecabacter* is a member of the *Alphaproteobacteria* and that it is related to the genera *Roseobacter* (Shiba, 1991a; Gosink et al., 1997) and *Sulfitobacter* (Sorokin, 1995; Gonzáles and Moran, 1997). Several different methods were employed in analyzing the 16S rDNA sequences, including distance, parsimony, and likelihood methods, using various parameters for each type of analysis. Some of the trees obtained by these various methods differed from each other depending on which evolutionary framework (distance, parsimony, or likelihood) and what specific assumptions (transition/transversion ratio, weighting sets, step matrices, etc.) were applied. Regardless of the method employed, *Octadecabacter* is rooted deeply within the *Rhodobacter* group (Maidak et al., 1999) but not within the genera *Paracoccus* or *Rhodobacter*. The most likely tree, as evaluated under a likelihood framework by the Kishino–Hasegawa test (Kishino and Hasegawa, 1989), is shown in Fig. BXII.α.78. Other phylogenetic relationships can be seen in Bowman et al. (1997a), Gonzáles and Moran (1997), and Labrenz et al. (1999).

Octadecabacter arcticus and *R. denitrificans* show DNA–DNA hybridization values of 35% ± 9%. *Octadecabacter antarcticus* and *R. denitrificans* have DNA–DNA hybridization values of 42% ± 15%. These values are below 70%, the minimum value required to be considered different isolates of the same species (Wayne et al., 1987).

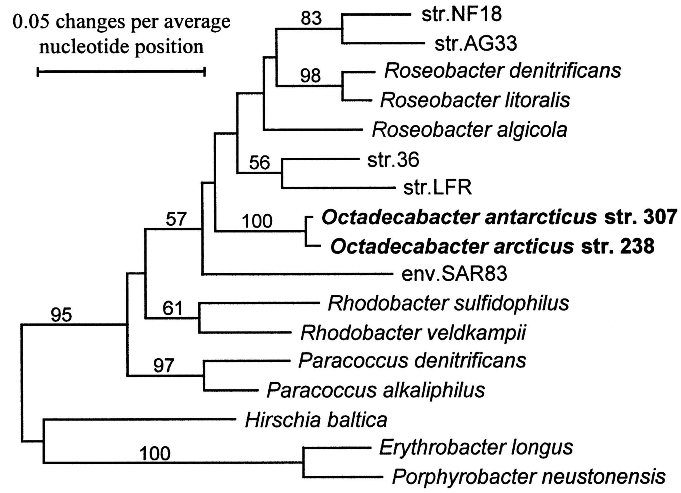

FIGURE BXII.α.78. Phylogenetic position of *Octadecabacter* in relation to *Roseobacter* and closely related species. This tree is depicted under a likelihood framework with a transition to transversion ratio of 1.15. The scale bar represents approximately 0.05 changes per average nucleotide position. Numbers above the branches indicate percent bootstrap support for that branch out of 100 likelihood bootstrap resamplings. (Reprinted with permission from J.J. Gosink, et al., Systematic and Applied Microbiology, 1997, *20:* 356–365.)

Differentiation of the species of the genus *Octadecabacter*

Characteristics differentiating *Octadecabacter arcticus* from *Octadecabacter antarcticus* are listed in Table BXII.α.65. Other characteristics are listed in Table BXII.α.66.

TABLE BXII.α.65. Characteristics differentiating between the species of the genus *Octadecabacter* and two unnamed *Octadecabacter* strains[a]

List of species of the genus Octadecabacter

1. **Octadecabacter arcticus** Gosink, Herwig and Staley 1998, 327[VP] (Effective publication: Gosink, Herwig and Staley 1997, 363.)
arc′ ti.cus. M.L. gen. *arcticus* of the arctic.

The characteristics are as described for the genus and listed in Tables BXII.α.65 and BXII.α.66, with the following additional information. Long irregular or pleomorphic rods from 0.6–0.8 × 2.4–4.0 μm. Known strains produce gas vesicles. The organisms require thiamine, nicotinic acid, and pantothenic acid for growth. Grow well on glycerol and mixed amino acids only in the presence of small amounts of yeast extract. Grow at temperatures from 4–15°C. Predominant fatty acids when grown on Marine medium 2216 at 10°C are $C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, or $C_{18:1\ \omega12t}$ (75%), $C_{16:1\ \omega7c}$ (8%), $C_{16:0}$ (6%), and $C_{10:0\ 3OH}$ (4%).

The mol% G + C of the DNA is: 57 (HPLC).

Type strain: 238.

GenBank accession number (16S rRNA): U73725.

[a]Symbols: +, positive; −, negative.

2. **Octadecabacter antarcticus** Gosink, Herwig and Staley 1998, 327[VP] (Effective publication: Gosink, Herwig and Staley 1997, 363.)
ant.arc′ ti.cus. M.L. gen. *antarcticus* of Antarctica

The characteristics are as described for the genus and listed in Tables BXII.α.65 and BXII.α.66, with the following additional information. Long irregular or pleomorphic rods 0.6–0.8 × 1.6–4.8 μm. Known strains produce gas vesicles. Grow well on L-glutamate and mixed amino acids in the presence of small amounts of yeast extract. Do not grow on vitamin-free media supplemented with only biotin, thiamine, nicotinic acid, and pantothenic acid. Growth temperature range is 4–10°C. On Marine Medium 2216 at 10°C the predominant fatty acids are $C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, or $C_{18:1\ \omega12t}$ (77%), $C_{16:1\ \omega7c}$ (12%), $C_{16:0}$ (6%), and $C_{10:0\ 3OH}$ (2%).

The mol% G + C of the DNA is: 56 (HPLC).

Type strain: 307, CIP 106732.

GenBank accession number (16S rRNA): U14583.

Genus XII. **Paracoccus** *Davis 1969, 384[AL] emend. Ludwig, Mittenhuber and Friedrich 1993, 366*

Rob J.M. van Spanning, Adriaan H. Stouthamer, Simon C. Baker and Henk W. van Verseveld

Pa.ra.coc′ cus. Gr. prep. *para* like, alongside of; Gr. n. *coccus* a grain, berry; M.L. masc. n. *Paracoccus* like a coccus.

Spherical cells 0.5–0.9 μm in diameter **or very short rod-shaped cells** 1.1–1.3 μm in diameter. **Occur singly, in pairs, or in small clusters.** Usually not encapsulated. **Gram negative.** Nonsporeforming and nonmotile. **Aerobic with a strictly respiratory metabolism.** ***N*-oxides** such as nitrate, nitrite, and nitrous oxide **can be used as terminal electron acceptors** for respiration under anaerobic conditions. **Nitrate is reduced to N_2** via nitrite, nitric oxide, and nitrous oxide (denitrification). Oxidase and catalase positive. **Chemoorganotrophic growth** occurs with a wide variety of organic compounds as carbon source. **Chemolithoautotrophic growth** occurs with CO_2 as carbon source, and H_2, methanol, methylamine, or thiosulfate as the electron-donating free-energy source. **Occur in water, soil, sewage, and sludge.**

The mol% G + C of the DNA is: 64–67.

Type species: **Paracoccus denitrificans** (Beijerinck and Minkman 1910) Davis 1969, 384 emend. Rainey, Kelly, Stackebrandt, Burghardt, Hiraishi, Kaayama and Wood 1999, 650 (*Micrococcus denitrificans* Beijerinck and Minkman 1910, 53.)

Further descriptive information

Paracoccus strains grow readily on ordinary media. No growth factors are required during heterotrophic growth. Colonies that are present on nutrient agar after 3 days incubation at 30°C are usually 2–4 mm in diameter, circular, smooth, low convex, moist, and opaque. The cells do not produce carotenoid pigments. The cell wall is of type II or III (Walther-Mauruschat et al., 1977) and its composition is typical for Gram-negative bacteria. It has a thickness of 25–55 nm. No special structures have been observed in response to changes in growth conditions (Kocur et al., 1968; Sleytr and Kocur, 1973; Walther-Mauruschat et al., 1977; Nokhal and Mayer, 1979). During growth with an excess of carbon or energy source, intracellular granules of poly-β-hydroxybutyrate (PHB) are set aside as reserve for carbon and energy. PHB enhances the viability of resting cells. No extracellular hydrolysis of PHB occurs.

Quinones The presence of ubiquinone-10 is a very characteristic feature of all bacteria belonging to this group (for references see Stouthamer, 1992). In general, ubiquinone-8 is characteristic for the *Betaproteobacteria* and ubiquinone-9 for the *Gammaproteobacteria.* The nature of the respiratory quinone is therefore an important chemotaxonomic trait.

Fatty acid analyses Fatty acid methyl ester analyses of members of the genus have shown that strain LMD 22.21 and relatives cluster together, while *P. denitrificans* GB17 and strain LMD 52.44 are well separated (Baker et al., 1995). Approximately 80% of the total fatty acids is oleic acid (Wilkinson et al., 1972). The predominant phospholipid is phosphatidylglycerol (52%) The

remaining phospholipids are mostly phosphatidylcholine (31%), phosphatidylethanolamine (5.8%), and cardiolipin (3.2%). Lipid A analyses confirm not only the present taxa of the purple nonsulfur bacteria (formerly *Rhodospirillaceae*), but also the phylogenetic relatedness of distinctly phototrophic to distinctly nonphototrophic bacteria, as was suggested by cataloging of 16S rRNA. For example, lipid A in lipopolysaccharides with ester-bound $C_{10:0\ 3OH}$ and the rare amide-linked $C_{14:0\ 3\ OXO}$ is common to the phototrophic *Rhodobacter capsulatus* and *Rhodobacter sphaeroides* and also to *P. denitrificans* and *P. versutus* (Weckesser and Mayer, 1988).

Metabolism Members of *Paracoccus* are versatile organisms that can adapt their metabolism to the prevailing environmental conditions (Stouthamer, 1980; Van Verseveld and Stouthamer, 1992; Van Spanning et al., 1995). They are nonfermentative, and they do not produce extracellular xenobiotics or metabolites. A wide variety of organic compounds may serve as sole carbon and free-energy sources during heterotrophic growth, including D-glucose, D-fructose, sucrose, trehalose, mannose, succinate, mannitol, choline, acetate, propionate, lactate, pyruvate, malonate, butyrate, malate, citrate, gluconate, *p*-hydroxybenzoate, histidine, leucine, proline, serine, asparagine, glutamine, ethanol, propanol, butanol, glycerol, and sorbitol (Vogt, 1965; Davis et al., 1969; Pichinoty et al., 1977c). No growth occurs on xylose, rhamnose, starch, gelatin, glycogen, lactose, cellulose, benzoate, phenol, tryptophan, arginine, threonine, ethanolamine, or urea. All enzymes of the tricarboxylic acid cycle are present in *Paracoccus*. Glucose is metabolized by the Entner–Douderoff pathway, by the hexose monophosphate pathway (Forget and Pichinoty, 1965), or by a combination of the two. The glycolytic pathway is absent (Slabas and Whatley, 1977).

During autotrophic growth, H_2, methanol, methylamine, carbon disulfide (Jordan et al., 1997), or thiosulfate (Friedrich and Mitrenga, 1981) can be used as free-energy sources. Oxidation of methanol is catalyzed by methanol dehydrogenase, a periplasmic enzyme encoded by the *mxa* gene cluster. The enzyme contains pyrroloquinoline quinone (PQQ) as a prosthetic group. Methylamine is oxidized by methylamine dehydrogenase, a periplasmic enzyme with a tryptophan tryptophyl quinone (TTQ) as prosthetic group. The enzyme is encoded by the *mau* gene cluster. The oxidation product of methanol and methylamine is formaldehyde, which is further oxidized via formate to CO_2 in the cytoplasm by formaldehyde and formate dehydrogenases. *Paracoccus* uses the Calvin cycle to fix CO_2 during autotrophic growth (Kornberg et al., 1960), and during carbon-limited mixed autotrophic/heterotrophic growth (Van Verseveld et al., 1979). Population analysis in a denitrifying methanol-fed sand filter in a municipal wastewater treatment plant revealed that 3.5% of the total cell counts corresponded to a *Paracoccus* sp., whereas in a parallel sand filter without methanol feed and no detectable denitrification only very few *Paracoccus* spp. could be detected (Neef et al., 1996). These observations indicate that autotrophic denitrifying conditions could provide the natural environmental niche for *P. denitrificans*, even though it has been difficult to grow axenic cultures under these conditions. *P. denitrificans* GB17 (formerly *Thiosphaera pantotropha*) differs from other strains by lacking the capacity to grow with methanol. However, methanol-utilizing mutants of GB17 have been isolated (Egert et al., 1993; Moir and Ferguson, 1993; Ras et al., 1995). In these GB17 mutants, methanol is oxidized by an altered ethanol dehydrogenase (Ras et al., 1995).

Two major pathways for the oxidation of thiosulfate exist in microorganisms (Kelly et al., 1997; Friedrich, 1998). In the first pathway, called the *Paracoccus* sulfur oxidation pathway, tetrathionate is not an intermediate. In the other pathway, tetrathionate is a free intermediate in the oxidation process. The first pathway is present in *P. versutus* and *P. denitrificans*. *Rhodobacter capsulatus* and *Rhodobacter sphaeroides* cannot oxidize thiosulfate (Imhoff and Trüper, 1992). Other *Rhodobacter* spp. and *Rhodopseudomonas palustris* can oxidize thiosulfate and possibly use the same type of enzyme as *P. denitrificans*. Recently the gene for sulfite dehydrogenase was cloned from *P. denitrificans* GB17 and was shown to be essential for thiosulfate oxidation (Wodara et al., 1997).

P. denitrificans is sensitive to potassium cyanide. Three cytochrome oxidases, ba_3, cbb_3, and aa_3 (de Gier et al., 1994) have been detected in *P. denitrificans*. The reduction of oxygen is coupled to the translocation of protons in the aa_3-type (van Verseveld et al., 1981) and ba_3-type (Puustinen et al., 1989; Richter et al., 1994) oxidases. The proton-pumping capacity of the cbb_3-type is still a matter of debate (de Gier et al., 1994; Raitio and Wikström, 1994).

Gases other than CO_2 produced by *Paracoccus* are nitric oxide, nitrous oxide, and dinitrogen during denitrification.

In the absence of oxygen, nitrate can serve as terminal electron acceptor for respiration. Nitrate is then reduced via nitrite, nitric oxide, and nitrous oxide, by the corresponding reductases (Boogerd et al., 1981; Timkovich et al., 1982; Snyder and Hollocher, 1987).

P. denitrificans is able to express two different types of nitrate reductase. One is membrane bound, encoded by the *narGHJI* gene cluster, and expressed during the shift from aerobic to anaerobic growth. The enzyme has its catalytic center facing the cytoplasm and has the ability to reduce chlorate as well. *In vivo*, both methyl and benzylviologens may act as electron donors to this enzyme. The other nitrate reductase is located in the periplasm, and is encoded by the *nap* operon. It is expressed independently of the oxygen concentration. This enzyme is unable to reduce chlorate. Both nitrate reductases carry molybdenum in their catalytic pocket.

Nitrite reductase is a periplasmic enzyme of the cd_1-type (Timkovich et al., 1982). It consists of two identical subunits of about 63 kDa, each subunit harboring one heme *c* and one heme d_1 (Moir et al., 1993). The X-ray structure shows that the two types of heme are located in separate domains (Fulop et al., 1993).

Nitric oxide reductase is a membrane-bound enzyme consisting of two subunits. The prosthetic groups are heme *c*, found in the small subunit, and two hemes *b* and a non-heme iron, found in the large subunit (Girsch and De Vries, 1997). With respect to its architecture and putative metal ligands, the latter subunit resembles subunit I of terminal heme-copper oxidases (Saraste and Castresana, 1994; Van der Oost et al., 1994).

Nitrous oxide reductase is a copper-containing dimeric enzyme found in the periplasm (Snyder and Hollocher, 1987). Studies on its counterpart in *Pseudomonas stutzeri* suggest that each monomer contains approximately four copper ions. Two of these form a binuclear copper center structurally similar to that of Cu_A in cytochrome *c* oxidases (Farrar et al., 1994).

The optimal pH for denitrification is between 7.0 and 8.5 and the optimal temperature is between 30 and 37°C. The rate of denitrification can be enhanced by adding a small amount of yeast extract.

P. denitrificans is susceptible to ampicillin, tetracycline, streptomycin, kanamycin, erythromycin, chloramphenicol, rifampi-

cin, and gentamicin. *P. denitrificans* is resistant to trimethoprim. Unable to fix nitrogen. There is no antigenic scheme available for *Paracoccus* species.

Paracoccus can use ammonium or nitrate as nitrogen sources. During oxidation of methylamine, the cell can use the released ammonia as nitrogen source. Two pathways serve for assimilation of ammonia in *P. denitrificans*, one with glutamate dehydrogenase operating at high ammonia concentrations, the other with glutamate-ammonia ligase and glutamate synthase at low concentrations (Mikes et al., 1991).

The distribution of metabolic systems among various selected species of the *Alphaproteobacteria* has been reviewed by Stouthamer (1992). Table BXII.α.67 is an update of the results from this publication. The division of the *Alphaproteobacteria* into subgroups is as given by Stouthamer (1992). When a property occurs only in some of the strains of a species, this is indicated in Table BXII.α.67 as "+". It is evident from Table BXII.α.67 that several pathways are very common in these bacteria. Denitrification, nitrogen fixation, hydrogenase formation, autotrophic CO_2 fixation by ribulose bisphosphate carboxylase, and methylotrophy are widespread, but others are very characteristic for but not limited to *Paracoccus*, such as heterotrophic nitrification, aerobic denitrification, and thiosulfate oxidation.

The physiological differences between *P. denitrificans* and *P. pantotrophus* are less fundamental than previously thought (Stouthamer et al., 1997). Heterotrophic nitrification was originally thought to be present only in strain GB17 but was later also detected in other *P. denitrificans* strains (Crossman et al., 1995). The key enzyme in this process, ammonia monooxygenase (AMO), has recently been purified from *P. denitrificans* (Moir et al., 1996a). The enzyme has a number of similarities with the AMO of the chemolithotrophic bacterium *Nitrosomonas europaea*. The hydroxylamine oxidase of *P. denitrificans* is completely different from that of *N. europaea* (Wehrfritz et al., 1993; Moir et al., 1996b) and donates electrons to the cytochrome bc_1 complex. The process of heterotrophic nitrification is thus a process that differs in a large number of aspects from chemolithotrophic nitrification.

Recently the influence of carbon source on aerobic denitrification has been studied with chemostat cultures of *P. denitrificans*. The occurrence of aerobic denitrification was found to be strongly stimulated by growth with reduced substrates, e.g., bu-

[f]All methanotrophs also oxidize ammonia to nitrite.

tyrate (Sears et al., 1997), suggesting that the process is used to increase the capacity for electron transfer.

Genetic aspects The molecular genetics of *P. denitrificans* have been studied in greater detail in the last decade and these efforts have been summarized in detail in Baker et al. (1998).

The *P. denitrificans* Pd1222 genome harbors at least five copies of an insertion sequence IS1248. In addition, two copies of an element referred to as an integration region have been reported (Van Spanning et al., 1995).

In three strains of *P. denitrificans*, DSM 65, DSM 413, and DSM 415, large plasmids of molecular mass greater than 300×10^6 Da were resolved (Gerstenberg et al., 1982). *P. denitrificans* DSM 413 has three chromosomes of 1.83, 1.16, and 0.67 Mbp (Winterstein and Ludwig, 1998). The two smaller chromosomes were suggested to be linear molecules. Essential genes coding for respiratory enzymes were found distributed over all three chromosomes without any obvious clustering on any of the three molecules. The total genomic size of *P. denitrificans* of 3.66 Mbp is in agreement with an earlier estimate using a different approach (Nokhal and Schlegel, 1983). Mutations have been introduced randomly by chemical mutagenesis methods (Harms et al., 1996) or by locus-specific gene exchange techniques (Van Spanning et al., 1991). Strain Pd1222, a derivative of DSM 413, was selected from the results of a mutagenesis approach for enhanced frequencies of conjugation. This mutant had defects in two restriction modification systems and is widely used as host in gene cloning and transposon mutagenesis experiments.

Enrichment and Isolation Procedures

The majority of *Paracoccus* strains can be enriched by culturing soil or mud samples in media containing CO_2 as carbon source and hydrogen, methanol, or methylamine as the free-energy source. The preferred electron acceptor under these growth conditions is oxygen. With nitrate, growth is very slow or absent (Vogt, 1965). Alternatively, *Paracoccus* can be enriched in anaerobic media supplemented with a heterotrophic carbon and energy source and nitrate as terminal electron acceptor, or in liquid minimal medium containing tartrate or succinate incubated under a nitrous oxide atmosphere (Pichinoty et al., 1977a, b, c). These approaches may not always be successful for the isolation of *P. denitrificans* because it is not one of the major denitrifiers in all types of soil (Gamble et al., 1977). *P. denitrificans* GB-17 can be isolated from wastewater and sulfide-rich ecosystems.

Maintenance Procedures

Stock cultures of *Paracoccus* strains can be maintained at room temperature in any rich agar-containing medium with Brain Heart Infusion (BHI, Difco) or Nutrient Broth (Difco) and 0.3% agar, pH 7.0. The cultures remain viable up to a year without subculturing if they are sealed with a rubber stopper or a cork that has been soaked in hot paraffin wax. Cultures survive for at least five years when frozen at −70°C in media to which 10–20% (w/v) glycerol has been added. Strains may also be preserved indefinitely by lyophilization.

Procedures for Testing Special Characters

In general, cultivation of *Paracoccus denitrificans* is possible in any size of bottle or glass fermenter. The organism has been studied exhaustively during continuous cultivation in the chemostat and the retentostat (chemostat with 100% biomass retention) (Jones et al., 1977; Meijer et al., 1977; Van Verseveld and Stouthamer, 1978; Van Verseveld et al., 1979, 1986). A medium widely used for large-scale cultivation is that described by Chang and Morris (1962). Sometimes it is necessary to add a trace elements solution (Boogerd et al., 1983). During autotrophic growth, 0.01% yeast extract and 0.05% sodium bicarbonate are added to initiate growth (Van Verseveld and Stouthamer, 1978).

Differentiation of the genus *Paracoccus* from other genera

Table BXII.α.67 indicates the differential characteristics of *Paracoccus*.

Taxonomic Comments

The type strain *Paracoccus denitrificans* ATCC 17741 (Davis et al., 1969), formerly designated *Micrococcus denitrificans*, was first isolated by Beijerinck (Beijerinck and Minkman, 1910; Nokhal and Schlegel, 1980). The following species have been regarded as close relatives of *Paracoccus denitrificans* and are placed in the same genus on the basis of 16S rRNA gene sequence analyses and DNA–DNA hybridization: *P. pantotrophus* (formerly designated *Thiosphaera pantotropha*) and *P. versutus* (formerly designated *Thiobacillus versutus*; Katayama et al., 1995). The recently isolated species *P. kocurii* (Ohara et al., 1990), *P. alcaliphilus* (Urakami et al., 1989b), *P. aminophilus* (Urakami et al., 1990b), *P. aminovorans* (Urakami et al., 1990b), *P. thiocyanatus* (Katayama et al., 1995), *P. solventivorans* (Siller et al., 1996), *P. marcusii* (Harker et al., 1998), *P. alkenifer* (Lipski et al., 1998), and *P. carotinifaciens* (Tsubokura et al., 1999) have also been placed in the genus *Paracoccus*. *P. halodenitrificans* has been moved from the genus *Paracoccus* into the genus *Halomonas* (Dobson and Franzmann, 1996).

The *c*-type cytochrome and protein profiles were compared for a number of cultures of *P. denitrificans* obtained from a range of culture collections. The cultures fell into two groups corresponding to the two original isolates of this bacterial species. Members of one group, which included NCIMB 8944, ATCC 13543, ATCC 17741, ATCC 19367, Pd 1222, and DSM 413, were similar or identical to LMD 22.21. The second group, including DSM 65 and LMG 4218, were similar or identical to LMD 52.44 (Goodhew et al., 1996). These groupings were not compatible with the recorded history of culture deposition. Mass spectrometry and amino acid sequence comparisons showed that the cytochrome c_{550} of the LMD 52.44 culture group differed by 16% from that of the LMD 22.21 group, and yet there was only 1% difference from the cytochrome c_{550} of *Thiosphaera pantotropha*. These results suggest that consideration should be given to creation of a new species of *P. pantotrophus*, which would include *Thiosphaera pantotropha* and *P. denitrificans* LMD 52.44. At the moment, *P. denitrificans* and *T. pantotropha* are combined in the *Paracoccus* genus (Ludwig et al., 1993), since the nucleotide sequence of the 16S rRNA genes of these latter two organisms was found to be the same.

Additional strains have been isolated in independent studies. Eleven strains were isolated by (Nokhal and Schlegel, 1983) and analyzed based on 235 characteristics. Together with DSM 413 and DSM 415, these strains were placed into four subgroups with similarities ranging from 74 to 88%. This grouping was in accordance with that deduced from DNA–DNA reassociation kinetics (Auling et al., 1980).

The genus *Paracoccus* belongs to the α-subdivision of nonsulfur purple bacteria, the so-called *Alphaproteobacteria* (Woese, 1987), and encompasses 13 defined species that have been included in the Validation Lists. Members of the genus *Paracoccus* fall in the

Rhodobacter group of the *Alphaproteobacteria*. Nearest neighbors are *Rhodobacter*, *Amaricoccus*, *Octadecabacter*, *Rhodovulum*, *Roseobacter*, *Sagittula* and *"Tetracoccus"*. They share a number of properties with *Paracoccus*, including the ability to grow anaerobically with nitrate. The resemblance of the respiratory networks is striking, and most components of the pathways show structural homology to one another. Analyses of 23S and 16S rRNA gene sequences indicated a close relationship to *Rhodobacter capsulatus* (Fox et al., 1980), suggesting that this organism and *Paracoccus denitrificans* arose from a common ancestor, after which it lost the genes encoding the photosynthetic apparatus. In addition, the amino acid sequence of cytochrome c_{550} from *P. denitrificans* most closely resembles that of cytochrome c_2 from *R. sphaeroides* and *R. capsulatus* (Dickerson, 1980a).

Differentiation of the species of the genus *Paracoccus*

The differential and other characteristics of the species of *Paracoccus* are indicated in Table BXII.α.68.

[a]For symbols see standard definitions.

[b]Recently, three additional species of *Paracoccus* have been described: *Paracoccus kondratievae* (Doronina and Trotsenko, 2000, 2001a), *Paracoccus seriniphilus* (Pukall et al., 2003), and *Paracoccus zeaxanthinifaciens* (Berry et al., 2003).

[c]Requires vitamin B_{12} (Doronina et al., 1998b).

List of species of the genus Paracoccus

1. **Paracoccus denitrificans** (Beijerinck and Minkman 1910) Davis 1969, 384 emend. Rainey, Kelly, Stackebrandt, Burghardt, Hiraishi, Kaayama and Wood 1999, 650 (*Micrococcus denitrificans* Beijerinck and Minkman 1910, 53.)
de.ni.tri'fi.cans. L. prep. *de* away from; L. n. *nitrum* soda; M.L. *nitrum* nitrate; M.L. v. *denitrifico* denitrify; M.L. part. adj. *denitrificans* denitrifying.

The description is as given for the genus and in Table BXII.α.68, with the following additional features. Cells are rod shaped, 0.4–0.5 × 1.1–1.7 µm, occurring singly or in pairs. Sometimes motile with a tuft of flagella. The optimal growth temperature is 30–37°C; the optimal pH for growth is 7.5–8. Electron acceptors are oxygen and nitrate. N_2 is produced from nitrate from respiration. S^0 is oxidized slowly. Tetrathionate and thiocyanate do not support growth. In addition to those mentioned in Table BXII.α.68, glycine, L-alanine, L-valine, L-leucine, L-isoleucine, L-threonine, L-cysteine, L-phenylalanine, L-tyrosine, L-histidine, L-aspartate, L-asparagine, L-glutamate, L-glutamine, L-lysine, L-arginine, L-ornithine, L-cellobiose, adipate, tartrate, sarcosine, creatine, *m*-hydroxybenzoate, *p*-hydroxybenzoate, glycerate, formaldehyde, lactate, and butyrate can serve as energy and carbon sources, but cyclohexanol, L-methionine, L-tryptophan, *p*-aminobenzoate, and DL-mandelate do not. Some strains can grow with carbon disulfide as sole source of carbon and energy. Some if not all strains contain megaplasmids of at least 450 kb in size. For other variations between strains, see Nokhal and Schlegel (1983), Urakami et al. (1989b), and Rainey et al. (1999).

The mol% G + C of the DNA is: 64–67 (T_m).

Type strain: ATCC 17741, DSM 65, DSM 413, LMD 22.21, LMG 4218.

GenBank accession number (16S rRNA): Y16927, Y16935, D13480, Y16928, X69159.

2. **Paracoccus alcaliphilus** Urakami, Tamaoka, Suzuki and Komagata 1989b, 118[VP]
al.ca.li.phi'lus. M.L. n. *alcali* from Arabic *al* end; *qaliy* soda ash; Gr. adj. *philum* loving; M.L. adj. *alcaliphilus* liking alkaline media.

The description is as given for the genus and in Table BXII.α.68, with the following additional features. Cells are coccoid or rod like, 0.5–0.9 × 0.9–2.0 µm occurring singly, in pairs, or in clusters. Light-scattering PHB inclusions are evident. The preferred electron acceptor is oxygen. Nitrite is produced from nitrate, but nitrate respiration is not performed. See Table BXII.α.68 for use of energy sources. Biotin is required for growth on minimal media. Optimal growth temperature, 30°C ; optimal pH for growth, 8–9. NaCl is inhibitory at concentrations >3%. Isolated from wastewater (activated sludge).

The mol% G + C of the DNA is: 64–66 (T_m).

Type strain: TK 1015, ATCC 51199, DSM 8512, JCM 7364.

GenBank accession number (16S rRNA): D32238.

3. **Paracoccus alkenifer** Lipski, Reichert, Reuter, Spröer and Altendorf 1998, 535[VP]
al.ke'ni.fer. M.L. n. *alkenum* unsaturated hydrocarbons; L. suff. *-fer* carrying; M.L. adj. *alkenifer* referring to the occurrence of unusual monounsaturated fatty acids in whole-cell hydrolysates.

The description is as given for the genus and in Table BXII.α.68, with the following additional features. Cells are coccoid or rod like, 0.4–0.6 × 0.9–1.7 µm. Nitrate is reduced to N_2. See Table BXII.α.68 for use of energy sources. Carbohydrates and amines are not utilized. Lactate, butyrate, hydroxybutyrate, asparagine, and acetone are utilized. Optimal growth temperature, 30°C; optimal pH for growth, 6–9. Isolated from biofilters used in treatment of waste gas from an animal rendering plant.

The mol% G + C of the DNA is: not reported.

Type strain: A901/1, DSM 11593.

GenBank accession number (16S rRNA): Y13827.

4. **Paracoccus aminophilus** Urakami, Araki, Oyanagi, Suzuki and Komagata 1990b, 289[VP]
a.mi.no'phi.lus. M.L. n. *aminum* amine; Gr. adj. *phila* loving; M.L. adj. *aminophilus* amine loving.

The description is as given for the genus and in Table BXII.α.68, with the following additional features. Cells are coccoid or rod like, 0.5–0.9 × 0.9–2.0 µm, occurring singly, in pairs, or in clusters. Light-scattering PHB inclusions are evident. The preferred electron acceptor is oxygen. Nitrite is produced from nitrate, but nitrate respiration is not performed. See Table BXII.α.68 for use of energy sources. Thiamine is required for growth on minimal media. NaCl is inhibitory at concentrations >3%. Optimal growth temperature, 30°C; optimal pH for growth, 6.5–8.0. Isolated from soil.

The mol% G + C of the DNA is: 68.5 (HPLC) or 70 (T_m).

Type strain: DM-15, ATCC 49673, DSM 8538, JCM 7686.

GenBank accession number (16S rRNA): D32239.

5. **Paracoccus aminovorans** Urakami, Araki, Oyanagi, Suzuki and Komagata 1990b, 289[VP]
a.mi.no'vo.rans. L. n. *aminum* amine; L. v. *voro* to eat, devour; L. part. adj. *vorans* eating; *aminovorans* amine eating.

The description is as given for the genus and in Table BXII.α.68, with the following additional features. Cells are coccoid or rod like, 0.5–0.9 × 0.9–2.0 µm, occurring singly, in pairs, or in clusters. Light-scattering PHB inclusions are evident. The preferred electron acceptor is oxygen. Nitrite is produced from nitrate, but nitrate respiration is not performed. See Table BXII.α.68 for use of energy sources. Thiamine is required for growth on minimal media. NaCl is inhibitory at concentrations >3%. Optimal growth temperature is 30–37°C; optimal pH for growth, 7–8. Isolated from soil.

The mol% G + C of the DNA is: 67-68 (T_m).

Type strain: DM-82, ATCC 49632, DSM 8537, JCM 7685.

GenBank accession number (16S rRNA): D32240.

6. **Paracoccus carotinifaciens** Tsubokura, Yoneda and Mizuta 1999, 281[VP]
ca.ro.ti.ni.fa'ci.ens. M.L. neut. n. *carotinum* carotene; L. part. adj. *faciens* making, producing; M.L. part. adj. *carotinifaciens* carotene/carotenoid-producing.

The description is as given for the genus and in Table BXII.α.68, with the following additional features. Cells are rod shaped, 0.3–1.0 × 1.0–5.0 µm. Motile by means of peritrichous flagella. Cells are elongated or swollen at the early stage of growth with 1% yeast extract present in liquid me-

dium. Nitrate is not reduced. Produces astaxanthin. Colonies are orange to red. Optimal growth temperature, 25–30°C, no growth at 37°C; optimal pH for growth, 8–9. Isolated from soil.

The mol% G + C of the DNA is: 67 (T_m).

Type strain: E-396, IFO 16121.

7. **Paracoccus kocurii** Ohara, Katayama, Tsuzaki, Nakamoto and Kuraishi 1990, 293[VP]

ko.cu′ri.i. M.L gen. n. *kocurii* of Kocur; named after Miloslav Kocur, Czechoslovakian bacteriologist.

The description is as given for the genus and in Table BXII.α.68, with the following additional features. Cells are rod shaped, 0.5–0.8 × 0.7–1.1 µm, occurring singly or in pairs. Light-scattering PHB inclusions are evident. The preferred electron acceptor is oxygen. Nitrogen is produced from nitrate. In addition to those mentioned in Table BXII.α.68, *n*-butyrate and lactate can serve as carbon and energy sources, but cyclohexanol, glycine, L-alanine, L-valine, L-leucine, L-isoleucine, L-threonine, L-cysteine, L-methionine, L-phenylalanine, L-tyrosine, L-histidine, L-tryptophan, L-aspartate, L-asparagine, L-glutamate, L-glutamine, L-lysine, L-arginine, L-ornithine, L-cellobiose, adipate, tartrate, *p*-hydroxybenzoate, *p*-aminobenzoate, and DL-mandelate do not. Thiamine is required for growth on minimal media. NaCl is inhibitory in concentrations at or above 3%. Optimal growth temperature, 25–30°C; optimal pH for growth, 6.6–8.2. Isolated from wastewater (activated sludge).

The mol% G + C of the DNA is: 71 (T_m).

Type strain: B, ATCC 49631, DSM 8536, JCM 7684.

GenBank accession number (16S rRNA): D32241.

8. **Paracoccus marcusii** Harker, Hirschberg and Oren 1998, 547[VP]

mar.cu′si.i. N.L. adj. *marcusii* referring to the late Menashe Marcus, an Israeli geneticist.

The description is as given for the genus and in Table BXII.α.68, with the following additional features. Cocci to short rods, 1–2 × 1.0–1.5 µm, occurring in pairs or short chains. Colonies are bright orange, due to the accumulation of carotenoids, including astaxanthin. Grows on a wide range of carbon sources. In addition to those mentioned in Table BXII.α.68, cellobiose, lactose, melibiose, gentiobiose, glucuronic acid, galacturonic acid, erythritol, xylitol, adonitol, arabitol, propionate, *cis*-aconitate, malonate, and alanine can serve as carbon and energy sources, but fucose, rhamnose, raffinose, starch, glycogen, *N*-acetylglucosamine, *N*-acetylgalactosamine, α-glycerolphosphate, glucose-1-phosphate, glucose-6-phosphate, 2,3-butanediol, Tween 40 and 80, asparagines, aspartate, glutamate, histidine, leucine, ornithine, phenylalanine, proline, serine, threonine, inosine, uridine, and thymidine do not. Weak growth in 6% NaCl. No growth at NaCl >8%. Optimal growth temperature, 25–30°C, weak growth at 35°C; optimal pH for growth, 7. Isolated as a contaminant on agar plates.

The mol% G + C of the DNA is: 66 (HPLC).

Type strain: MH1, DSM 11574.

9. **Paracoccus methylutens** Doronina, Trotsenko, Krausova and Suzina 1998c, 1083[VP] (Effective publication: Doronina, Trotsenko, Krausova and Suzina 1998b, 235.)

me.thyl.u′tens. M.L. neut. n. *methylum* methyl compound; L. part. adj. *utens* using; *methylutens* using methyl groups.

The description is as given for the genus with the following additional features. It is a facultative methylotrophic species capable of growth on dichloromethane, methanol, methylamine, and formate, but not formaldehyde. Nitrate is reduced to nitrite. Grows on a wide range of organic substrates, but not on acetamide, rhamnose, raffinose, or trehalose. Its major fatty acid is $C_{18:1\ \omega7}$.

The mol% G + C of the DNA is: 67 (T_m).

Type strain: DM12, VKM B-2164.

10. **Paracoccus pantotrophus** (Robertson and Kuenen 1984) Rainey, Kelly, Stackebrandt, Burghardt, Hiraishi, Katayama and Wood 1999, 650[VP] (*Thiosphaera pantotropha* Robertson and Kuenen 1984, 91.)

pan.to′troph.us. Gr. pre. *panto* all; Gr. n. *trophos* feeder; M.L. adj. *pantotrophus* omnivorous.

The description is as given for the genus and in Table BXII.α.68, with the following additional features. Cocci occurring singly, in pairs, or short chains. In addition to those mentioned in Table BXII.α.68, fumarate can be used as electron acceptor, acetoin is produced, grows on adipate, propionate, acetone, propane-1,2-diol, isopropanol, glutamate, isoleucine, leucine, alanine, histidine, proline, propanol, acetol, and propionaldehyde, and does not grow on pimelate, methylacetate, methyl ethyl ketone, propylene oxide, dulcitol, and glycogen. Autotrophic growth on sulfide, thiosulfate, and hydrogen under both aerobic and denitrifying conditions by the type strain. All three substrates can be used for mixotrophic growth. Some strains are capable of aerobic denitrification. Some strains are capable of aerobic growth on methanol and formate. Some strains contain plasmids of 85–110 kb in size and megaplasmids greater than 450 kb in size. Optimal growth temperature, 37°C (range 15–42°C); optimal pH for growth, 8 (range 6.5–10.5). Isolated from a sulfide-oxidizing, effluent treatment pilot plant.

The mol% G + C of the DNA is: 66 (T_m).

Type strain: ATCC 35512, DSM 2944 , LMD 82.5.

GenBank accession number (16S rRNA): Y16933.

11. **Paracoccus solventivorans** Siller, Rainey, Stackebrandt and Winter 1996, 1129[VP] emend. Lipski, Reichert, Reuter, Spröer and Altendorf 1998, 535.

sol.ven.ti.vo′rans. L. v. *solvo* melt, free; M.L. neut. n. *solventum* solvent; L. v. *voro* to eat, devour; L. part. adj. *vorans* eating; *solventivorans* solvent-eating.

The description is as given for the genus and in Table BXII.α.68, with the following additional features. This organism has a Gram-negative cell wall architecture, but the Gram stain reaction is variable. Cells are coccoid or rod like, 0.4–0.5 × 0.9–1.5 µm. Light-scattering PHB inclusions are evident. NaCl is inhibitory at concentrations >0.2%. Optimal growth temperature, 30–37°C; optimal pH for growth, 7–8. No vitamin addition is required. The electron acceptors are oxygen and nitrate. N_2 is produced from nitrate from respiration. Acetone is oxidized to CO_2 and metabolized to PHB. Besides acetone and in addition to Table BXII.α.68, 2-butanone, 2-propanol, fumarate, glutamate, aspartate, asparagine, α-ketoglutarate, isoleucine, glycine, propionate, *n*-butyrate, 3-hydroxybutyrate, acetoacetate, and Casamino Acids (Difco) can serve as carbon and energy sources. Many other substrates are not utilized. Acetone is degraded via acetoacetate.

The mol% G + C of the DNA is: 68.5 (HPLC) or 70 (T_m).
Type strain: L1, DSM 6637.
GenBank accession number (16S rRNA): Y07705.

12. **Paracoccus thiocyanatus** Katayama, Hiraishi and Kuraishi 1996, 625[VP] (Effective publication: Katayama, Hiraishi and Kuraishi 1995, 1475.)
thi.o.cy.a'na.tus. Gr. n. *thium* sulfur; Gr. n. *kyanos* dark blue; M.L. adj. *thiocyanatus* referring to the ability to use thiocyanate.

The description is as given for the genus and in Table BXII.α.68, with the following additional features. Cells are rod shaped, 0.5–0.7 × 0.8–1.3 µm, occurring singly or in pairs. Polyhedral inclusion bodies (carboxysomes) are absent in cells. Optimal growth temperature, 30–35°C; optimal pH for growth, 7.0–8.5. The addition of thiamine is required for growth in minimal media. The electron acceptors are oxygen and nitrate. N_2 is produced from nitrate from respiration. Thiocyanate is oxidized to CO_2. S^0 is oxidized slowly. Thiosulfate is oxidized to tetrathionate by chemoorganotrophically grown cells or to sulfate by thiocyanate-grown cells. Tetrathionate does not support growth. The organism is catalase and oxidase positive. Besides thiocyanate and in addition to those mentioned in Table BXII.α.68, L-alanine, L-serine, L-leucine, L-isoleucine, L-glutamate, L-proline, L-histidine, L-phenylalanine, propionate, *n*-butyrate, glutarate, *m*-hydroxybenzoate, and *p*-hydroxybenzoate serve as carbon and energy sources, but L-aspartate, L-tryptophan, L-cysteine, cellobiose, cyclohexanol, oxalate, adipate, pimelate, *o*-hydroxybenzoate, *p*-aminobenzoate, and DL-mandelate do not.

The mol% G + C of the DNA is: 66.5 (HPLC) or 67.6 (T_m).
Type strain: THI 011, IAM 12816, IFO 14569.

13. **Paracoccus versutus** (Harrison 1983) Katayama, Hiraishi and Kuraishi 1996, 625[VP] (Effective publication: Katayama, Hiraishi and Kuraishi 1995, 1476) (*Thiobacillus versutus* Harrison 1983, 216.)
ver.su'tus. L. adj. *versutus* versatile.

Cells are rod shaped, 0.4–0.5 × 1.1–1.7 µm, occurring singly or in pairs. Nonsporeforming. Motile with a tuft of flagella. Optimal growth temperature, 30–37°C; optimal pH for growth, 7.5–8.0. No vitamin addition is required. The electron acceptors are oxygen and nitrate. N_2 is produced from nitrate from respiration. S^0 is oxidized slowly. Tetrathionate and thiocyanate do not support growth. The organism is catalase and oxidase positive. In addition to those mentioned in Table BXII.α.68, L-alanine, L-serine, L-leucine, L-isoleucine, L-aspartate, L-glutamate, L-proline, L-histidine, L-phenylalanine, propionate, *n*-butyrate, 2-oxoglutarate, glutarate, *m*-hydroxybenzoate, and *p*-hydroxybenzoate serve as carbon and energy sources, but L-tryptophan, L-cysteine, cellobiose, cyclohexanol, oxalate, pimelate, *o*-hydroxybenzoate, *p*-aminobenzoate, and DL-mandelate do not.

The mol% G + C of the DNA is: 67–68 (T_m).
Type strain: A2, ATCC 25364, CCM 2505, DSM 582, IAM 12814.
GenBank accession number (16S rRNA): Y16932.

Genus XIII. **Rhodobaca** *Milford, Achenbach, Jung and Madigan 2001, 793[VP] (Effective publication: Milford, Achenbach, Jung and Madigan 2000, 25)*

JOHANNES F. IMHOFF

Rho.do.bac'ca. Gr. n. *rhodon* the rose; L. fem. n. *baca* berry; M.L. fem. n. *Rhodobaca* red (rose) berry.

Cells are ovoid or rod shaped, are motile by polar flagella, and divide by binary fission. **Gram negative; belong to the *Alphaproteobacteria*.** Phototrophically grown cells **form vesicular internal photosynthetic membranes**. The color of phototrophic cultures is yellow to yellow-brown, while aerobic cultures are pink to red. **Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spheroidene series.**

Photoheterotrophic growth occurs under anoxic conditions in the light with a variety of organic compounds as carbon and electron sources. **Chemotrophic growth occurs by aerobic respiration.** Growth factors are required.

Mesophilic bacterium with an elevated temperature optimal and best growth at alkaline pH and in the presence of low concentrations of mineral salts.

Habitats: alkaline soda lakes of low to moderate salinity.
The mol% G + C of the DNA is: 58.8.
Type species: **Rhodobaca bogoriensis** Milford, Achenbach, Jung and Madigan 2001, 793 (Effective publication: Milford, Achenbach, Jung and Madigan 2000, 25.)

FURTHER DESCRIPTIVE INFORMATION

In many phenotypic properties, *Rhodobaca bogoriensis* resembles *Rhodobacter* and *Rhodovulum* species. Characteristic properties that reflect adaptation to the natural environment, African soda lakes (Lake Bogoria, Kenya), are the high pH-optimal at pH 9 and the temperature optimal at 39°C (Milford et al., 2000). No growth occurs below 30°C. Good growth is from 0–6% NaCl with an optimum from 1–2%. *Rhodobaca bogoriensis* apparently is unable to fix dinitrogen and does not grow photoautotrophically, either with hydrogen or with sulfide as electron donors. Sulfide is oxidized to extracellular elemental sulfur (Milford et al., 2000). Spectral properties of whole cells indicate the presence of only one light-harvesting pigment complex (LHI, core antenna complex) unlike *Rhodobacter* and *Rhodovulum* species, but similar to bacteria such as *Rhodospirillum rubrum*, *Rhodobium marinum*, *Rhodocista centenaria*, *Rhodovibrio sodomense*, *Rhodospira trueperi*, and *Roseospirillum parvum*. The sequence of the 16S rDNA clearly distinguishes *Rhodobaca* from *Rhodobacter* and *Rhodovulum* species but also shows the association of this bacterium with these two genera in the *Alphaproteobacteria* (see Fig. 3 [p. 129] in the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A. Differentiating phenotypic characteristics are given in Table BXII.α.46 of the chapter on the genus *Rhodobacter*.)

Enrichment and Isolation Procedures

Standard media and techniques for enrichment and isolation of purple nonsulfur bacteria are suitable for *Rhodobaca* species (see chapter Genus *Rhodospirillum*). Media for the enrichment of *Rhodobaca* species should have alkaline pH and contain 1–6% mineral salts.

Maintenance Procedures

Cultures are well preserved by standard techniques in liquid nitrogen, by lyophilization or storage at −80°C in a mechanical freezer.

Differentiation of the genus *Rhodobaca* from other genera

Characteristic properties of *Rhodobaca* are the ovoid to rod-shaped cell morphology, the presence of vesicular internal membranes, and the content of carotenoids of the spheroidene series. All these properties are shared with *Rhodovulum* and *Rhodobacter* species. A clear differentiation of *Rhodobaca* from *Rhodobacter* and *Rhodovulum* species is possible based on 16S rDNA sequences (see Fig. 3 [p. 129] in the introductory chapter "Anoxygenic Phototrophic Purple Bacteria"., Volume 2, Part A. Differentiating phenotypic characteristics are given in Table BXII.α.46 of the chapter on the genus *Rhodobacter*.)

List of species of the genus Rhodobaca

1. **Rhodobaca bogoriensis** Milford, Achenbach, Jung and Madigan 2001, 793[VP] (Effective publication: Milford, Achenbach, Jung and Madigan 2000, 25.)
bo.go.ri.en′sis. M.L. fem. adj. *bogoriensis* pertaining to Lake Bogoria, a soda lake in Kenya, Africa.

Cells are ovoid to rod shaped, 0.8–1.0 × 0.8–1.5 μm. Cells are motile by means of polar flagella. Internal photosynthetic membranes appear as vesicles.

Cultures grown anaerobically in the light are yellow to yellowish brown. When grown in the presence of oxygen, the color turns to red. Absorption spectra of living cells show maxima at 376–378, 450–455, 478–480, 508–513, 590–592, 802–805, and 860–863 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spheroidene series, with demethylspheroidenone as major component.

Photoheterotrophic growth occurs anaerobically in the light with a variety of organic compounds. No evidence for photoautotrophic growth with H_2 or sulfide as electron donors. Chemoheterotrophic growth aerobically in the dark occurs at the full oxygen tension of air. Carbon sources supporting excellent phototrophic growth include acetate, pyruvate, malate, succinate, fumarate, butyrate, valerate, mannitol, heptanoate, xylose, glucose, fructose, and sucrose. Ammonia, aspartate, glutamate, asparagine, glutamine, and Casamino acids are used as nitrogen sources; N_2 fixation is absent. Sulfate assimilation is present. Biotin and thiamine are required as growth factors; vitamin B_{12} is growth stimulatory.

Mesophilic and alkaliphilic bacterium with optimal growth at pH 9.0 (range: 7.5–10.0), 39°C (range: 30–45°C), and in the presence of 1–2% NaCl.

Habitat: alkaline and saline soda lakes exposed to the light and with reduced oxygen concentrations.

The mol% G + C of the DNA is: 58.8 (T_m).

Type strain: LBB1, ATCC 700920.

GenBank accession number (16S rRNA): AF248638.

Genus XIV. Rhodovulum *Hiraishi and Ueda 1994a, 21*[VP]

Johannes F. Imhoff

Rho.do′ vu.lum. Gr. n. *rhodon* rose; L. dim. n. *ovulum* small egg; M.L. neut. n. *Rhodovulum* small red egg.

Cells are ovoid to rod shaped, are motile by means of flagella or nonmotile, and divide by binary fission. **Gram negative; belong to the *Alphaproteobacteria*.** Phototrophically grown cells **form vesicular internal photosynthetic membranes**. **Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spheroidene series.** The color of phototrophic cultures is yellow-green to yellow-brown, while aerobic cultures are pink to red. **Ubiquinone 10 is the major quinone. Major fatty acids are $C_{18:1}$ (predominant), $C_{18:0}$, and $C_{16:0}$.**

Cells grow preferably photoheterotrophically under anoxic conditions in the light. **Photoautotrophic growth may occur with sulfide, thiosulfate, hydrogen, and ferrous iron.** The final oxidation product of sulfide is sulfate. **Chemotrophic growth in the dark occurs under microoxic to oxic conditions and under anoxic conditions by fermentation and oxidant-dependent metabolism.** Polysaccharides, poly-β-hydroxybutyric acid, and polyphosphates may be present as storage products. Growth factors are required.

Mesophilic marine bacteria that require sodium chloride for growth.

Habitats: marine and hypersaline environments rich in organic matter, containing hydrogen sulfide, and exposed to the light.

The mol% G + C of the DNA is: 62.1–73.2.

Type species: **Rhodovulum sulfidophilum** (Hansen and Veldkamp 1973) Hiraishi and Ueda 1994a, 21 (*Rhodopseudomonas sulfidophila* Hansen and Veldkamp 1973, 55; *Rhodobacter sulfidophilus* Imhoff, Trüper, and Pfennig 1984, 342.)

Enrichment and Isolation Procedures

Standard techniques and media for the isolation of phototrophic bacteria in agar dilution series and on agar plates can be applied for *Rhodovulum* species, if appropriate concentrations of salts are included (see chapter Genus *Rhodospirillum*; Biebl and Pfennig, 1981; Imhoff, 1988; Imhoff and Trüper, 1992). Media containing 2–3% NaCl will be selective for *Rhodovulum* species. Under these conditions, enrichment cultures set up for purple nonsulfur bacteria will often yield *Rhodovulum* species as dominant members. Media for enrichment and isolation with organic substrates, or, for most species, autotrophic conditions with reduced sulfur compounds or hydrogen, may be chosen. Vitamins must be supplied. For *R. iodosum* and *R. robiginosum*, media with ferrous iron and containing 2.5–5% NaCl provide selective conditions.

Maintenance Procedures

Cultures are well preserved by standard techniques in liquid nitrogen, by lyophilization, or storage at −80°C in a mechanical freezer.

Differentiation of the genus *Rhodovulum* from other genera

Differentiation of the genera and species of *Rhodobacter*, *Rhodobaca*, and *Rhodovulum* is possible based on 16S rDNA sequences (see Fig. 3 [p. 129] in the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A, and by DNA–DNA hybridization. Differentiating phenotypic characteristics are given in Table BXII.α.46 of the chapter on the genus *Rhodobacter*.)

Taxonomic Comments

Species of this genus (*R. sulfidophilum*, *R. adriaticum*) have formerly been included in the genus *Rhodopseudomonas*. The recognition of morphologically and chemotaxonomically distinct characteristics and early phylogenetic analyses led to their separation from *Rhodopseudomonas* and classification in the genus *Rhodobacter* (Imhoff et al., 1984). With the availability of 16S rDNA sequences and additional species and isolates, it became apparent that the marine and halophilic species that depend on NaCl form a group phylogenetically separate from the freshwater species. Both groups were taxonomically separated and the marine species transferred to the new genus *Rhodovulum* (Hiraishi and Ueda, 1994a). The newly described *Rhodobacter euryhalinus* (Kompantseva, 1985) was also included in this new genus as *Rhodovulum euryhalinum*.

Differentiation of the species of the genus *Rhodovulum*

Characteristic properties to differentiate species of *Rhodovulum* are summarized in Tables BXII.α.69 and BXII.α.70.

List of species of the genus Rhodovulum

1. **Rhodovulum sulfidophilum** (Hansen and Veldkamp 1973) Hiraishi and Ueda 1994a, 21[VP] (*Rhodopseudomonas sulfidophila* Hansen and Veldkamp 1973, 55; *Rhodobacter sulfidophilus* Imhoff, Trüper, and Pfennig 1984, 342.)
sul.fi.do′phi.lum. M.L. n. *sulfidum* sulfide; Gr. adj. *philos* loving; M.L. adj. *sulfidophilum* sulfide loving.

Cells are ovoid to rod shaped, 0.6–0.9 × 0.9–2.0 μm, motile by means of polar flagella. Eventually, slime may be produced and short straight chains may be formed. Internal photosynthetic membranes appear as vesicles. Color of cell suspensions depends on the redox state of the culture and is from yellowish green through yellowish brown to dark brown and brown-red. In the presence of oxygen, cultures are red. Absorption spectra of living cells show maxima at 374–378, 451–455, 480–489, 508–512, 588–592, 800–805, and 850–855 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spheroidene series with spheroidene and hydroxyspheroidene, which are converted to their corresponding ketocarotenoids under oxic conditions and thereby cause the color change to red.

Preferentially grow photoheterotrophically under anoxic conditions in the light using a variety of organic compounds as carbon sources and electron donors. Photoautotrophic growth occurs with sulfide, thiosulfate, and molecular hydrogen as electron donors. Sulfide and thiosulfate are oxidized to sulfate without intermediary accumulation of elemental sulfur; elemental sulfur is oxidized slowly. In mineral media sulfide is tolerated up to 5–6 mM; in the presence of complex nutrients such as 0.01% yeast extract,

the tolerance is 7–8 mM. Chemotrophic growth is possible under oxic conditions in the dark. Carbon sources utilized are shown in Table BXII.α.70.

Ammonia and, in most strains, dinitrogen but not nitrate are used as nitrogen sources. Sulfate is assimilated and can serve as sole sulfur source under photoheterotrophic growth conditions and during growth with molecular hydrogen. In addition, sulfite, thiosulfate, cysteine and reduced glutathione are used as sulfur sources. Biotin, niacin, thiamine, and *p*-aminobenzoic acid are required as growth factors.

Mesophilic marine bacterium with optimal growth at pH 6.5–8.0 (with sulfide as electron donor) or at pH 5.0–7.5 (if grown with malate), 30–35°C, and 1–6% NaCl.

Habitats: marine sediments and coastal marine waters containing hydrogen sulfide and rich in organic matter.

The mol% G + C of the DNA is: 68.9–73.2 (T_m) and 66.3–66.6 (HPLC).

Type strain: Hansen W4, ATCC 35886, DSM 1374.

GenBank accession number (16S rRNA): D16423, D13475.

2. **Rhodovulum adriaticum** (Neutzling, Imhoff, and Trüper 1984) Hiraishi and Ueda 1994a, 22[VP] (*Rhodopseudomonas adriatica* Neutzling, Imhoff and Trüper 1984, 503; *Rhodobacter adriaticus* Imhoff, Trüper and Pfennig 1984, 342.)
a.dri.a′ ti.cum. M.L. adj. *adriaticum* pertaining to the Adriatic Sea.

Cells are ovoid to rod shaped, 0.5–0.8 × 1.3–1.8 µm, nonmotile, often occurring in short straight chains, form capsules, and produce slime. Internal photosynthetic membranes appear as vesicles. Color of cell suspensions is yellowish brown to dark brown. Absorption spectra of living cells show maxima at 374–378, 447–450, 475–480, 508–512, 588–590, 802–805, and about 869 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spheroidene series.

Photoheterotrophic growth occurs under anoxic conditions in the light with a variety of organic compounds. Photoautotrophic growth is possible with sulfide, elemental sulfur, and thiosulfate as electron donor. During oxidation of sulfide to sulfate, elemental sulfur is intermediately formed outside the cells. Molecular hydrogen is not used. Sensitive to oxygen, but microaerobic growth in the dark is possible. In the presence of ascorbate as a reductant, phototrophic growth is stimulated. Carbon sources utilized are shown in Table BXII.α.70.

Good nitrogen sources are ammonia, dinitrogen and some amino acids; growth with urea is poor. Nitrate is not assimilated but is reduced to nitrite. Sulfate is not assimilated. Growth depends on reduced sulfur sources such as sulfide, thiosulfate, cysteine, and elemental sulfur. Biotin and thiamine are required; niacin stimulates growth.

Mesophilic marine bacterium with optimal growth at pH 6.5–7.0 (pH range: 6.9–8.5), 25–30°C, and 2.5–7.5% NaCl.

Habitats: marine sediments and coastal marine waters containing hydrogen sulfide and rich in organic matter.

The mol% G + C of the DNA is: 64.9-66.7 (T_m).

Type strain: Imhoff 6II, ATCC 35885, DSM 2781.

GenBank accession number (16S rRNA): D16418, D13476.

3. **Rhodovulum euryhalinum** (Kompantseva 1989b) Hiraishi and Ueda 1994a, 22[VP] (*Rhodobacter euryhalinus* Kompantseva 1989b, 205.)
eu.ry.ha.li'num. Gr. adj. *eurys* wide; Gr. n. *hals* salt; M.L. adj. *euryhalinum* living in a wide range of salinity.

Cells are ovoid to rod shaped, 0.7–1.0 × 1.5–3.0 μm, motile by polar flagella, divide by binary fission and often occur in short straight chains. Internal photosynthetic membranes appear as vesicles. Color of anaerobic cultures is greenish yellow, yellowish brown, to dark brown. Aerobic cultures are red. Absorption spectra of living cells show maxima at 378, 450–460, 479–486, 509–517, 592, 805, and 855 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spheroidene series.

Photoheterotrophic growth occurs under anoxic conditions in the light with a variety of organic compounds. Photoautotrophic growth is possible with sulfide, thiosulfate, and hydrogen as electron donor. During oxidation of sulfide to sulfate, elemental sulfur is intermediately formed outside the cells. Chemotrophic growth in the dark occurs with organic substrates and under autotrophic conditions with sulfide at microoxic conditions. Carbon sources utilized are shown in Table BXII.α.70. Ammonia is used as nitrogen source. Most strains do not assimilate sulfate, but depend on reduced sulfur sources; sulfide, cysteine, and cystine are used. Biotin, thiamine, niacin, and *p*-aminobenzoate are required as growth factors.

Mesophilic marine bacterium with optimal growth at pH 7.0–8.0, 25–35°C, and 0.5–12% NaCl. No growth in the absence of NaCl.

Habitats: marine sediments, coastal marine waters, and continental salt waters containing hydrogen sulfide and rich in organic matter.

The mol% G + C of the DNA is: 62.1–68.6 (T_m); type strain: 66.3 (T_m) and 65.5 (HPLC).

Type strain: Kompantseva KA-65, DSM 4868.

GenBank accession number (16S rRNA): D13479, D16426.

4. **Rhodovulum iodosum** Straub, Rainey and Widdel 1999, 734[VP]
i.o.do'sum. Gr. adj. *iodes* violet, rusty; M.L. adj. *iodosum* indicating the formation of rusty ferric iron deposits.

Cells are ovoid to rod shaped, 0.5–0.8 × 2.4–3.8 μm, nonmotile and divide by binary fission. Color of strictly anaerobically grown cell suspensions is yellowish to brown. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spheroidene series. Photoheterotrophic growth occurs under anoxic conditions in the light using a variety of organic compounds.

Photoautotrophic growth occurs with sulfide, sulfur, thiosulfate, and molecular hydrogen as electron donors. In addition, ferrous iron serves as photosynthetic electron donor. During growth on iron sulfide, ferric iron and sulfate are formed. Chemotrophic growth under oxic conditions in the dark is possible (with acetate as carbon source). Under anoxic dark conditions, no growth occurs by fermentation or with nitrate, ferric iron, DMSO, and TMAO as electron acceptors. Carbon sources utilized are shown in Table BXII.α.70.

Ammonia is used as a nitrogen source. Sulfate is not assimilated, but reduced sulfur sources are required. Thiosulfate, elemental sulfur, sulfide, and cysteine can be used, but not sulfate and sulfite. Biotin and niacin are required as growth factors.

Mesophilic marine bacterium with optimal growth at pH 7.0–7.3 (with acetate as substrate) or pH 6.5 (pH range: 6.3–6.8, with ferrous iron as substrate), 20–25°C, and 2.5–5% NaCl (range: 2–7%).

Habitats: intertidal mud flats.

The mol% G + C of the DNA is: 66 (HPLC).

Type strain: N1, DSM 12328.

GenBank accession number (16S rRNA): Y15011.

5. **Rhodovulum robiginosum** Straub, Rainey and Widdel 1999, 734[VP]
ro.bi.gi.no'sum. M.L. adj. *robiginosum* rusty, indicating the formation of rusty ferric iron deposits.

Cells are ovoid to rod shaped, 0.5–0.8 × 1.6–3.2 μm, nonmotile, and multiply by binary fission. Color of strictly anaerobically grown cell suspensions is yellowish to brown. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spheroidene series.

Grow photoheterotrophically under anoxic conditions in the light using a variety of organic compounds, and photoautotrophically with sulfide, sulfur, thiosulfate, and molecular hydrogen as electron donors. In addition, ferrous iron serves as photosynthetic electron donor. During growth on iron sulfide, ferric iron and sulfate are formed. Chemotrophic growth under oxic conditions in the dark is possible (with acetate as carbon source). Under anoxic dark conditions, no growth occurs by fermentation or with nitrate, ferric iron, DMSO, and TMAO as electron acceptors. Carbon sources utilized are shown in Table BXII.α.70.

Ammonia is used as a nitrogen source. Sulfate is not assimilated, but reduced sulfur sources are required. Thiosulfate, elemental sulfur, sulfide, and cysteine can be used, but not sulfate and sulfite. Biotin, niacin, and vitamin B_{12} are required as growth factors.

Mesophilic marine bacterium with optimal growth at pH 7.3–7.7 (with acetate as substrate) or pH 6.5 (pH range: 6.3–6.8, with ferrous iron as substrate), 25–28°C, and 2.5–5% NaCl (range: 1–7%).

Habitats: intertidal mud flats.

The mol% G + C of the DNA is: 69 (HPLC).

Type strain: N2, DSM 12329.

GenBank accession number (16S rRNA): Y15012.

6. **Rhodovulum strictum** Hiraishi and Ueda 1995, 325[VP]
stric'tum. M.L. part. n. adj. *strictum* strict, accurate, referring to the fact that the cells require strict growth conditions.

Cells are ovoid to rod shaped, 0.6–1.0 × 1.0–2.5 μm, motile by means of polar flagella and divide by binary fission. Phototrophically grown cells contain internal photosynthetic membranes of the vesicular type. Photosynthetic cultures are yellow-green to yellow-brown, while aerobic cultures grown in the dark are pink to red. Colonies that develop aerobically on agar media in the dark are circular, convex, with entire margins, and red in color. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spheroidene series.

Facultative photoheterotrophic bacteria that can grow anaerobically in the light or aerobically in the dark at full atmospheric oxygen tension. Sulfide and thiosulfate are used as electron donors for phototrophic growth, with sulfate as the final oxidation product.

Good carbon sources for phototrophic growth are formate, acetate, propionate, butyrate, lactate, pyruvate, fumarate, malate, succinate, glycolate, fructose, alanine, leu-

cine, Casamino acids, peptone, and yeast extract. Weak or slow growth occurs with valerate, caproate, tartrate, citrate, arabinose, and glucose. No or little growth occurs with caprylate, pelargonate, malonate, sucrose, galactose, mannose, adonitol, mannitol, sorbitol, glycerol, methanol, ethanol, propanol, asparagine, aspartate, or glutamate. Sulfate is assimilated as sole sulfur source. Biotin, *p*-aminobenzoic acid, and thiamine are required as growth factors.

Mesophilic, marine bacterium with optimal growth at pH 8.0–8.5 (pH range: 7.5–9.0), 30–35°C, and in the presence of 0.8–1% NaCl (range: 0.25–3.0%).

Habitat: tidal and seawater pools and similar marine environments.

The mol% G + C of the DNA is: 67.3–67.7 (HPLC).

Type strain: MB-G2, JCM 9220.

GenBank accession number (16S rRNA): D16419.

Genus XV. Roseibium *Suzuki, Muroga, Takahama and Nishimura 2000, 2155*[VP]

THE EDITORIAL BOARD

Ro.sei' bi.um. M.L. adj. *roseus* rose/pink; Gr. n. *bios* life; M.L. neut. n. *Roseibium* pink life.

Gram-negative aerobic chemoheterotrophic motile rods (0.5–0.8 × 1.0–4.0 µm for most strains). Peritrichous flagella. **Produce bacteriochlorophyll *a* aerobically**. **Do not grow as anaerobic phototrophs.** Catalase and oxidase positive. Produce phosphatase and nitrate reductase. Major cellular fatty acid $C_{18:1}$.

The mol% G + C of the DNA is: 57.6–63.4 (HPLC).

Type species: **Roseibium denhamense** Suzuki, Muroga, Takahama and Nishimura 2000, 2155.

FURTHER DESCRIPTIVE INFORMATION

Roseibium strains were isolated from marine environments including sand and surfaces of red algae (Shiba et al., 1991; Suzuki et al., 2000).

All *Roseibium* strains tested were ONPG positive and produced indole. They hydrolyzed gelatin and utilized L-aspartate, butyrate, L-glutamate, and pyruvate. They produced acid from D-fructose, D-glucose, maltose, and D-ribose. All strains were Voges–Proskauer negative and did not produce H_2S. They were unable to utilize ethanol, glycolate, or methanol and did not produce acid from lactose or L-arabinose. None hydrolyzed Tween 80, starch, or alginate. All were streptomycin and chloramphenicol sensitive and tetracycline and penicillin resistant (Suzuki et al., 2000).

Analysis of 16S rDNA sequences placed the *Roseibium denhamense* and *R. hamelinense* type strains in the *Alphaproteobacteria* (Suzuki et al., 2000).

ENRICHMENT AND ISOLATION PROCEDURES

These bacteria were isolated from seawater, sand, and the surfaces of marine organisms from the coasts of Australia (Shiba et al., 1991; Suzuki et al., 2000). Procedures and media used are given by Shiba et al. (1991).

DIFFERENTIATION OF THE SPECIES OF THE GENUS *ROSEIBIUM*

R. denhamense utilizes acetate, fumarate, and DL-malate; *R. hamelinense* does not. *R. hamelinense* utilizes DL-lactate; *R. denhamense* does not. *R. denhamense* produces acid from D-galactose and D-xylose; *R. hamelinense* does not. *R. hamelinense* grows in 0% NaCl; *R. denhamense* does not.

List of species of the genus Roseibium

1. **Roseibium denhamense** Suzuki, Muroga, Takahama and Nishimura 2000, 2155[VP]
den.ha.men' se. M.L. adj. *denhamense* referring to Denham, Australia, the source of the type strain.

Description as for the genus with the following additional characteristics: utilizes acetate, fumarate, and DL-malate; produces acid from D-galactose and D-xylose; does not grow in 0% NaCl.

The mol% G + C of the DNA is: 57.6–60.4 (HPLC).

Type strain: OCh 254, JCM 19543.

GenBank accession number (16S rRNA): D85832.

2. **Roseibium hamelinense** Suzuki, Muroga, Takahama and Nishimura 2000, 2155[VP]
ha.me.li.nen' se. M.L. adj. *hamelinense* referring to Hamelin Pool, Australia, the source of the type strain.

Description as for the genus with the following additional characteristics: utilizes DL-lactate and grows in 0% NaCl.

The mol% G + C of the DNA is: 59.2–63.4 (HPLC).

Type strain: OCh 368, JCM 10544.

GenBank accession number (16S rRNA): D85836.

Genus XVI. Roseinatronobacter *Sorokin, Tourova, Kuznetsov, Bryantseva and Gorlenko 2000b, 1415*[VP] *(Effective publication: Sorokin, Tourova, Kuznetsov, Bryantseva and Gorlenko 2000a, 81)*

THE EDITORIAL BOARD

Ro.se.i.nat.ro.no.bac' ter. M.L. adj. *roseus* pink; M.L. n. *natron* soda; M.L. masc. n. *bacter* rod; M.L. n. *Roseinatronobacter* pink rod from soda lake.

Gram-negative, strictly aerobic, heterotrophic, nonmotile, lemon-shaped rods (0.5–0.8 × 0.8–2.2 µm); cells single or in chains. **pH optimal 10**. [Na^+] optimal 0.4–0.6 M. **Produce bacteriochlorophyll *a*. Oxidize thiosulfate to sulfate. Do not grow autotrophically.**

The mol% G + C of the DNA is: 61.5 (T_m).

Type species: **Roseinatronobacter thiooxidans** Sorokin, Tourova, Kuznetsov, Bryantseva and Gorlenko 2000b, 1415 (Effective publication: Sorokin, Tourova, Kuznetsov, Bryantseva and Gorlenko 2000a, 82.)

Further descriptive information

The organism was isolated from an alkaline lake (Sorokin et al., 2000a).

Roseinatronobacter thiooxidans ALG 1 oxidizes thiosulfate to sulfate; addition of thiosulfate to cultures growing aerobically on organic substrates increases the amount of biomass produced; thus, it is able to grow lithoheterotrophically with thiosulfate. *Roseinatronobacter thiooxidans* ALG 1 also produces bacteriochlorophyll *a* but fails to grow autotrophically in the light in the absence of oxygen. Substrates used include acetate, aspartate, benzoate, caproate, caprylate, citrate, fructose, fumarate, glucose, glutamate, glycerol, glycolate, glyoxalate, lactate, maleate, mannitol, propionate, pyruvate, sorbitol, succinate, and valerate. Nitrate can be reduced to nitrite; nitrate, nitrite, ammonium ion, and amino acids can be used as sources of nitrogen (Sorokin et al., 2000a).

Analysis of 16S rDNA sequences placed *Roseinatronobacter* in the *Alphaproteobacteria* (Sorokin et al., 2000a).

Enrichment and Isolation Procedures

This organism was obtained from an alkaline liquid enrichment containing acetate and thiosulfate (Sorokin et al., 2000a).

List of species of the genus Roseinatronobacter

1. **Roseinatronobacter thiooxidans** Sorokin, Tourova, Kuznetsov, Bryantseva and Gorlenko 2000b, 1415^{VP} (Effective publication: Sorokin, Tourova, Kuznetsov, Bryantseva and Gorlenko 2000a, 82.)
   thi.o.oxi.dans′. Gr. n. *thios* sulfur; M.L. part. adj. *thiooxidans* sulfur-oxidizing.
   Description: same as given for the genus.
   The mol% G + C of the DNA is: 61.5 (T_m).
   Type strain: ALG 1, DSM 13087.
   GenBank accession number (16S rRNA): AF249749.

Genus XVII. **Roseivivax** *Suzuki, Muroga, Takahama and Nishimura 1999a, 632*^{VP}

Christopher Rathgeber and Vladimir V. Yurkov

Ro.se.i.vi′ vax. M.L. adj. *roseus* rose colored, pink; L. adj. *vivax* living; M.L. masc. n. *Roseivivax* pink living organism.

Cells are Gram-negative, slender rods 0.5–1.0 × 1.0–5.0 µm. Motile by means of subpolar flagella. Form pink colonies when grown on agar media due to the presence of carotenoid pigments. **Grow heterotrophically and produce bacteriochlorophyll (Bchl) *a* under aerobic conditions. Reproduction occurs by binary fission. Do not grow anaerobically under illuminated conditions.** The habitat is saline lakes.

The mol% G + C of the DNA is: 59.7–64.4.

Type species: **Roseivivax halodurans** Suzuki, Muroga, Takahama and Nishimura 1999a, 632.

Further descriptive information

Two species of *Roseivivax* are presently described, *Roseivivax halodurans* and *Roseivivax halotolerans*. Phylogenetically these species belong to the *Alphaproteobacteria*, and are most closely related to members of the genera *Roseobacter*, *Sagittula*, *Octadecabacter*, and *Sulfitobacter*. Both species form circular, smooth, slightly convex, entire, glistening, opaque, pink colonies on agar media. Although all isolated strains produce photosynthetic pigments, they grow only under aerobic conditions, and do not grow anaerobically even in the presence of light. This peculiarity is common to all representatives of the so-called aerobic phototrophic bacteria.

Cells are slender rods 0.5–1.0 × 1.0–5.0 µm, and reproduce by binary fission. Cells are motile by means of subpolar flagella.

Optimal growth occurs at pH between 7.5 and 8.0, and at temperatures between 27°C and 30°C. *Roseivivax* species show a broad tolerance for saline conditions, with growth occurring between 0% and 20% NaCl. A variety of organic substrates can be utilized for growth, although the specific substrates utilized vary between species. Members of this genus are catalase and oxidase positive, produce indole, but do not produce H_2S. Voges–Proskauer test is negative, ONPG reaction is positive.

The major cellular fatty acid present is $C_{18:1}$ and the major quinone is ubiquinone Q-10, with smaller amounts of ubiquinones Q-7, Q-8, and Q-9.

Enrichment and Isolation Procedures

Both *R. halodurans* and *R. halotolerans* were isolated from the saline lake, Lake Clifton, on the west coast of Australia. *R. halodurans* was isolated from a sample containing charophytes, whereas *R. halotolerans* was isolated from a sample containing epiphytes, which had developed on living stromatolites. Strains were grown on PPES-II medium (Suzuki et al., 1999a) and pure cultures were obtained by replating of separate colonies.

Maintenance Procedures

Both *Roseivivax* spp. can be maintained on PPES-II slant agar culture medium (Shiba et al., 1991).

Differentiation of the genus *Roseivivax* from other genera

Genus *Roseivivax* can be differentiated from other known genera based on 16S rRNA gene sequence analysis, as the two known members form a distinct cluster within the *Alphaproteobacteria*. Members of this genus are related to members of the aerobic phototrophic genus *Roseobacter*, but can be differentiated from them by differences in absorption spectrum characteristics. *Roseivivax* shows an absorption spectrum similar to that of *Erythrobacter longus* (Nishimura et al., 1994), with a major peak at 871–873 nm and a smaller peak at 803–805 nm, which correspond to Bchl *a* incorporated into light-harvesting complex I and reaction centers, respectively. In contrast, the absorption spectrum of *Roseobacter* shows a major peak at about 806 nm due to the

presence of an unusual bacteriochlorophyll-protein complex, B806, as well as a smaller peak at about 870 nm, due to the light-harvesting complex I.

Roseivivax forms circular pink colonies when grown on agar media. Growth occurs heterotrophically under aerobic conditions, but not under anaerobic conditions even in the light. This peculiarity differentiates *Roseivivax* from all known genera of the purple nonsulfur bacteria, which possess Bchl *a* and can grow under both conditions, aerobic dark and anaerobic light.

Members of the genus *Roseivivax* can be differentiated from each other based on differences in 16S rRNA gene sequence, homology of the DNA, and absorption spectrum characteristics, as well as physiological and biochemical properties, including salt requirement, carbon sources utilized, presence of urease, phosphatase, gelatinase, and the ability to reduce nitrate (Table BXII.α.71).

Taxonomic Comments

Shiba et al. (1991) described several strains of aerobic bacteriochlorophyll *a*-containing bacteria isolated from different saline locations on the east and west coasts of Australia. These strains were divided into four groups (GI, GII, GIII, and GIV), based on cell color, type of absorption spectrum, and cell morphology. *R. halotolerans* and *R. halodurans* were placed into the GII group along with 17 other similar strains.

However, based on DNA–DNA hybridization studies, this group was further divided into four subgroups based on DNA homology. *R. halotolerans* and *R. halodurans* fell outside of these four subgroups, indicating that the genus *Roseivivax* is not closely related to any of the other strains in the GII group (Nishimura et al., 1994).

16S rRNA gene sequence analysis shows that *Roseivivax* forms a separate cluster within the *Alphaproteobacteria*. The closest relatives are members of the genera *Roseobacter*, *Sagittula*, *Octadecabacter*, and *Sulfitobacter*.

ha.lo.to'le.rans. Gr. n. *hals* salt; L. pres. part. *tolerans* tolerating; M.L. part. adj. *halotolerans* salt tolerating.

Gram-negative rods, 0.5–1.0 × 1.0–5.0 µm, motile by subpolar flagella, form circular pink colonies on agar media. Cells contain Bchl *a* organized into reaction center and light harvesting complexes, exhibiting absorption spectrum peaks at 805 and 871 nm, respectively. Require salt for growth, able to tolerate high salinity with growth occurring between 0.5 and 20.0% NaCl. Aerobic heterotrophs, do not grow anaerobically under illuminated conditions. Substrates utilized as sole carbon source are D-glucose, D-fructose, D-xylose, acetate, butyrate, citrate, DL-lactate, DL-malate, pyruvate, succinate, L-aspartate, and L-glutamate. Does not grow on fumarate, glycolate, ethanol, methanol, L-arabinose, D-galactose, lactose, maltose, D-ribose, or sucrose. Hydrolyze gelatin, do not hydrolyze Tween 80, starch, or alginate. Produce catalase, oxidase, and urease. Do not have phosphatase or nitrate reductase activity. Produce indole but not H_2S, Voges–Proskauer test is negative, ONPG reaction is positive.

Optimal growth occurs at pH 7.5–8.0, and temperature 27–30°C. Resistant to penicillin and tetracycline, but susceptible to chloramphenicol and streptomycin. Habitat: epiphytes growing on living stromatolites in Lake Clifton, a saline lake on the west coast of Australia.

The mol% G + C of the DNA is: 59.7 (HPLC).

Type strain: Och 210, ATCC 700842, CIP 105984, JCM 10271, NBRC 16686.

GenBank accession number (16S rRNA): D85831.

Genus XVIII. **Roseobacter** *Shiba 1991b, 331^{VP} (Effective publication: Shiba 1991a, 144)*

Tsuneo Shiba and Johannes F. Imhoff

Ro.se.o.bac'ter. M.L. adj. *roseus* rose-colored, pink; M.L. masc. n. *bacter* equivalent of Gr. neut. n. *bacterion* a rod; M.L. masc. n. *Roseobacter* pink rod-shaped bacterium.

Cells are ovoid or rod shaped, motile by subpolar flagella, divide by binary fission. They are **Gram negative** and are members of the ***Alphaproteobacteria***. Colonies are circular, smooth, slightly convex, and pink-to-red in color. Absorption spectra of cell suspensions have major maxima in the near infrared region at 805–807 nm and a smaller one at 868–873 nm (Fig. BXII.α.79). **Bacteriochlorophyll (BChl) *a*** is present. The major carotenoid is spheroidenone. Phosphatidylglycerol and diphosphatidylglycerol are present. The main cellular fatty acid is $C_{18:1}$.

Aerobic chemoorganotrophic bacteria. Do not grow phototrophically and do not produce photosynthetic pigments under anoxic conditions in the light. Carbon sources and electron donors supporting growth are simple organic compounds. Gelatin and Tween 80 are hydrolyzed. Catalase and oxidase are present. Biotin, thiamine and nicotinic acid are required as growth factors.

The major respiratory quinone is ubiquinone-10.

Mesophilic and neutrophilic bacteria from the marine environment. Optimal growth is at pH 7.0–8.0 and 20–30°C. Low concentrations of sodium ions are required.

The mol% G + C of the DNA is: 56–60.

Type species: **Roseobacter litoralis** Shiba 1991b, 331 (Effective publication: Shiba 1991a, 144.)

Further descriptive information

Roseobacter is an aerobic chemoheterotrophic bacterium containing bacteriochlorophyll (Shiba and Harashima, 1986). According to 16S rDNA sequence similarity, it is closely related to *Sulfitobacter*, *Staleya*, *Sagittula*, *Octadecabacter*, *Ruegeria*, *Antarctobacter*, *Roseovarius*, *Roseivivax*, and *Marinosulfonomonas*, which form a cluster of bacteria in the *Alphaproteobacteria* that have been isolated from marine environments. Of these bacteria only *Roseovarius*, *Roseivivax*, and *Staleya* contain BChl *a*.

The requirement of oxygen for photosynthesis and BChl synthesis in *R. denitrificans* is in contrast to the inhibitory effect of oxygen on photosynthesis and bacteriochlorophyll synthesis in anoxygenic phototrophic purple bacteria (Harashima et al., 1982; Shiba, 1984, 1987; Okamura et al., 1985; Nishimura et al., 1996; Porra et al., 1996; Kortlüke et al., 1997).

BChl synthesis in *Roseobacter* requires oxygen and dark conditions (Shioi and Doi, 1988; Takamiya et al., 1992). Even though the bacteria grow anaerobically with nitrate or trimethylamine-*N*-oxides (TMAO) as terminal electron acceptor, BChl is not synthesized under these conditions (Arata et al., 1988). The 13′-oxo group of the isocyclic ring E of BChl is derived from molecular oxygen via an oxygenase, whereas the same biosynthetic step in *Rhodobacter sphaeroides* is an anaerobic process (Porra et al., 1996).

The photosynthetic apparatus of *Roseobacter* is similar to that found in the anaerobic phototrophic bacteria of the *Rhodobacteraceae*. In *R. denitrificans*, BChl *a* is esterified with phytol as in

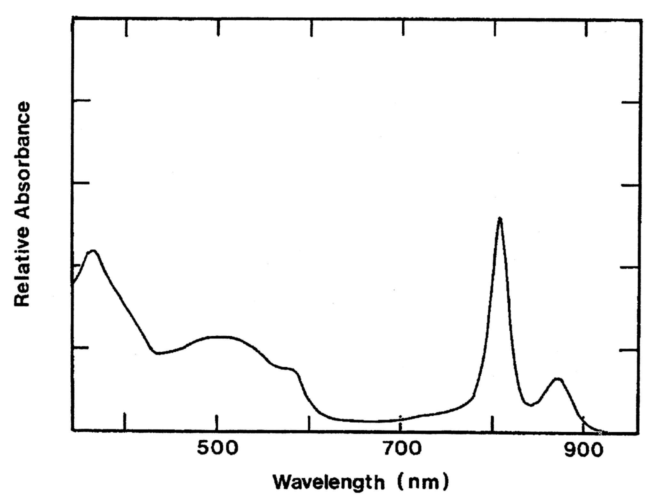

FIGURE BXII.α.79. Absorption spectrum of a membrane fraction of *Roseobacter litoralis* (Reproduced with permission from T. Shiba, Systematic and Applied Microbiology *14:* 140–145, 1991, ©Urban & Fischer Verlag.)

Rhodobacter and many anoxygenic phototrophic purple bacteria (Shiba, 1991a). The major carotenoid is spheroidenone, an oxoderivative of spheroidene present in *Rhodobacter* species (Harashima and Nakada, 1983). Two BChl-protein complexes, RC-870 and B806, have been isolated from *R. denitrificans* (Shimada et al., 1985). RC-870 corresponds to a reaction center-light harvesting complex (RC-LH1 complex) of the anoxygenic phototrophic purple bacteria with which the complex purified from *R. denitrificans* shares almost identical absorption spectra. One mole of the RC contains 4 mol of BChl *a*, 2 mol of bacteriopheophytin *a*, 4 mol of cytochrome c_{554}, 2 mol of ubiquinone-10 and an unknown amount of carotenoids. The B806 complex corresponds to the B800-850 (LH2) of anoxygenic phototrophic purple bacteria, but lacks the absorption maximum at approx. 850 nm. The BChl-proteins of *R. denitrificans* seem to be integrated in vesicular internal membrane structures. The diameter of the vesicles, 60–120 nm, is larger than that of the anaerobic photosynthetic bacteria (40–60 nm) (Iba et al., 1988). The outer layer of *R. denitrificans* is characterized by a lipopolysaccharide containing no heptose, as in *Rhodobacter* (Neumann et al., 1995).

Roseobacter spp. are aerobic chemoheterotrophic bacteria that are unable to grow phototrophically under anoxic conditions. Light is utilized by *R. denitrificans* as an auxiliary energy source for ATP synthesis only under oxic conditions (Shiba, 1984; Okamura et al., 1985). A photosynthetic electron transfer system operates under anaerobic conditions, if the bacteria can utilize nitrate, nitrite, or TMAO as the terminal oxidant (Arata et al., 1988; Takamiya et al., 1988). Since this photosynthetic system competes with the respiratory system for the same electron transfer component, light suppresses the respiratory activity (Harashima et al., 1982). Therefore, there is no difference in exponential growth in the light and in the dark. A positive effect of light on growth is observed only when respiratory activity is suppressed under certain environmental conditions. For example, growth yield is enhanced only when cultures are illuminated at stationary growth phase (Shioi, 1986; Harashima et al., 1987). The viability of *R. denitrificans* is also enhanced by light in starvation survival media lacking energy-yielding substrates (Shiba, 1984).

Roseobacter has been isolated from green seaweed (Shiba et al., 1979; Shiba, 1991a). Although *Roseobacter* species have not been isolated from seawater, a rDNA clone SAR83, which is phylogenetically closely related to *Roseobacter denitrificans*, is predominant in the bacterial plankton population of Sargasso Sea (Britschgi and Giovannoni, 1991; Fuhrman et al., 1993). Many aerobic bacteriochlorophyll-containing bacteria, the relationship of which to *Roseobacter* is not yet clarified, have been isolated from cyanobacterial patches, seaweeds, sea grasses, sea sands, and surface seawater. The population of aerobic bacteriochlorophyll-containing bacteria may comprise as much as 20–50% of the total aerobic chemoheterotrophic bacteria (Shiba et al., 1991; Shiba, 1995).

Enrichment and Isolation Procedures

Roseobacter strains have been isolated on agar plates with a modified PPES-II medium (Shiba, 1989) which contains per liter: 2 g polypeptone (Nihon Pharmaceutical Co.), 1 g proteose–peptone no. 3 (Difco), 1 g Bacto soytone (Difco), 1 g Bacto yeast extract (Difco), 0.1 g ferric citrate, 700 ml artificial seawater (Lyman and Fleming, 1940), and 300 ml distilled water. Inclusion of iron strongly enhances BChl synthesis. The pH is adjusted to 7.6–7.8. The agar plates are incubated at 20–25°C. Pink- or red-pigmented colonies are formed on agar plates.

Shioi (1986) used a medium which contains in 1 liter of distilled water: 20 g NaCl, 5.0 g $MgCl_2 \cdot 6H_2O$, 2.0 g Na_2SO_4, 0.5 g KCl, 0.5 g $CaCl_2 \cdot 2H_2O$, 0.2 g $NaHCO_3$, 0.1 g ferric citrate, 2.0 g yeast extract (Difco), 1.0 g polypeptone, 1.0 g Casamino acids, and 1.0 ml glycerol. The growth yield in this medium is approximately twice as high as that in PPES-II medium. Elimination of the trace elements Br, Sr, B, and F from the medium of Shioi (1986) has no effect on growth.

Maintenance Procedures

Roseobacter can be maintained at 20°C as stab cultures in media containing 0.4% agar (Difco). Cultures should be transferred monthly. Maintenance on agar slant cultures at room temperature is not recommended. The bacteria remain viable for 6 months when slant cultures are kept at −80°C. Cultures may also be preserved in liquid nitrogen or by lyophilization.

Differentiation of the genus *Roseobacter* from other genera

Roseobacter differs from anoxygenic phototrophic bacteria in the *Rhodobacteraceae* in its inability to perform photosynthesis under anoxic conditions. Based on 16S rDNA sequence analysis, the genus is most closely related to *Sulfitobacter*, *Staleya*, *Sagittula*, *Octadecabacter*, *Ruegeria*, *Antarctobacter*, *Roseovarius*, *Roseivivax*, and *Marinosulfonomonas* (Sorokin, 1995; González et al., 1997b; Gosink et al., 1997; Holmes et al., 1997; Labrenz et al., 1998, 1999; Uchino et al., 1998; Pukall et al., 1999; Suzuki et al., 1999a; Labrenz et al., 2000). It can be differentiated from these bacteria by pigment and phospholipid composition, capabilities for degradation of organic substances, and other properties. Unlike *Roseobacter*, cells of *Sulfitobacter*, *Sagittula*, *Octadecabacter*, *Ruegeria*, and *Antarctobacter* do not contain bacteriochlorophyll. Although *Staleya*, *Roseivivax*, and *Roseovarius* contain BChl *a*, their absorption spectra do not show the large peak at ~800 nm. Phosphatidylethanolamine is present in the cells of *Staleya* and *Roseovarius* but not in *Roseobacter*. Tween 80 is hydrolyzed by *Roseobacter*, *Staleya*, and *Roseovarius tolerans* strain EL-52, but not by species of the other genera. *Staleya*, *Roseovarius*, and *Antarctobacter* can grow at 150% seawater but *Roseobacter* cannot. *Roseobacter* differs from *Marinosulfonomonas* and *Sagittula* in lacking the capacity for methylotrophic growth (Holmes, et al., 1997). *Roseobacter* can grow at 30°C but the gas-vacuolated bacterium *Octadecabacter* cannot (Gosink et al., 1997). Differential characteristics of the genus *Roseobacter* and related genera are shown in Table BXII.α.72.

Taxonomic Comments

The genus *Roseobacter* was proposed for aerobic chemoheterotrophic bacteria which contain BChl *a* and have a strict requirement of oxygen for synthesis of bacteriochlorophyll (Shiba, 1991a).

Subsequently, *Roseobacter algicola* and *Roseobacter gallaeciensis* were included in the genus *Roseobacter* based only on 16S rDNA sequence information, although their phenotypic characteristics were not coincident with the definition of the genus *Roseobacter* (Lafay et al., 1995; Ruiz-Ponte et al., 1998). Neither species contains BChl *a*. Data on levels of DNA–DNA reassociation to the type species of *Roseobacter litoralis* are lacking (Lafay et al., 1995). In addition, the phylogenetic position of *Roseobacter algicola* is more distant from *Roseobacter litoralis* and *R. denitrificans* than are *Sagittula*, *Sulfitobacter*, and *Octadecabacter* (González et al., 1997b; Labrenz et al., 1999).

Roseobacter algicola has been reassigned to a new genus as *Rue-*

geria algicola (Uchino et al., 1998) and according to 16S rDNA analysis constitutes a robust monophyletic cluster with *R. gallaeciensis* (Suzuki et al., 1999a). Neither species is considered in this chapter.

List of species of the genus Roseobacter

1. **Roseobacter litoralis** Shiba 1991b, 331[VP] (Effective publication: Shiba 1991a, 144.)
li.to.ra′ lis. L. gen. n. *litoris* of the seashore; M.L. masc. adj. *litoralis* belonging or pertaining to the seashore.

Cells are rod-to-ovoid shaped, 0.6–0.9 × 1.2–2.0 µm, motile by subpolar flagella. Cell suspensions and colonies are pink. Cell suspensions show a major absorption band at 805–807 nm and a minor one at 868–873 nm. Bacteriochlorophyll *a* esterified with phytol is present. The major carotenoid is spheroidenone. Phosphatidylglycerol and diphosphatidylglycerol are present. The main cellular fatty acid is $C_{18:1}$.

Strictly aerobic chemoheterotrophic bacteria that grow on several organic substrates under oxic conditions. They produce photosynthetic pigments under aerobic conditions, but are unable to grow photosynthetically in the absence of oxygen. Under oxic conditions, photosynthetic energy generation is possible. Methanol is not utilized. Dissimilatory nitrate reducing activity is absent. Chemoautotrophic growth with H_2 is not possible. Biotin, thiamin, and nicotinic acid are required as growth factors.

Optimal growth is at pH 7–8 and 20–30°C. Sodium ions are required.

Habitat: surface of high-tidal seaweeds.

The mol% G + C of the DNA is: 57.2 ± 0.9 (HPLC).

Type strain: OCh149, ATCC 49566, DSM 6996, IFO 15278.

GenBank accession number (16S rRNA): X78312.

2. **Roseobacter denitrificans** Shiba 1991a, 331[VP] (Effective publication: Shiba 1991a, 144.)
de.ni.tri′ fi.cans. M.L. part. adj. *denitrificans* denitrifying.

Cells are rod-to-ovoid shaped, 0.6–0.9 × 1.0–2.0 µm, motile by subpolar flagella. Internal photosynthetic membranes are of vesicular type. Cell suspensions and colonies are pink. Cell suspensions show a major absorption band at 805–807 nm and a minor one at 868–873 nm. Bacteriochlorophyll *a* esterified with phytol is present. The major carotenoid is spheroidenone. The major quinone is ubiquinone-10. Phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylcholine are present. The main cellular fatty acid is $C_{18:1}$.

Growth occurs chemoheterotrophically under oxic conditions with several organic substrates. They produce photosynthetic pigments under aerobic conditions, but are incapable of photosynthetic growth in the absence of oxygen. Under oxic conditions, photosynthetic energy generation is possible. Methanol is not utilized. Photosynthetic activity is also found in the presence of nitrate or trimethylamine-*N*-oxide as electron acceptors. Nitrate is reduced to N_2O.

Chemoautotrophic growth with H_2 is not possible. Biotin, thiamin, and nicotinic acid are required as growth factors.

Optimal growth is at pH 7–8 and 20–30°C. Sodium ions are required.

Habitat: surface of high-tidal seaweeds.

The mol% G + C of the DNA is: 59.6 ± 0.5 (HPLC).

Type strain: OCh114, ATCC 33942, DSM 7001, IFO 15277.

GenBank accession number (16S rRNA): L01784, M59063.

Genus XIX. **Roseovarius** *Labrenz, Collins, Lawson, Tindall, Schumann and Hirsch 1999, 145^{VP}*

MATTHIAS LABRENZ AND PETER HIRSCH

Ro'se.o.va'ri.us. L. adj. *roseus* rosy; L. adj. *varius* diverse, varied; M.L. masc. n. *Roseovarius* a variably rosy bacterium.

Rods, one or both cell poles pointed, multiplying by monopolar growth, i.e., by a budding process. Gram negative. Daughter cells may be motile. No resting stages are known. **Aerobic**, with a strictly respiratory type of metabolism. **Intracellular granules of poly-β-hydroxybutyrate (PHB) are present. Bacteriochlorophyll *a* (bchl *a*) may be produced.** Cells have an absolute requirement for Na^+. Temperature range for growth <3–43.5°C, salinity range for growth <10 to >150‰ of artificial seawater (ASW), NaCl tolerance range <1.0 to 10.0% and pH range for growth 5.3 to >9. **Catalase and oxidase weakly positive.** Do not grow photoautotrophically with H_2/CO_2 (80:20) or photoorganotrophically with acetate or glutamate. Occur in marine habitats.

The mol% G + C of the DNA is: 62–64.

Type species: **Roseovarius tolerans** Labrenz, Collins, Lawson, Tindall, Schumann and Hirsch 1999, 145.

FURTHER DESCRIPTIVE INFORMATION

Visible growth of *R. tolerans* appears at 20°C after 3–5 d on medium PYGV (Staley, 1968) prepared with 25‰ (or 40‰) artificial seawater (ASW; Lyman and Fleming, 1940) or on R2A agar (Difco, Detroit) with the appropriate ASW concentration. Colonies are circular, smooth, convex, 1–2 mm in diameter and red, pink, beige to light red, beige, or whitish beige. Cell sizes: 0.7–1.0 × 1.1–2.2 μm. Cell growth appears to be monopolar since one cell end is usually more narrow and shorter, which indicates a budding process (Hirsch, 1974a). In PHBA medium (Labrenz et al., 1998), motility can be observed. Small daughter cells show predominantly tumbling motion and only rarely directed movements, but flagella were not observed.

Bchl *a* is found in strains EL-78, EL-83, EL-171, and EL-172^T in cell suspensions grown in the dark (Labrenz et al., 1999). Absorbances characteristic of bchl *a* with a large peak at 877–879 nm and smaller ones at 799–802 nm and 589–591 nm are similar to maxima found in bchl *a*-containing anoxygenic phototrophs (Biebl and Drews, 1969), but they differ from the maxima of bchl *a*-containing *Roseobacter denitrificans* and *Roseobacter litoralis* (Shiba, 1991a) or *Staleya guttiformis* (Labrenz et al., 2000). Under identical growth conditions, bchl *a* could not be detected in suspensions or methanolic extracts of *R. tolerans* strains EL-52, EL-90, EL-164, or EL-222. Even concentrated extracts of these strains lacked bchl *a* when thin layer chromatography was applied. The *in vitro* absorption spectra of methanolic *R. tolerans* extracts show a large peak at 767–769 nm and smaller ones at 605–607, 699–700 nm, and around 350 nm. Unlike *Roseobacter denitrificans* or *Staleya guttiformis,* the production of bchl *a* by these EL-strains is repressed in constant dim light.

Colony colors of strains EL-83 and EL-171 were white-beige to beige during the first six years of cultivation; at that time these strains did not produce bchl *a*. Then the colony colors changed to light red and *in vivo* bchl *a* spectra had a small peak at 868–871 nm. Five months later, colonies of EL-83 became pinkish and since then this strain produces bchl *a* just as EL-78 and EL-172^T do. Methanolic extracts of all four bchl-producing EL-strains have identical absorption spectra. Unlike in *Roseobacter denitrificans*, vesicular intracytoplasmatic membrane systems (Harashima et al., 1982) are not found in ultrathin sections of aerobically and dark grown cells of EL-172^T. *R. tolerans* has an absolute requirement for Na^+, but not for K^+, Mg^{2+}, Ca^{2+}, Cl^-, or SO_4^{2-}.

In the presence of available nitrogen, *Roseovarius tolerans* uses acetate, pyruvate, malate, succinate, butyrate, or glutamate, but not citrate, methanesulfonic acid, methanol, or α-D-glucose. Without any added nitrogen compounds, this species grows weakly on acetate, pyruvate, succinate, malate, or butyrate. Glutamate is used with and without an additional source of combined nitrogen. No growth on glucose anaerobically in the absence of nitrate. Metabolism of carbon sources tested with the Biolog system is described in Labrenz et al. (1999). Strain EL-222 grows microaerophilically.

The peptidoglycan of *R. tolerans* contains *m*-diaminopimelic acid. Respiratory quinone is Q10. Phospholipids present are: diphosphatidylgycerol, phosphatidylglycerol, phosphatidylcholine, and phosphatidylethanolamine as well as an unknown phospholipid and an aminolipid. The dominant fatty acid is $C_{18:1}$ (70.2%); other characteristic fatty acids are $C_{18:2}$ (10.6%), $C_{12:0\ 2OH}$ (2.4%), $C_{12:1\ 3OH}$ (3.6%), $C_{16:1}$ (0.8%), $C_{16:0}$ (6.2%), and $C_{18:0}$ (0.8%).

Comparative 16S rRNA gene sequence analysis shows *R. tolerans* to be a member of the *Alphaproteobacteria.* Highest 16S rRNA gene sequence relatedness (93–95%) is displayed with species of the genus *Ruegeria* (Uchino et al., 1998), viz. *R. algicola* (Lafay et al., 1995) as well as with *Roseobacter*, *Antarctobacter*, *Sagittula*, *Staleya*, *Octadecabacter*, and *Sulfitobacter*. (See Fig. BXII.α.71 of the chapter describing the genus *Antarctobacter.*)

ENRICHMENT AND ISOLATION PROCEDURES

Two enrichment procedures may be used for *R. tolerans*: (1) Original water samples (0.5 ml) are spread directly on agar plates of medium PYGV prepared with water of 72‰ salinity or with 67‰ or 130‰ ASW salinity. The same procedure may be carried out with Sabouraud–Dextrose–Agar prepared with 72‰ salinity water. Incubation is at 4°C or 15°C in the dark or at 4.1 μmol photons m^{-2} s^{-1}. Pure cultures are isolated by several dilution transfers on the corresponding agar media. (2) Original water samples (50 ml) are amended with 1 ml of a filter-sterilized solution of 2.5 mg/ml Bacto Yeast Extract prepared in ASW (72‰); incubation at 15°C and in dim light of 4.1 μmol photons m^{-2} s^{-1}.

Maintenance Procedures

Strains of *Roseovarius tolerans* can initially be cultivated on PYGV or R2A agar with 25‰ or 40‰ ASW. After incubation at 8–33°C to allow abundant growth, cultures may be maintained at 4°C for 6 months. They can also be preserved indefinitely by lyophilization or frozen at −72°C in 15% glycerol (v/v).

Procedures for Testing Special Characters

For the study of 16S rRNA gene fragments, PCR amplification is recommended as described by Hudson et al. (1993) and Labrenz et al. (1999).

Differentiation of the genus *Roseovarius* from other genera

Table BXII.α.73 lists characteristics of *Roseovarius* that differentiate it from other morphologically, physiologically, or chemotaxonomically similar organisms. Fig. BXII.α.71 of the chapter describing the genus *Antarctobacter* presents an unrooted tree showing phylogenetic relationships of *Roseovarius tolerans* with closely related *Alphaproteobacteria*.

Taxonomic Comments

The combination of respiratory lipoquinone, fatty acid, and polar lipid data indicates that *R. tolerans* belongs with organisms (at the genus or family rank) within the *Alphaproteobacteria*. $C_{18:1}$ is the characteristic fatty acid for the *Alphaproteobacteria* whereas $C_{18:2}$ occurs in most cases in *R. tolerans* and *Roseobacter* spp. These two groups are differentiated by fatty acids in lower proportions, such as $C_{12:0\ 2OH}$ and $C_{12:1\ 3OH}$ (*R. tolerans*), or $C_{10:0\ 2OH}$ and $C_{14:1\ 3OH}$ (*Roseobacter denitrificans* and *Roseobacter litoralis*) (Labrenz et al., 2000). When grown on Bacto Marine Broth (Difco), *Ruegeria algicola* lacks these characteristic fatty acids. However, the polar lipid patterns of *Roseovarius tolerans* and *Ruegeria algicola* are nearly identical (Labrenz et al., 1999) and they differ from those of *Roseobacter denitrificans*, *Roseobacter litoralis*, or *Antarctobacter heliothermus*. In addition, the mol% G + C ratio of *Ruegeria algicola* (64–65) resembles that of *R. tolerans* (62–64) but differs from that of other *Roseobacter* species (56.3–60.1). Comparative 16S rRNA gene sequence analysis, chemotaxonomic, biochemical, and physiological studies clearly show the close relationship of *Roseobacter denitrificans* with *Roseobacter litoralis*. On the other hand, *Ruegeria algicola* appears to be more related to, albeit different from, *Roseovarius tolerans*, as shown by physiological and fatty acid data (Labrenz et al., 1999).

16S rRNA gene sequencing data indicate the affiliation of *R. tolerans* with the *Alphaproteobacteria*; specifically, there is an association with the *Roseobacter* cluster, which also includes *Ruegeria*, *Staleya*, *Sulfitobacter*, *Antarctobacter*, *Sagittula*, *Octadecabacter*, *Silicibacter*, and a *Prionitis lanceolata* gall symbiont. Sequence divergence values of >5% (4.7% to *Ruegeria algicola*) show *R. tolerans* to be phylogenetically distinct from all currently recognized members of the *Proteobacteria*. Furthermore, bootstrap resampling shows *R. tolerans* does not possess a particularly significant phylogenetic affinity with any individual species within the abovementioned *Roseobacter* cluster.

List of species of the genus Roseovarius

1. **Roseovarius tolerans** Labrenz, Collins, Lawson, Tindall, Schumann and Hirsch 1999, 145[VP]
to'le.rans. L. part. adj. *tolerans* enduring stress conditions.

Rods with a size of 0.74–0.83 × 1.34–1.94 µm. Further morphological descriptions as for the genus. Physiological and nutritional characteristics are presented in Table BXII.α.74. Optimal growth occurs between 8°C and 33.5°C with salt concentrations of 1.0–8.0% NaCl or with 10–130‰ ASW. Optimal pH for growth is 5.9 to >9.0. Colonies on medium PYGV or R2A + 25 (or 40‰) ASW are smooth, convex, and red, pinkish, beige to red, beige, or whitish beige. Isolated from hypersaline, meromictic, and heliothermal Ekho Lake, East Antarctica.

The mol% G + C of the DNA is: 62–64 (HPLC).

Type strain: EL-172, DSM 11457.

GenBank accession number (16S rRNA): Y11551.

Additional Remarks: Reference strains include EL-222, DSM 11463.

Genus XX. Rubrimonas *Suzuki, Muroga, Takahama, Shiba and Nishimura 1999b, 204*[VP]

Christopher Rathgeber and Vladimir V. Yurkov

Ru.bri.mo′ nas. L. adj. *ruber* reddish; Gr. n. *monas* unit; M.L. fem. n. *Rubrimonas* reddish monad.

***Rubrimonas* cells are Gram-negative, short to ovoid rods, 1.0–1.5 × 1.2–2.0 μm. Motile by polar flagella. Division occurs by binary fission.** Forms pink circular colonies when grown on agar media. **Pink coloration is due to the presence of carotenoid pigments. Cells grow heterotrophically under aerobic conditions and produce bacteriochlorophyll (Bchl) *a*. No growth occurs under anaerobic conditions even in the light.** Habitat is saline lakes.

The mol% G + C of the DNA is: 70.4–74.8.

Type species: **Rubrimonas cliftonensis** Suzuki, Muroga, Takahama, Shiba and Nishimura 1999b, 204.

Further descriptive information

Rubrimonas cliftonensis is the only species presently described. Phylogenetically, *Rubrimonas* falls within the *Alphaproteobacteria* forming a separate branch. The closest relative is *Rhodobacter veldkampii* with a 16S rDNA sequence similarity of 89.8%.

R. cliftonensis forms circular, smooth, slightly convex, opaque, pink colonies when grown on agar medium. Cells grown in PPES-II media (Suzuki et al., 1999b) are ovoid rods 1.0–1.5 × 1.2–2.0 μm. Optimal growth occurs at pH 7.5–8.0 and temperature 27–30°C. NaCl is required, with growth occurring in media supplemented with 0.5–7.5% NaCl.

R. cliftonensis is an obligately aerobic heterotroph that produces Bchl *a* under aerobic conditions. Incapable of anaerobic growth even under illumination. A wide variety of organic substrates can be used to support heterotrophic growth, which is typical of other aerobic phototrophic bacteria. Cells utilize D-glucose, L-arabinose, D-fructose, D-galactose, D-ribose, D-xylose, citrate, glycolate, pyruvate, and ethanol. Acids are produced from sugars. Urease, phosphatase, and nitrate reductase are produced (See genus Table BXII.α.71 in Genus *Roseivivax*).

The absorption spectrum of membrane fractions shows a major absorbance peak at 806 and a smaller peak at 871 nm, indicating the presence of Bchl *a* organized into light-harvesting II and light-harvesting I complexes, respectively. This absorption spectrum is similar to that found among members of the genus *Roseobacter*, indicating a similar organization of the photosynthetic apparatus (Nishimura et al., 1994).

The major cellular fatty acid is $C_{18:1}$, making up 68–70% of the cellular fatty acid profile. $C_{16:0}$, $C_{18:0}$, $C_{20:0}$, $C_{19:1}$, and $C_{14:0\ 3OH}$ are found in smaller quantities. The principal ubiquinone is Q-10, making up 98–99% of the quinone content; trace amounts of the quinones Q-8 and Q-9 are also present.

Enrichment and Isolation Procedures

R. cliftonensis was isolated from water samples taken from Lake Clifton, an isolated saline lake on the west coast of Australia. Lake Clifton is a ground water-fed lake, which exhibits a large range in salinity from 14.5 kg/m^3 to 31.5 kg/m^3 (~1.5–3.2%) (Rosen et al., 1996). Samples were plated on PPES-II agar medium (Suzuki et al., 1999b). Pure cultures were obtained by replating of separate colonies.

Maintenance Procedures

R. cliftonensis can be maintained on PPES-II slant agar culture medium. Long-term storage procedures have not been described.

Differentiation of the genus *Rubrimonas* from other genera

Genus *Rubrimonas* can be differentiated from other genera based on 16S rRNA gene sequence, as well as a relatively high mol% G + C content of 74.8. *R. cliftonensis* forms a distinct branch only distantly related to other phototrophic and nonphototrophic genera. The nearest relative is *Rhodobacter veldkampii*, a purple nonsulfur bacterium. *Rubrimonas* is an obligately aerobic phototrophic bacterium, which forms circular pink colonies on agar media due to the presence of carotenoid pigments. It can be distinguished from nonphototrophic genera by absorption spectrum peaks at 806 and 871 nm, corresponding to the presence

of Bchl *a*. Aerobic phototrophic bacteria are distinguished from closely related purple nonsulfur bacteria by their inability to utilize light for anaerobic photosynthetic growth.

Taxonomic Comments

Shiba et al. (1991) described several strains of aerobic bacteriochlorophyll *a*-containing bacteria from saline locations on the east and west coasts of Australia. Thirty-seven strains were divided into four groups (GI, GII, GIII, and GIV) based on cell color, type of absorption spectrum, and cell morphology. DNA–DNA hybridization studies have shown that the two strains making up the GIII group were not closely related to members of the other three groups (Nishimura et al. 1994), and they were subsequently described as *Rubrimonas cliftonensis*.

16S rDNA sequence analysis shows that *Rubrimonas* forms a separate branch within the *Alphaproteobacteria*, with no close relatives. The nearest relative is *Rhodobacter veldkampii* with 89.8% sequence similarity.

List of species of the genus Rubrimonas

1. **Rubrimonas cliftonensis** Suzuki, Muroga, Takahama, Shiba and Nishimura 1999b, 204[VP]
clif.to.nen′ sis. M.L. adj. *cliftonensis* referring to Lake Clifton, Australia, the source of the type strain.

Gram-negative short to ovoid rods (1.0–1.5 × 1.2–2.0 μm), motile possessing polar flagella, divide by means of binary fission. Form circular, pink colonies when grown on agar media. Cells produce Bchl *a* under aerobic conditions, giving rise to absorption spectrum peaks at 806 and 871 nm, corresponding to Bchl *a* incorporated into light-harvesting II and light-harvesting I complexes respectively. Produce carotenoid pigments. Obligately aerobic heterotroph, incapable of anaerobic growth even under illuminated conditions. Utilize D-glucose, L-arabinose, D-fructose, D-galactose, D-ribose, D-xylose, citrate glycolate, pyruvate, and ethanol. Do not utilize acetate, fumarate, DL-lactate, DL-malate, succinate, methanol, L-glutamate, lactose, or sucrose. Acids are produced from sugars. Do not hydrolyze starch, gelatin, alginate, or Tween 80. Cells produce catalase, oxidase, nitrate reductase, phosphatase, and urease. Voges–Proskauer test and ONPG reaction are negative. Produce indole but not H_2S.

NaCl is required, with growth occurring at concentrations ranging from 0.5 to 7.5%. Optimal growth occurs at pH 7.5–8.0 and temperature 27–30°C. Cells are resistant to penicillin and are susceptible to chloramphenicol, streptomycin, and tetracycline. Habitat: saline lake water from Lake Clifton, Australia.

The mol% G + C of the DNA is: 74.0–74.8 (HPLC).
Type strain: Och317, CIP 105913, JCM 10189.
GenBank accession number (16S rRNA): D85834.

Genus XXI. **Ruegeria** *Uchino, Hirata, Yokota and Sugiyama 1999, 1[VP] (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 208)*

The Editorial Board

Rue.ger′ ia. M.L. *-ia* ending; M.L. fem. n. *Ruegeria* honoring Rueger, a German microbiologist, for his contribution to the taxonomy of marine species of *Agrobacterium*.

Gram-negative, **ovoid to rod-shaped cells**, 0.6–1.6 × 1.0–4.0 μm. Motile by polar flagella, or nonmotile. Do not form spores. **Aerobic.** Oxidase and catalase positive. No photosynthetic growth. Bacteriochlorophyll *a* is absent. **Major quinone is ubiquinone 10.**

The mol% G + C of the DNA is: 55–59.

Type species: **Ruegeria atlantica** (Rüger and Höfle 1992) Uchino, Hirata, Yokota and Sugiyama 1999, 1 (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 208) (*Agrobacterium atlanticum* Rüger and Höfle 1992, 141.)

List of species of the genus Ruegeria

1. **Ruegeria atlantica** (Rüger and Höfle 1992) Uchino, Hirata, Yokota and Sugiyama 1999, 1[VP] (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 208) (*Agrobacterium atlanticum* Rüger and Höfle 1992, 141.)
at.lan′ ti.ca. M.L. adj. *atlantica* pertaining to the Atlantic Ocean as the locality.

Gram-negative, ovoid to rod-shaped cells, 0.6–1.6 × 1.0–4.0 μm. Motile by polar flagella or nonmotile. Do not form spores. Aerobic. Oxidase and catalase positive. Non-photosynthetic. Bacteriochlorophyll *a* is absent. Nonmotile. Nitrate reduced to nitrite. Seawater or Na^+ required for growth. Major fatty acid is $C_{18:1}$. 3-Hydroxy fatty acids are $C_{12:0\ 3OH}$ and $C_{14:1\ 3OH}$. 2-Hydroxy fatty acid is $C_{16:0\ 2OH}$. Major quinone is ubiquinone 10.

The mol% G + C of the DNA is: 55–58.
Type strain: 1480, ATCC 700000, CIP 105975, DSM 5823, IAM 14463, IFO 15792.
GenBank accession number (16S rRNA): D88526.

2. **Ruegeria algicola** (Lafay, Ruimy, Rausch de Traubenberg, Breittmayer, Gauthier and Christen 1995) Uchino, Hirata, Yokota and Sugiyama 1999, 1[VP] (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 209) (*Roseobacter algicola* Lafay, Ruimy, Rausch de Traubenberg, Breittmayer, Gauthier and Christen 1995, 295.)
al.gi′ co.la. L. n. *alga* algae; L. subst. *cola* dweller; M.L. n. *algicola* algae dweller.

Gram-negative, ovoid to rod-shaped cells, 0.6–1.6 × 1.0–4.0 μm. Motile by means of one or two subpolar flagella. Do not form spores. Aerobic. Oxidase and catalase positive.

Not photosynthetic. Bacteriochlorophyll *a* is absent. Cells are ovoid during exponential growth. Colonies on salt-containing agar are beige when young, pinkish beige after 96 h. Optimal temperature 25–30°C. No denitrification. The following tests are positive: oxidase, catalase, gelatinase, esculinase, β-galactosidase, and amylase. Do not accumulate polyhydroxybutyrate. Isolated from a culture of the toxin-producing dinoflagellate *Prorocentrum lima* PLV2. Require Na^+ for growth. Major fatty acid is $C_{18:1}$. 3-Hydroxy fatty acids are $C_{12:0\ 3OH}$, $C_{10:0\ 3OH}$, and $C_{14:1\ 3OH}$. 2-Hydroxy fatty acids are absent. Major quinone is ubiquinone 10.

The mol% G + C of the DNA is: unknown.

Type strain: FF3, ATCC 51440, DSM 10251, IAM 14591.

GenBank accession number (16S rRNA): X78315.

3. **Ruegeria gelatinovorans** (Rüger and Höfle 1992) Uchino, Hirata, Yokota and Sugiyama 1999, 1[VP] (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 209) (*Agrobacterium gelatinovorum* Rüger and Höfle 1992, 141.)

ge.la.ti.no' vor.ans. M.L. gelatin; L. v. *voro* to devour; M.L. adj. *gelatinovorans* gelatin-devouring.

Gram-negative, ovoid to rod-shaped cells, 0.6–1.6 × 1.0–4.0 μm. Motile by means of polar flagella. Do not form spores. Aerobic. Oxidase and catalase positive. Not photosynthetic. Bacteriochlorophyll *a* is absent. Nitrate reduced to nitrite. Acids produced from glycerol but not glucose, fructose, maltose, or xylose. Isolated from seawater of the Baltic Sea. Require seawater or Na^+ for growth. Major fatty acids are $C_{18:1}$ and $C_{18:0}$. 3-Hydroxy fatty acid is $C_{12:0\ 3OH}$. 2-Hydroxy fatty acids are absent. Major quinone is ubiquinone 10.

The mol% G + C of the DNA is: 59.

Type strain: B6, ATCC 25655, DSM 5887, IAM 12617.

GenBank accession number (16S rRNA): D88523.

Genus XXII. **Sagittula** *González, Mayer, Moran, Hodson and Whitman 1997b, 778*[VP]

José M. González

Sa.git' tu.la. L. fem. n. *sagittula* small arrow, referring to the shape of the bacterium.

Rod-shaped cells, 0.9 × 2.3 μm. Gram negative. Cells attach by one pole to particles of cellulose and lignocellulose by means of a polar holdfast structure that can be seen by electron microscopy. Endospores and cysts are not formed. Capsules are produced. **Intracellular granules of polyhydroxybutyrate are formed. Aerobic, having a strictly aerobic type of metabolism with oxygen as the terminal electron acceptor.** Do not denitrify. Colonies are nonpigmented. Bacteriochlorophyll *a* is not present. **Oxidase and catalase positive. Sea-salt-based medium is required for growth.** Chemoorganotrophic. Methanol, various carbohydrates and amino acids, and some aromatic compounds such as *p*-coumarate, cinnamate, ferulate, and vanillate are utilized. Organic nitrogen compounds, ammonium, and nitrate serve as nitrogen sources. **Cellulose is hydrolyzed. Synthetic lignin preparations are partially solubilized and mineralized in the presence of glucose.** 16S rRNA gene sequence analysis positions this genus in a group of marine bacteria (except for the moderate halophile *Silicibacter*) within the family *Rhodobacteraceae*. Isolated from a salt marsh at 2% salinity on the coast of Georgia, USA, by enrichment with lignin-rich pulp mill effluent.

The mol% G + C of the DNA is: 65.0.

Type species: **Sagittula stellata** González, Mayer, Moran, Hodson and Whitman 1997b, 778.

Further descriptive information

As seen by electron microscopy, each cell has a holdfast structure at one pole and the cell envelope has numerous surface vesicles derived from the outer membrane (Fig. BXII.α.80). Cells form rosettes and aggregates, especially at the stationary phase of growth.

Sagittula contains the following major fatty acids: $C_{16:0}$, $C_{18:0}$, $C_{12:1\ 3OH}$, $C_{19:0\ cyclo\ \omega 8c}$, $C_{18:1\ \omega 7c}$, $C_{18:1\ \omega 9t}$, and $C_{18:1\ \omega 12t}$.

The only species in the genus was isolated from a salt marsh at 2% salinity on the coast of Georgia, USA, by enrichment with the high-molecular-weight fraction of pulp mill effluent. Although the species so far includes only one strain, closely related organisms were detected by molecular techniques in unpolluted coastal water, which receives high inputs of lignocellulosic material from aquatic plants.

Enrichment and Isolation Procedures

The type strain was isolated on YTSS[1] agar plates from a marine enrichment community growing on the high-molecular-weight fraction of a black liquor sample from pulp mill effluent, which is rich in lignin, lignin byproducts, and other plant polymers in a smaller proportion (González et al., 1997b). The original inoculum was from a salt marsh on the coast of Georgia, USA. The enrichment medium consisted of filter-sterilized seawater containing 5 mM NH_4NO_3, 1 mM KH_2PO_4, and the liquor fraction at a concentration of 20 mg C per liter. This medium was inoculated with cloudy, brown-green seawater from the salt marsh. Flasks were incubated aerobically with shaking. After enrichment, the organism was isolated on YTSS agar plates incubated at room temperature.

Maintenance Procedures

The type strain is maintained in YTSS broth with 15% glycerol and 15% DMSO at −70°C. Lyophilized cultures are also used.

Differentiation of the genus *Sagittula* from other genera

Table BXII.α.75 lists characteristics differentiating *Sagittula* from other aerobic marine bacteria. *Sagittula* does not oxidize sulfite, and this characteristic distinguishes it from *Sulfitobacter*. The absence of bacteriochlorophyll *a* production, major fatty acids, and the mol% G + C content of the DNA distinguish it from *Roseobacter denitrificans*, *Roseobacter litoralis*, and *Octadecabacter*. Temperature tolerance is different from *Octadecabacter* and *Silicibacter* (Table BXII.α.75). 16S rRNA gene sequences of *Sagittula* and *"Marinosulfonomonas"* show a low level of homology (90%).

1. YTSS agar (g/l distilled water): yeast extract, 4.0; tryptone (Difco), 2.5; sea salts (Sigma Chemical Co., St. Louis, MO), 20; and agar, 18. YTSS broth is the same except that agar is omitted.

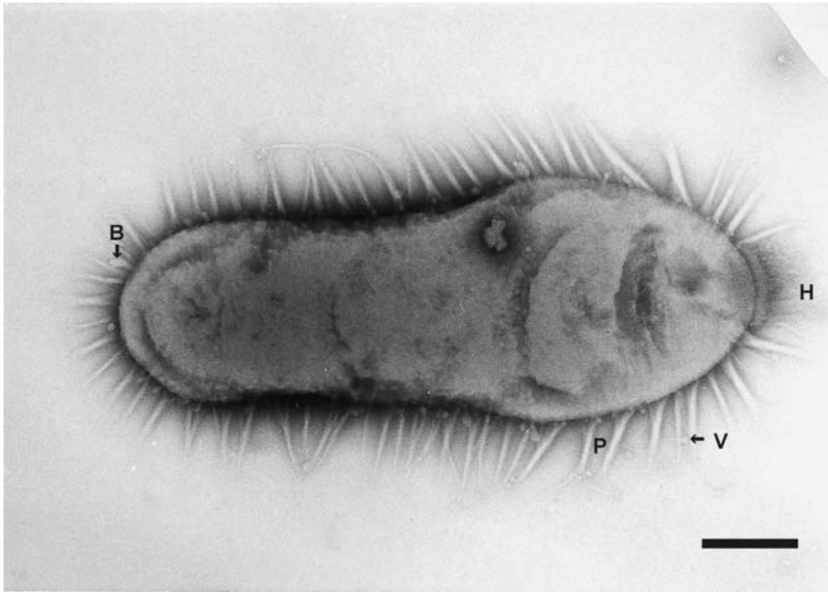

FIGURE BXII.α.80. Electron micrograph of *Sagittula stellata*. Negatively stained. Cells are covered by polysaccharides fibrils (*P*) and blebs (*B*). Vesicles (*V*) are also seen unattached. Holdfast structure (*H*) at the wider cell pole is indicated. The cells attach to cellulose and lignocellulose particles by the wider pole. Bar = 0.2 μm. (Courtesy of F. Mayer).

Taxonomic Comments

Based on 16S rRNA gene sequence analysis, the closest related genera are *Sulfitobacter*, *Roseobacter*, *Ruegeria*, *Octadecabacter*, *Silicibacter*, and *"Marinosulfonomonas"*. The genus has a signature secondary structure since a deletion corresponding to Helix 11 of the 16S rRNA occurs. This deletion spans 11 bases starting at position 200 (*E. coli* numbering system).

List of species of the genus Sagittula

1. **Sagittula stellata** González, Mayer, Moran, Hodson and Whitman 1997b, 778[VP]
stel.la′ta. L. adj. *stellata* starry, here referring to the cell arrangement.

Colonies on marine agar 2216 are light cream colored.

The characteristics are as described for the genus with the following additional information. The cells show polarity, the width of one half is greater than that of the other. The holdfast structure is located at the thicker pole. Vesicles are not only seen on the cell surface but also are free in the medium. The cells occur singly and arranged as rosettes, especially at stationary phase, and form short chains in marine broth 2216.

Growth occurs between pH 5.5 and 8.5; optimal, 7.5. The temperature range for growth is 4-41°C; optimal, 30°C. Sea-salt-based medium is required for growth. Vitamins are required for optimal growth. Does not grow in the absence of a source of fixed nitrogen.

Growth occurs on methanol, the salts of various organic acids, monosaccharides, disaccharides, amino acids, and ar-

omatic compounds. Among the latter are lignin-related compounds such as *p*-coumarate, cinnamate, ferulate, and vanillate. Cells also utilize organic sulfur compounds and similar compounds that are produced by aquatic plants and algae, such as dimethylsulfoniopropionate, 3-mercaptopropionate, methanethiol, and glycine betaine. Strain E-37 quickly oxidizes dimethylsulfide to dimethylsulfoxide in aerobic conditions without further degradation of dimethylsulfoxide (González et al., 1999). Strain E-37 was able to solubilize and partially mineralize artificial lignin in the presence of glucose.

The mol% G + C of the DNA is: 65.0 (HPLC).

Type strain: E-37, ATCC 700073; CIP 105237, DSM 11524.

GenBank accession number (16S rRNA): U58356.

Genus XXIII. **Staleya** *Labrenz, Tindall, Lawson, Collins, Schumann and Hirsch 2000, 310*[VP]

MATTHIAS LABRENZ AND PETER HIRSCH

Sta' ley.a. M.L. fem. n. *Staleya* named after the American microbiologist J.T. Staley in recognition of his work on budding and appendaged bacteria and his contributions to polar microbiology.

Rods, one or both cell poles narrower, multiplying by monopolar growth, i.e., by a budding process. Gram negative. Cells may be motile. No resting stages known. **Aerobic**, with a strictly respiratory type of metabolism. **Intracellular granules of poly-β-hydroxybutyrate (PHB) are present.** Cells have a weak requirement for Na^+. Temperature range for growth <4–32°C, salinity range <10 to <150‰ of artificial seawater (ASW), NaCl tolerance range <1.0–4.0% and pH tolerance range 5.3–6.5 to >9. Oxidase and weakly catalase positive. Do not grow photoautotrophically with H_2/CO_2 (80:20) or photoorganotrophically with acetate or glutamate. Bacteriochlorophyll *a* (BChl *a*) may be produced. Occur in marine habitats.

The mol% G + C of the DNA is: 55–56.

Type species: **Staleya guttiformis** Labrenz, Tindall, Lawson, Collins, Schumann and Hirsch 2000, 310.

FURTHER DESCRIPTIVE INFORMATION

Visible growth of *S. guttiformis* appears at 20°C after 3–5 d on medium PYGV (Staley, 1968) prepared with 25‰ artificial seawater (ASW; Lyman and Fleming, 1940). Colonies are circular, smooth, convex, 1–3 mm in diameter and beige, older colonies also pink. Cell sizes: 1.0–1.5 × 1.5–8.9 µm. Cell growth appears to be monopolar since one cell end is usually more narrow and shorter, which indicates a budding process (Hirsch, 1974a). Rosettes are formed frequently. Cells are motile with one flagellum.

Bacteriochlorophyll *a* is found in older, dark-grown cell suspensions of *Staleya guttiformis*. Absorbance values characteristic of BChl *a* have a large peak at 861–862 nm, and smaller ones at 800–802 nm and 590–592 nm. They differ from maxima of the BChl *a*-containing *Roseobacter denitrificans* and *Roseobacter litoralis* (Shiba, 1991a) or *Roseovarius tolerans* (Labrenz et al., 1999). Unlike *Roseovarius tolerans*, the production of BChl *a* by *S. guttiformis* is not totally repressed in constant dim light.

S. guttiformis has a weak requirement for Na^+, but not for K^+, Mg^{2+}, Ca^{2+}, Cl^- or SO_4^{2-}.

Cells do not grow on glucose anaerobically in the absence of nitrate. Metabolism of carbon sources tested with the Biolog system is described by Labrenz et al. (2000). Acetoin or acids are not produced from glucose. Neither sulfide nor indole is produced. Do not reduce nitrate anaerobically.

The peptidoglycan of *S. guttiformis* contains *m*-diaminopimelic acid. Respiratory quinone is Q-10. Phospholipids present are: phosphatidylglycerol, phosphatidylcholine, and phosphatidylethanolamine as well as an unknown aminolipid. The predominant fatty acid is $C_{18:1\ \omega7c}$ (79.7%); other characteristic fatty acids are $C_{10:0\ 3OH}$ (5.9%), $C_{14:1\ 3OH}$ (2.1%), $C_{16:0}$ (3.9%), $C_{18:0}$ (0.7%), $C_{18:2}$ (5.3%), and $C_{19:1}$ (1.4%).

Comparative 16S rRNA gene sequence analysis shows that *S. guttiformis* is a member of the *Alphaproteobacteria*. Highest 16S rRNA gene sequence relatedness (98%) is displayed with *Sulfitobacter mediterraneus* (Pukall et al., 1999), a new species described simultaneously with *Staleya*. In addition, high sequence relatedness is observed with *Sulfitobacter pontiacus* (Sorokin, 1995), *S. brevis* (Labrenz et al., 2000), *Roseobacter denitrificans* and *Roseobacter litoralis* (Shiba, 1991a). Other species belonging to the *Alphaproteobacteria* show lower levels of relatedness. An unrooted tree depicting the phylogenetic relationships of *S. guttiformis* and its closest relatives is shown in Fig. BXII.α.71 of the chapter describing the genus *Antarctobacter*. The results of treeing analyses showed that this species phylogenetically clusters with *Sulfitobacter* spp.

ENRICHMENT AND ISOLATION PROCEDURES

An enrichment procedure used for *S. guttiformis*: Original water samples (1.0 ml) are spread directly on medium PYGV agar plates prepared with water of 15‰ salinity. Incubation is at 15°C at 4.1 µmol photons $m^{-2}\ s^{-1}$.

MAINTENANCE PROCEDURES

Staleya guttiformis can initially be cultivated on PYGV agar with 10–40‰ ASW. After incubation at 12–20°C to allow abundant growth, cultures may be maintained in a refrigerator (4°C) for 6 months. They can also be preserved by lyophilization or frozen at −72°C in 15% glycerol (v/v).

PROCEDURES FOR TESTING SPECIAL CHARACTERS

For the study of 16S rRNA gene fragments, PCR amplification is recommended as described by Hudson et al. (1993) and Labrenz et al. (1998).

DIFFERENTIATION OF THE GENUS *STALEYA* FROM OTHER GENERA

Table BXII.α.76 lists characteristics of *Staleya* that differentiate it from other morphologically, physiologically, or chemotaxonomically similar organisms. Fig. BXII.α.71 of the chapter describing the genus *Antarctobacter* presents an unrooted tree showing phylogenetic relationships of *Staleya guttiformis* with closely related *Alphaproteobacteria.*

Taxonomic Comments

Sequencing of 16S rRNA genes confirmed *S. guttiformis* is a member of the *Alphaproteobacteria*. The combination of respiratory lipoquinone, fatty acid, and polar lipid data also indicates that it belongs with bacteria (above the species rank) of the *Alphaproteobacteria* (Labrenz et al., 2000). Comparative 16S rRNA gene sequence analysis shows that *S. guttiformis* is specifically associated with the *Sulfitobacter–Roseobacter* cluster, but not with *Ruegeria algicola* or *Roseobacter gallaeciensis*. It is evident from treeing analyses that the genus *Roseobacter*, as currently recognized, is interspersed with several other taxa. This is also reflected by the affiliation of the former *Roseobacter algicola* with the genus *Ruegeria* (Uchino et al., 1998).

The chemotaxonomic data indicate that members of the genus *Roseobacter* (i.e., *R. litoralis* and *R. denitrificans*) have a distinctive polar lipid composition, in which both species have phosphatidylglycerol, diphosphatidylglycerol, and an unidentified amino lipid as the major components. In contrast, *S. guttiformis*, *Sulfitobacter brevis*, and *S. pontiacus* all synthesized phosphatidylglycerol, phosphatidylethanolamine, and phosphatidylcholine, together with the same unidentified amino lipid. This polar lipid composition serves to distinguish these two groups from one another.

Phylogenetically, *S. guttiformis* is closely related to *Sulfitobacter* spp. Morphologically, it is also more similar to *Sulfitobacter* than to *Roseobacter* strains: its cells multiply by monopolar growth (a budding process) and form rosettes. The ability to oxidize sulfite and thereby to increase growth characterizes *S. pontiacus* (Sorokin, 1995). *S. mediterraneus* grows also to higher cell densities with 10 mM sulfite in an acetate-supplemented medium (Pukall et al., 1999). *S. brevis* tolerates lower initial sulfite concentrations in an acetate-supplemented medium than *S. pontiacus*, but not so low as *Staleya guttiformis* (Labrenz et al., 2000).

Especially, chemotaxonomic data indicate differences between *Staleya* and *Sulfitobacter*. *Staleya* does not synthesize the fatty acids $C_{16:1}$, $C_{17:1}$, $C_{17:0}$, or $C_{18:1\ 10CH_3}$ as well as the phospholipid diphosphatidylglycerol. Examination of the mol% G + C base content showed that the value for *Staleya* was about 6% lower than that for the *Sulfitobacter* type species, *S. pontiacus*.

Other differences concerned BChl *a*, which was present in *Staleya guttiformis*, as shown by *in vivo* absorption bands at 800–802 and 861–862 nm. These peaks were clearly absent from *Roseobacter* spp. and *Sulfitobacter* cells. The importance of BChl *a* for a taxonomic separation of these aerobic bacteria has been questioned (Labrenz et al., 1999).

In conclusion, bacteria of the *Staleya–Sulfitobacter–Roseobacter* cluster appear to be phylogenetically quite closely related, but are phenotypically very diverse, which makes their taxonomic separation difficult. 16S rDNA sequence data and similarities in chemotaxonomic data make it appear likely that the genera *Staleya*, *Sulfitobacter*, and *Roseobacter* share a common ancestor (Labrenz et al., 1999). Presently, *Staleya* is placed between *Roseobacter* (Shiba, 1991a) and *Sulfitobacter* (Sorokin, 1995).

Genus XXIV. **Stappia** *Uchino, Hirata, Yokota and Sugiyama 1999, 1[VP] (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 208)*

The Editorial Board

Stap.pi.a. M.L. dim. *-ia* ending; M.L. fem. n. *Stappia* honoring Stapp, a Belgian microbiologist, for his contribution to the taxonomy of marine species of *Agrobacterium*.

Gram-negative **rods**, 0.6–1.0 × 2.0–4.0 µm. Motile by means of polar flagella. Do not form spores. **Aerobic.** Nonphototrophic. Oxidase and catalase positive. Seawater or Na^+ required for growth. Major fatty acids are $C_{18:1}$ and $C_{18:0}$. 3-Hydroxy fatty acid is $C_{14:0\ 3OH}$. 2-Hydroxy fatty acids are absent. **Major quinone is ubiquinone 10.** Isolated from marine sediment and seawater.

The mol% G + C of the DNA is: 59.

Type species: **Stappia stellulata** (Rüger and Höfle 1992) Uchino, Hirata, Yokota and Sugiyama 1999, 1 (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 208) (*Agrobacterium stellulatum* Rüger and Höfle 1992, 141.)

List of species of the genus Stappia

1. **Stappia stellulata** (Rüger and Höfle 1992) Uchino, Hirata, Yokota and Sugiyama 1999, 1[VP] (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 208) (*Agrobacterium stellulatum* Rüger and Höfle 1992, 141.)
stel′ lu.la.ta. M.L. fem. n. *stella* star-shaped; M.L. adj. *stellulata* star-shaped.

Gram-negative rods, 0.6–1.0 x 2.0–4.0 µm. Motile by means of polar flagella. Do not form spores. Aerobic. Nonphototrophic. Oxidase and catalase positive. Seawater or Na^+ required for growth. Nitrate is not reduced to nitrate but is reduced to gas. No acid from glucose, maltose, or mannitol after 4–6 weeks. Major fatty acids are $C_{18:1}$ and $C_{18:0}$. 3-Hydroxy fatty acid is $C_{14:0\ 3OH}$. 2-Hydroxy fatty acids are absent. Major quinone is ubiquinone 10. Isolated from marine sediment and seawater.

The mol% G + C of the DNA is: 59.

Type strain: ATCC 15215, CIP 105977, DSM 5886, IAM 12621, IFO 15764.

GenBank accession number (16S rRNA): D88525.

2. **Stappia aggregata** (ex Ahrens 1968) Uchino, Hirata, Yokota and Sugiyama 1999, 1[VP] (Effective publication: Uchino, Hirata, Yokota and Sugiyama 1998, 208.)
ag.gre.ga′ ta. L. adj. *aggregatus* joined together, referring to the frequent formation of rosettes.

Gram-negative rods, 0.6–1.0 × 2.0–4.0 µm. Motile by means of polar flagella. Do not form spores. Aerobic. No photosynthetic growth. Oxidase and catalase positive. Seawater or Na^+ required for growth. Nitrate is not reduced to nitrate but is reduced to gas. No acid from glucose or xylose. Weak or variable acid production from fructose, glycerol, and maltose after 4–6 weeks. Major fatty acids are $C_{18:1}$ and $C_{18:0}$. 3-Hydroxy fatty acid is $C_{14:0\ 3OH}$. 2-Hydroxy fatty acids are absent. Major quinone is ubiquinone 10. Isolated from marine sediment and seawater.

The mol% G + C of the DNA is: 59.

Type strain: B1, ATCC 25650, IAM 12614, NCMB 2208.

GenBank accession number (16S rRNA): D88520.

Genus XXV. **Sulfitobacter** *Sorokin 1996, 362[VP] (Effective publication: Sorokin 1995, 304)*

DIMITRY Y. SOROKIN, FRED A. RAINEY, RICHARD I. WEBB AND JOHN A. FUERST

Sul.fi.to.bac′ter. M.L. n. *sulfitum* sulfite; M.L. masc. form *bacter* Gr. neut. n. *bactrum* rod; M.L. masc. n. *Sulfitobacter* sulfite rod.

Rod-shaped cells 0.5–1.0 × 1.0–3.0 μm. Often dumbbell shaped, with a tendency for polar growth. **Motile by means of 1–5 subpolar flagella.** Gram negative. Inside the cells, the nucleoid and polar region are often in separate compartments. **Obligately aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Obligately chemoorganotrophic, but can use energy from the oxidation of thiosulfate and sulfite during growth in the presence of an organic carbon source. Cells cannot grow autotrophically with sulfur compounds or hydrogen as electron donors, but are able to oxidize thiosulfate, sulfur, and sulfite to sulfate.** Can grow in presence of at least 10 mM sulfite; some strains can grow with up to 60 mM sulfite. **NaCl is required for growth.** Mesophilic. Neutrophilic.

The mol% G + C of the DNA is: 59–62.

Type species: **Sulfitobacter pontiacus** Sorokin 1996, 362 (Effective publication: Sorokin 1995, 304.)

FURTHER DESCRIPTIVE INFORMATION

Ultrastructure Many cells of *Sulfitobacter pontiacus*, especially taken from batch culture, display an unusual compartmentalized cell ultrastructure (Fig. BXII.α.81). At least some cells appear to possess a major cell compartment bounded by a single membrane and containing the cell's nucleoid as well as electron-dense ribosome-like particles. A less electron-dense cytoplasm surrounds the compartment, with a larger region of this material at one pole comprising a polar cap. Such organization appears in thin sections whether cells are either chemically fixed or cryofixed and processed via cryosubstitution. An indication of such a structure may also be apparent from negatively stained whole cells (Sorokin, 1995). This type of cell organization has been referred to as a pirellulosome, an organelle reported previously only in the genus *Pirellula* (Lindsay et al., 1997), a member of the order *Planctomycetales*, which is a distinct phylogenetic lineage within the domain *Bacteria*. Members of at least two genera of planctomycetes (*Pirellula* and *Gemmata*) display unusual compartmented cell organization (Fuerst and Webb, 1991; Fuerst, 1995). Pirellulosomes of *S. pontiacus* differ from those in *Pirellula* in that in cells of the latter a nucleoid is always clearly visible as a condensed fibrillar region even after cryosubstitution, whereas in *Sulfitobacter* a condensed nucleoid in the pirellulosome is not clearly apparent in cryosubstituted cells, but is revealed after chemical fixation. This absence of distinct nucleoid in cryosubstituted cells is typical of the limited model bacteria so far examined by cryosubstitution. The occurrence of membrane-bounded nucleoid-containing cell compartments of analogous organization in two phylogenetically widely separated members of separate divisions or phyla of the domain *Bacteria* suggests either retention of an ancient characteristic of cell organization within deeply divergent lineages or convergent evolution of an analogous structure with similar function.

Metabolism Although *Sulfitobacter* species are obligate heterotrophs, *S. pontiacus* possesses a unique ability to derive additional metabolic energy from sulfite oxidation under substrate-limiting conditions, thus belonging to a specific type of lithoheterotrophs. The high tolerance to sulfite has also been demonstrated for other *Sulfitobacter* species but whether or not they are capable of sulfite oxidation and sulfite-dependent lithoheterotrophy remains unclear.

Habitat Sulfur-oxidizing chemolithoheterotrophic bacteria of the type represented by *S. pontiacus* rather than the autotrophic thiobacilli were found to dominate the sulfate-forming population in the Black Sea. This can be explained by better adaptation of these versatile heterotrophs to the conditions of the redox layer of the Black Sea, where relatively diluted upward fluxes of reduced sulfur compounds meet downward fluxes of organic matter from the euphotic surface layer. Recently, it was reported that bacteria closely related to *Sulfitobacter* represent a substantial part of heterotrophic population in littoral marine environments (González and Moran, 1997; Pukall et al., 1999).

Sulfitobacter brevis was isolated from the hypersaline lake, Ekho Lake, in East Antarctica (Vestfold Hills). The salinity of this lake increases with depth, with the formation of interface layers. *Sulfitobacter mediterraneus* was isolated from a microcosm prepared with natural seawater from the Mediterranean Sea.

ENRICHMENT AND ISOLATION PROCEDURES

Sulfitobacter pontiacus, together with other strains of sulfate-producing chemolithoheterotrophic bacteria from the Black Sea, were enriched on mineral medium containing seawater and thiosulfate. Although pure cultures of such bacteria cannot be grown on synthetic mineral media and demand an organic carbon source, the low amount of organic matter present in seawater, in combination with inorganic energy source allows selection of chemolithoheterotrophs. Pure cultures can be successfully grown on A medium with the following composition (per liter): NaCl, 20.0 g; HEPES (N-[2-hydroxyethyl]piperazine-N′-[ethane-sulfonic acid]), 7 g ; K_2HPO_4, 1.0 g; NH_4Cl, 0.5 g; $MgSO_4 \cdot 7H_2O$, 1.0 g; $CaCl_2 \cdot 2H_2O$, 0.2 g; sodium acetate, 2.8 g; sodium thiosulfate, 2.5 g; yeast extract, 0.5 g; trace elements solution (Pfennig and Lippert, 1966), 1 ml; final pH 7.8. Short-term preservation of the active cultures (<1 month) is possible by storage of agar slopes at 4°C. Best survival during long-term storage (6–12 months) was registered when concentrated cultures were kept at −70°C with glycerol (15% v/v final concentration).

For the enrichment of *Sulfitobacter brevis*, 50 ml of saline Ekho Lake water (salinity 15‰) was amended with a filter-sterilized solution of 12.5 mg/ml. Oxoid yeast extract and incubated at 15°C under dim light. Colonies were obtained on PYGV agar[1] containing 25‰ (v/v) artificial seawater.

Enrichment of *Sulfitobacter mediterraneus* was accomplished by preparing a microcosm filled with 300 liters of natural seawater collected from a depth of 1 m at a station (42° 31′ N, 03° 11′ E) located about 2400 m from Banyuls-sur-Mer , France (Mediterranean Sea) and filtered through a 200-μm nylon mesh. At various times, isolation was performed by spreading 0.1 ml of 1:10, 1:100, and 1:1000 dilutions of the seawater onto plates of Marine Agar 2216 (Difco). Between 30 and 50 colonies were selected from each sampling time. Isolates were preserved by freezing at −80°C in 40% glycerol or by storing at 20°C on marine agar.

1. PYGV medium consists of (per liter): Bacto peptone (Difco), 0.25; Bacto yeast extract (Difco), 0.25; Hutner's basal mineral salt solution HBM (Cohen-Bazire et al., 1957), 20 ml; and vitamin solution No. 6 (van Ert and Staley, 1971), 10 ml. The medium is solidified with 18 g agar. For salt-requiring organisms, the medium is supplemented with 25‰ artificial sea water (ASW; Lyman and Fleming, 1940.

Bar = 1 µm. *B*, Thin-sectioned chemically fixed cell showing a major pirellulosome cell compartment (*P*) bounded by a single membrane and containing fibrillar nucleoid and electron-dense particulate cytoplasm and less electron-dense polar regions continuous with cytoplasm surrounding the membrane-bounded compartment. Bar = 0.1 µm. *C–D*, Thin-sectioned cryosubstituted cells, showing a major pirellulosome compartment (*P*) containing relatively large electron-dense particles bounded by a single membrane and a polar cap continuous with cytoplasm surrounding the pirellulosome. Bar = 0.1 µm.

Differentiation of the genus *Sulfitobacter* from other genera

Table BXII.α.78 provides some characteristics that can be used to differentiate this genus from the closely related genera of the *Roseobacter* cluster.

Taxonomic Comments

The original description of *Sulfitobacter pontiacus* was based on two closely related strains, which had a DNA–DNA reassociation value of about 90%: strain ChLG 10 (DSM 10014^T) and ChLG 5 (DSM 10015), isolated from the Black Sea (Sorokin, 1995). 16S rRNA gene sequence analysis revealed another representative of this species, strain SED3, isolated from the littoral waters near Australia (Ward-Rainey et al., 1996). Although different morphologically, this strain possesses a highly active sulfite dehydrogenase, typical for *Sulfitobacter*, and it showed a high percentage of DNA–DNA reassociation (>70%) with the type strain ChLG 10.

Phylogenetic analyses based on 16S rDNA sequence comparison demonstrate that *S. pontiacus* belongs to the *Alphaproteobacteria*, with its closest relatives being two of the three species of the aerobic bacteriochlorophyll-containing erythrobacteria of the genus *Roseobacter*, namely *Roseobacter litoralis* and *Roseobacter denitrificans* (Fig. BXII.α.82). The 16S rDNA sequence of *S. pontiacus* strain ChLG 10 has 96.7% and 97.5% similarity to the 16S

rDNA sequences of *Roseobacter denitrificans* and *Roseobacter litoralis*, respectively. The only other complete 16S rDNA sequence with a high similarity to the *S. pontiacus* strain ChLG 10 sequence is that of strain S34, a marine bacterium isolated from the Sargasso Sea (Suzuki et al., 1997). With a 16S rDNA similarity value of 99.2% between the sequences of strain S34 and strain ChLG 10, it seems clear that strain S34 is a member of the genus *Sulfitobacter* and most probably an additional strain of the species *S. pontiacus.*

In the 16S rDNA sequence databases, there are additional partial (<500 nucleotides) sequences to which that of *S. pontiacus* (ChLG 10) shows greater than 98% sequence similarity. These sequences include those of the isolates EE-36 (99.7%), GAI-21 (98.8%) (González and Moran, 1997), and SED3 (99.3%) (Ward-Rainey et al., 1996). The high similarity between these sequences demonstrates the wide geographical distribution of strains of the genus *Sulfitobacter.*

The relatedness of *Sulfitobacter* to members of the genus *Roseobacter* is not surprising, considering that the class *Alphaproteobacteria* contains many species able to oxidize sulfur compounds, both photo- and chemotrophically. They are likely descendents of the purple nonsulfur bacteria, in particular of *Rhodobacter* species. It could be speculated that colorless sulfate-forming lithoheterotrophs, like *S. pontiacus*, descended from the purple nonsulfur bacteria via erythrobacteria. In fact, some of the latter are capable of oxidizing reduced sulfur compounds (Yurkov et al., 1994b). Experiments with representatives of the genus *Roseobacter* demonstrated that the atypical *Roseobacter* species, *R. algicola*, was able to oxidize thiosulfate and sulfite to sulfate and possessed moderate sulfite dehydrogenase activity.

Analysis of nearly complete 16S rRNA gene sequences showed that the type strain of *S. brevis* was 96.5–98% similar to that of *S. pontiacus.* A high degree of sequence similarity occurred with *Roseobacter denitrificans* and *Roseobacter litoralis.* No significant DNA–DNA reassociation occurred between *S. brevis* and *S. pontiacus* (Labrenz et al., 2000).

16S rDNA sequence analysis of the type strain of *Sulfitobacter mediterraneus* indicated 98.2% similarity to the type strain of *S. pontiacus.* DNA–DNA reassociation experiments indicated a 46% hybridization value between the two species. Except for a quantitative difference in fatty acid composition, there are no distinct phenotypic differences between the two species (Pukall et al., 1999).

Differentiation of the species of the genus *Sulfitobacter*

No clear-cut differences between the three species were found. The real differentiation was achieved based on DNA–DNA hybridization and 16S rDNA analysis. The presence of sulfite dehydrogenase and the ability to grow lithoheterotrophically with sulfur compounds remains to be tested for *S. brevis* and *S. mediterraneus.*

List of species of the genus Sulfitobacter

1. **Sulfitobacter pontiacus** Sorokin 1996, 362[VP] (Effective publication: Sorokin 1995, 304.)
pon.ti.a′ cus. Gr. n. *Pontus* Black Sea; M.L. adj. *pontiacus* from the Black Sea.

Cells grown in batch cultures vary in shape and size from regular rods (0.5–0.8 × 1.0–1.5 μm) to swollen filaments (up to 20 μm) and are very rarely motile. Bud-like minicells often appear in such cultures, especially when grown on solid medium. Cells grown in continuous culture are more regular, mostly motile rods with sharp edges, often arranged in rosettes (Fig.BXII.α.81a).

Sulfitobacter pontiacus benefits from the oxidation of reduced sulfur compounds such as thiosulfate and sulfite, being able to oxidize these to sulfate. This ability was proven in experiments with acetate-limited continuous culture (thiosulfate- or sulfite-dependent increase of specific growth yield) and with washed cells (sulfite-dependent ATP production). An extremely active, AMP-independent, soluble sulfite dehydrogenase allows *S. pontiacus* to grow in the presence of very high concentrations of sulfite in acetate-limited continuous culture, which was not demonstrated previously even for chemolithoautotrophic sulfur-oxidizing bacteria. During cultivation, the bacterium gradually adapts to increasing sulfite concentrations and, at the same time, the specific biomass yield and the efficiency of acetate utilization increases.

Sole carbon and energy sources include acetate, propionate, butyrate, pyruvate, lactate, gluconate, acids of the Krebs cycle (except citrate and *cis*-aconitate), glycerol, glutamate, proline, aspartate, asparagine, serine, L-α-alanine, ornithine, and arginine as the sole carbon and energy sources. Ammonium salts and some amino acids are used

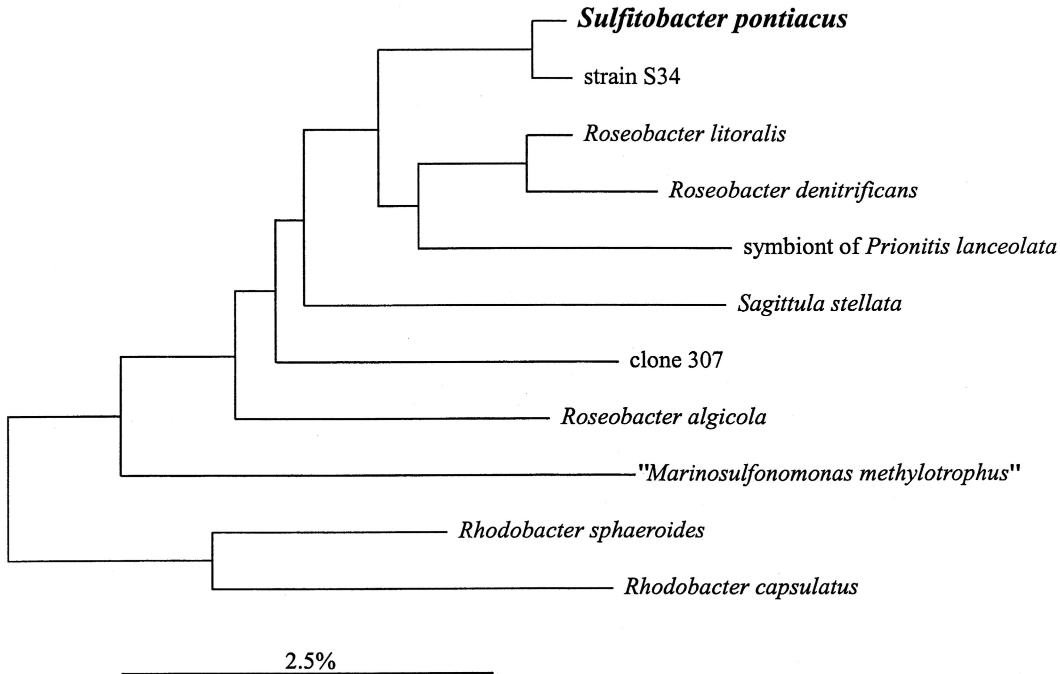

FIGURE BXII.α.82. Phylogenetic dendrogram based on comparison of 16S rDNA sequences indicating the position of *S. pontiacus* and its closest relatives within the *Alphaproteobacteria*. The dendrogram was reconstructed from evolutionary distances (Jukes and Cantor, 1969) by the neighbor-joining method (Saitou and Nei, 1987). Bar = 2.5 inferred nucleotide changes per 100 nucleotides. The accession numbers of the sequences used in these analyses are as follows: *Sulfitobacter pontiacus* (Y13155), strain S34 (U87407), *Roseobacter litoralis* (X78312), *Roseobacter denitrificans* (M59063), symbiont of *Prionitis lanceolata* (U37762), *Sagittula stellata* (U58356), clone 307 (U14583), *Roseobacter algicola* (X78315), *"Marinosulfonomonas methylotrophus"* (U62894), *Rhodobacter sphaeroides* (X53854), and *Rhodobacter capsulatus* (D16428).

as nitrogen sources. Growth on a mineral medium with acetate is stimulated by the presence of yeast extract and biotin. NaCl is required for growth; range, 5–80 g/l; optimal, 20–25 g/l). Temperature range for growth is 4–35°C (optimal, 22–25°C). The pH range for growth is 6.5–8.5 (optimal, 7.5–7.8).

No hydrolytic activities are present. Catalase and oxidase positive. Cytochromes c_{551}, b_{558}, and cytochrome *c* oxidase aa_3 are detectable in cell-free extracts. Isolated from the sulfide-oxygen interface water of the Black Sea.

The mol% G + C of the DNA is: 61.7–62.5 (T_m).

Type strain: ChLG 10, DSM 10014, VKM B-2022.

GenBank accession number (16S rRNA): Y13155.

2. **Sulfitobacter brevis** Labrenz, Tindall, Lawson, Collins, Schumann and Hirsch 2000, 311[VP]
bre′vis. L. adj. *brevis* short, referring to the short cells.

Rods with one or both cell poles pointed, multiplying by monopolar growth, i.e., by a budding process. Cell sizes vary: 0.8–1.0 × 1.1–1.5 μm, with a mean size of 0.9 × 1.3 μm. Rosettes may be formed. Cells may be motile. Poly-β-hydroxybutyrate granules may be present. Endospores are not formed. On PYGV + ASW the colonies are smooth, convex, and yellowish brown. Do not grow photoautotrophically with H_2/CO_2 (80:20) or photoorganotrophically with acetate or glutamate. Peroxidase, catalase, and oxidase positive. Bacteriochlorophyll *a* is not produced.

Optimal growth temperature, 3–26°C. NaCl requirement, 1.0–2.0% NaCl or 10–80‰ ASW. Optimal pH for growth, 7.5–8.0. Cells have a requirement for pantothenate and thiamin, a weak requirement for biotin and nicotinic acid, and none for vitamin B_{12}. Tween 80 is hydrolyzed, but not alginate, gelatin, DNA, or starch. Growth occurs on acetate, pyruvate, malate, succinate, citrate, butyrate, or glutamate, but not on methanesulfonic acid or methanol. α-D-Glucose is utilized weakly. Cells are susceptible to chloramphenicol, streptomycin, penicillin G, polymyxin B, and tetracycline, but not to nalidixic acid. Nitrate is not reduced. H_2S and indole are not produced. Methyl red and Voges–Proskauer negative.

Polar lipids present are diphosphatidylgycerol, phosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, and an unknown aminolipid. Dominant fatty acids are $C_{18:1\ \omega 7c}$ and $C_{18:1\ \omega 9c}$, and $C_{18:2}$ is present as two isomers. Other characteristic fatty acids are $C_{10:0\ 3OH}$, $C_{14:1\ 3OH}$, $C_{16:0}$, and $C_{18:0}$. Major respiratory quinone is Q-10. Source: water sample from Ekho Lake, Antarctica.

The mol% G + C of the DNA is: 57.9–58.1 (HPLC).

Type strain: EL-162, DSM 11443.

GenBank accession number (16S rRNA): Y16425.

3. **Sulfitobacter mediterraneus** Pukall, Buntefuß, Frühling, Rohde, Kroppenstedt, Burghardt, Lebaron, Bernard and Stackebrandt 1999, 518[VP]
me.di.ter.ra.ne′us. N.L. adj. *mediterraneus* pertaining to the Mediterranean Sea.

Cells grown on marine agar at 25°C are rod shaped, 1–3 × 0.5–0.8 μm. Cells are motile by means of 1–5 subpolar flagella. Bacteria grown on marine agar, supplemented with acetate, tend to form rosettes and contain poly-β-hydroxy-

butyrate granules. Colonies on Marine agar are 1.2–1.4 mm in diameter, circular, convex, with entire or undulate margin, translucent and cream-colored. Temperature range for growth, 4–35°C; optimal, 17–28°C. pH range for growth, 6.5–8.5; optimal, 7.0–7.5. NaCl (2–80 g/l, optimal 15–20 g/l) is required for growth. Catalase and oxidase positive. Bacteriochlorophyll *a* is not present.

In minimal media with or without the addition of yeast extract or vitamins, growth occurs at 28°C with glucose, mannitol, gluconate, adipate, acetate, malate, pyruvate, lactate, propionate, butyrate, serine, proline, ornithine, alanine, asparagine, glutamate, and glycerol. Glutarate, *cis*-aconitate, tryptophan, caprate, urea, arabinose, and mannose are not utilized. Weak growth is detected with aspartate. Nitrate is not reduced. Utilization of citrate and maltose is stimulated in media containing yeast extract or biotin. Utilization of *N*-acetylglucosamine and activity of arginine hydrolase, β-glucosidase, and gelatin hydrolase are induced after a longer incubation period (>3 d). Phenylacetate is used after 24 h incubation at 25°C. Growth occurs on 10 mM sulfite in acetate (10 mM)-supplemented HEPES (*N*-[2-hydroxyethyl]piperazine-*N*′-[ethane-sulfonic acid]) medium. In TSB[2] medium containing 3% NaCl, the main fatty acid is *cis*-11 octadecenoic acid. Hexadecanoic acid occurs in smaller amounts. Signature nucleotides for 16S rDNA are located at positions 418–425 (C-G), 591–648 (C-G), 592–647 (A-U), and 599–639 (A-U). Isolated from coastal waters of the west Mediterranean Sea.

The mol% G + C of the DNA is: 59 (HPLC).

Type strain: CH-B427, DSM 12244.

GenBank accession number (16S rRNA): Y17387.

2. Tryptone Soya Broth was used for FAME analysis of *Sulfitobacter mediterraneus* and is available from Oxoid.

Genus Incertae Sedis XXVI. **Rhodothalassium** *Imhoff, Petri and Süling 1998, 797*[VP]

Johannes F. Imhoff

Rho′do.tha.las′si.um. Gr. n. *rhodon* the rose; Gr. adj. *thalassios* belonging to the sea; M.L. neut. n. *Rhodothalassium* the rose belonging to the sea.

Cells are vibrioid to spiral-shaped, motile by means of polar flagella and multiply by binary fission. **Gram-negative members of the *Alphaproteobacteria*.** Internal photosynthetic membranes are present as lamellar stacks lying parallel to the cytoplasmic membrane. Photosynthetic pigments are **bacteriochlorophyll *a*** (esterified with phytol) and **carotenoids of the spirilloxanthin series**. **Ubiquinones and menaquinones with 10 isoprene units (Q-10 and MK-10) are present. Major cellular fatty acids are $C_{18:1}$, $C_{18:0}$, and $C_{16:0}$**, with $C_{18:1}$ as dominant component (~60% of total fatty acids). **Cells grow preferably photoheterotrophically** under anoxic conditions in the light. **Chemotrophic growth is possible under oxic conditions in the dark.** Amino acids may be required as growth factors. **Obligately halophilic bacteria that require NaCl or sea salt for growth**, have salt optima above seawater salinity and an extended salt tolerance. Habitat: anoxic zones of hypersaline environments such as salterns and salt lakes that are exposed to the light.

The mol% G + C of the DNA is: 64.0.

Type species: **Rhodothalassium salexigens** (Drews 1982) Imhoff, Petri and Süling 1998, 797 (*Rhodospirillum salexigens* Drews 1982, 384.)

Further descriptive information

Rhodothalassium salexigens at present is the only representative of this genus. It is a moderately halophilic bacterium that requires elevated concentrations of salt for growth and is among the few extremely halotolerant species (up to 20% of salts) of the purple nonsulfur bacteria. Glycine betaine is accumulated as osmoticum and compatible solute in response to the external salt concentrations (Imhoff, 1992; Severin et al., 1992). Growth depends on glutamate as a growth factor or nitrogen source (Madigan et al., 1984). Cultures grown in the presence of 4 mM glutamate and dinitrogen form readily detectable amounts of nitrogenase (Madigan et al., 1984). The cell wall of *Rhodothalassium salexigens* contains peptidoglycan and proteins but lacks glycolipids and lipopolysaccharides (Golecki and Drews, 1980; Weckesser et al., 1995). Growth of *Rhodothalassium salexigens* is inhibited by a number of antibiotics such as tetracycline, chloramphenicol, penicillin, ampicillin, cycloserine, nisin, vancomycin, and bacitracin, but not by oxacillin (Drews, 1981). Additional properties are given in Table BXII.α.79.

Enrichment and Isolation Procedures

Rhodothalassium salexigens appears to be widely distributed in hypersaline environments such as salterns and salt lakes. Several strains of this species have been isolated from a saltern at the Mediterranean shore of Spain (Rodriguez-Valera et al., 1985). Standard techniques for isolation of purple nonsulfur bacteria in agar dilution series and on agar plates can be applied to *Rhodothalassium* species (Imhoff, 1988; Imhoff and Trüper, 1992). Media with neutral pH and elevated salt concentrations containing complex nutrients are suitable for their enrichment. A modification of the medium of Golecki and Drews (1980) has been successfully used and a recipe is given below (see also Imhoff, 1988).[1] *Rhodothalassium salexigens* also grows well on the complex medium of Nissen and Dundas (1984).

Maintenance Procedures

Cultures are well preserved by standard techniques in liquid nitrogen, by lyophilization or storage at −80°C in a mechanical freezer.

Differentiation of the genus *Rhodothalassium* from other genera

With respect to the natural environment, the obligate requirement for salt, cell morphology, and internal membrane structure, *Rhodothalassium* is clearly distinguished from other spiral-shaped phototrophic *Alphaproteobacteria*. In addition, it has a characteristic fatty acid and quinone composition and is clearly separated from other phototrophic purple bacteria by its 16S rDNA sequence. Major differentiating properties between *Rhodothalassium salexigens* and other phototrophic *Alphaproteobacteria* can be

1. The medium contains (per liter): 100 g NaCl, 3.5 g $MgCl_2 \cdot 6H_2O$, 0.3 g KH_2PO_4, 10 mM sodium malate, 1.5 g yeast extract, 1.5 g protease peptone, and 1 ml trace element solution SLA. The initial pH is adjusted to 7.0.

TABLE BXII.α.79. Properties of *Rhodothalassium salexigens*[a]

Characteristic	*Rhodothalassium salexigens*
Cell diameter (μm)	0.6–0.7

seen by comparing Table BXII.α.1 in the chapter for the genus *Rhodospirillum* with Table BXII.α.79. Carbon sources used can be compared between Table BXII.α.2 in the chapter for the genus *Rhodospirillum* and Table BXII.α.79. The phylogenetic relationship of these bacteria based on 16S rDNA sequences is presented in Fig. 1 (p. 124) in the introductory chapter on "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A.

Taxonomic Comments

Because of its spiral shape and phototrophic capacity, *Rhodothalassium salexigens* was originally assigned to the genus *Rhodospirillum*, which comprised all spiral-shaped purple nonsulfur bacteria at that time (Drews, 1981). High diversity among these bacteria was revealed by their chemical composition in regard to fatty acids and quinones, but also in respect to the structure of internal membrane systems, to growth factor requirement and salt dependency. Because of outstanding phenotypic differences and the great genetic distance from the type species of this genus, *Rhodospirillum rubrum*, and to other purple nonsulfur bacteria, it was reclassified as *Rhodothalassium salexigens* (Imhoff et al., 1998).*

**Editorial Note:* Based on 16S rDNA sequence information, *Rhodothalassium salexigens* forms a distinct phylogenetic lineage, separate from other so-called "purple nonsulfur bacteria." This separation is so significant that it precludes inclusion of the genus *Rhodothalassium* in any of the families of the *Alphaproteobacteria*. Though its phylogenetic position would allow *Rhodothalassium* to be considered a separate family, 16S rDNA sequence evidence is only available from a single strain. Therefore, further data should be obtained prior to assigning this genus to a family. At present, the genus *Rhodothalassium* is considered a *genus incertae sedis* with distant affiliations to the families *Rhodospirillaceae*, *Rhodobacteraceae*, and *Rhizobiaceae*.

List of species of the genus Rhodothalassium

1. **Rhodothalassium salexigens** (Drews 1982) Imhoff, Petri and Süling 1998, 797[VP] (*Rhodospirillum salexigens* Drews 1982, 384.)
sal.ex' i.gens. L. n. *sal* salt; L. part. adj. *exigens* demanding; M.L. adj. *salexigens* salt-demanding.

Cells are rod-shaped to spiral, 0.6–0.7 × 1–6 μm; one complete turn of a spiral is 0.8–0.9 μm wide. Internal photosynthetic membranes occur as lamellae lying parallel to the cytoplasmic membrane. Color of anaerobically grown liquid cultures is red. Absorption maxima of living cells are at 375, 485, 515, 550, 590, 800, 840, and 875 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series with spirilloxanthin as the predominant component. Cells grow photoheterotrophically under anoxic conditions in the light with various organic compounds as carbon and electron sources or under oxic conditions in the dark. Carbon compounds assimilated are shown in Table BXII.α.79. Photoautotrophic growth with molecular hydrogen, sulfide, or thiosulfate as electron donor is not possible. Ammonia or dinitrogen cannot serve as sole nitrogen source; casein hydrolysate is used as a carbon and nitrogen source. Glutamate is required for growth, but no other growth factors are required. Obligately and moderately halophilic bacterium with optimal growth at 40°C (range 20–45°C), pH 6.6–7.4, and 6–8% NaCl (range: 5–20% NaCl). No growth occurs in the absence of salt. Habitat: anoxic zones of hypersaline environments such as salterns and partially evaporated pools of seawater with decaying plants that are exposed to the light.

The mol% G + C of the DNA is: 64.0 (Bd, T_m).

Type strain: WS 68, ATCC 35888, DSM 2132.

GenBank accession number (16S rRNA): D14431.

Order IV. **Sphingomonadales** *ord. nov.*

Eiko Yabuuchi and Yoshimasa Kosako

Sphing.o.mon.a.da'les. M.L. fem. n. *Sphingomonas* type genus of the order; *-ales* ending to denote an order; M.L. fem. pl. n. *Sphingomonadales* the order of *Sphingomonas*.

Gram-negative, nonsporeforming rod-shaped, ovoid, or pleomorphic cells. Reproduction is usually by binary fission, but in some members, polar growth or budding has been observed by electron microscopy. Motile or nonmotile. **Instead of lipopolysaccharide (LPS) in cell wall, glucuronosyl ceramide (SGL-1) and 2-OH myristic acid are present, without 3-OH acids.** Instead of $C_{14:0\ 2OH}$ **nonhydroxy myristic acid in *Zymomonas mobilis*. Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor, with the exception of the genus *Zymomonas*, which is **facultatively anaerobic and has a strictly fermentative type of metabolism.** Some species synthesize bacteriochlorophyll *a* and are **facultative phototrophs**. **Chemoheterotrophic**. **The major respiratory quinone is ubiquinone Q-10** in those genera that have been tested. Belong to the class *Alphaproteobacteria*. Free living and widely distributed in nature.

[a]Order I. *Rhodospirillales* [AL]; II. *Rickettsiales*[AL]; III. *Rhodobacterales*; IV. *Sphingomonadales*; V. *Caulobacterales*[AL]; VI. *Rhizobiales*.

[b]Same strain as EY 2395^{T}.

[c]RDP, Ribosomal Data Project.

The mol% G + C of the DNA is: 59–68.5; (*Z. mobilis*, 49.1).

Type genus: **Sphingomonas** Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990b, 321 (Effective publication: Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990a, 116) emend. Takeuchi, Hamana and Hiraishi 2001, 1414; emend. Yabuuchi, Kosako, Fujiwara, Naka, Matsunaga, Ogura and Kobayashi 2002, 1489.

Further descriptive information

If motile, motility is by means of polar or subpolar-monotrichous, polar-multitrichous, or peritrichous flagella.

In addition to SGL-1, galacturonosyl ceramide (SGL-1′) is detected in several species. SGL-1 is commercially used to moisturize human skin.

No data are available concerning the quinones of *Zymomonas mobilis*.

Strains of some species biodegrade dibenzo-*p*-dioxin and related compounds. Cells that are aggregated or attached to goethite (α-FeOOH) particles inactivate chlorine (Gauthier et al., 1999). Some extracellular polysaccharides, e.g., sphingan (Pollock, 1993), are of industrial use.

Strains of the genera have been isolated from a variety of environments, including chemically contaminated soil, subsurface sediment, river water, seawater, alkaline spring, hot springs, distilled water, sewage, plants, hospitals, or found in association with diseased plant and human hosts. The wide variety of isolation sources is reflected in the nutritional diversity of the organisms.

Circumscription of the Order Yabuuchi et al. (1990a) transferred the species *Pseudomonas paucimobilis* Holmes et al. 1977a (previously known as CDC group IIK-2) to a new genus, *Sphingomonas*, as the type species, *Sphingomonas paucimobilis*. Eventually, the genus was expanded to include 34 species. These were later included in a new family, *Sphingomonadaceae*, by Kosako et al. (2000a). This family is presently the only family in the order *Sphingomonadales* and contains nine genera.

The percent similarity of the 16S rDNA oligonucleotide sequences of the various members of *Sphingomonadales* to that of the type species of the genus *Sphingomonas* ranges from 90.4% to 97.7%. The percent similarity of the 16S rDNA of five other orders in the *Alphaproteobacteria* ranges from 83.4% to 87.6% (Table BXII.α.80). Analysis of the 16S rDNA sequences indicates a close relationship of *Zymomonas mobilis* to the genus *Sphingomonas* (Fig. BXII.α.83). Signature nucleotide sequences of the 16S rDNA (Table BXII.α.81) and the dendrogram of six type species of *Sphingomonadaceae* (Fig. BXII.α.84) indicate the base of construction of this order. The mol% G + C of the DNA ranges from 59 to 68.5, with the exception of *Z. mobilis*, which has a value of 49.1.

It is unlikely that levels of 16S rDNA sequence similarity or the presence or absence of specific cellular components can define the order. It is now apparent that phenotypic characteristics such as flagellar morphology, fermentation vs. nonfermentation of glucose, fermentative vs. respiratory metabolism, and (as mentioned by Kondratieva et al., 1992) the synthesis of bacteriochlorophyll *a* cannot be used as a key characteristic to exclude any genus or family from the order. It is possible that development of new, easy-to-use identification methods based on molecular techniques such as DNA-tips might be able to accurately differentiate the taxa within the order.

TABLE BXII.α.81. Signature sequences of 16S rDNA oligonucleotides among the members of Class *Alphaproteobacteria*

Genus I. **Sphingomonas** *Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990b, 321^VP (Effective publication: Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990a, 116) emend. Takeuchi, Hamana and Hiraishi 2001, 1414; emend. Yabuuchi, Kosako, Fujiwara, Naka, Matsunaga, Ogura and Kobayashi 2002, 1489*

Eiko Yabuuchi and Yoshimasa Kosako

Sphin.go.mo′ nas. Gr. gen. n. *sphingos* of sphinx; Gr. n. *monad* unit, monad; M.L. fem. n. *Sphingomonas* a sphingosine-containing monad.

Straight or slightly curved rods or ovoid cells 0.2–1.4 × 0.5–4.0 μm. Gram negative. Asporogenous. Reproduction in most species is by binary fission; budding or asymmetric division as visualized by electron microscopy occurs in two species. Motile or nonmotile. A rosette-like aggregation caused by polar fimbriae occurs in some species. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Anaerobic nitrate respiration does not occur. Esculin is hydrolyzed. **Two species with bacteriochlorophyll *a* are facultative photoorganotrophs.** Colony color varies from orange or yellow to white to nonpigmented. Catalase positive. Oxidase positive or negative. **Glucuronosyl-(1→1)-ceramide (SGL-1), galacturonosyl-β(1→1)-ceramide (in several species), and 2-hydroxymyristic acid occur, but not 3-hydroxy fatty acids** (Table BXII.α.83, Figs. BXII.α.85, BXII.α.86, and BXII.α.87). The lipopolysaccharide (LPS) of the cell wall is replaced by sphingolipids (Figs. BXII.α.88 and BXII.α.89). $C_{18:1\ \omega9t}$ and $C_{18:1\ \omega7c}$ are the major nonpolar fatty acids and **2-hydroxymyristic acid** is the major 2-hydroxy acid (Table BXII.α.84). Some species are opportunistic pathogens, causing meningitis, septicemia, peritonitis, and neonatal infections in intensive care units. Pathogenicity toward animals is not known. **Free living** in natural and man-made environments.

The mol% G + C of the DNA is: 59–68.

Type species: **Sphingomonas paucimobilis** (Holmes, Owen, Evans, Malnick and Wilcox 1977a) Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990b, 321 (Effective publication: Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990a, 116) (*Pseudomonas paucimobilis* Holmes, Owen, Evans, Malnick and Wilcox 1977a, 133.)

Further descriptive information

Cellular and flagellar morphology Cell sizes range from 0.4 × 1.4 μm in *S. paucimobilis* to 0.7–1.2 × 1.3–4.0 μm in *S. xenophaga*. By Gram staining, the cells of the type strains of most species are straight or slightly curved rods with rounded ends, whereas those of *S. echinoides* have sharp ends (Stolz et al., 2000). Electron micrographs of *S. natatoria* and *S. ursincola* have revealed a budding type of reproduction, but this has not been seen in photomicrographs of Gram-stained preparations. A rosette-like arrangement was reported in *S. paucimobilis* (Yabuuchi et al., 1979), *S. natatoria* (*B. natatorius* Sly 1985), and *S. echinoides* Heumann and Marx (1964) described the star (rosette)-formation of the organism and illustrated the phenomenon by electron micrographs. Cells aggregated or attached to goethite (α-FeOOH) particle inactivate chlorine (Gauthier et al., 1999). The aggregation is caused by attachment and irreversible contraction of the monopolar fimbriae of two or more cells.

Diffuse spreading growth does not occur on 0.3% semisolid agar plates in *S. capsulata* and 13 other species. These are recognized as nonmotile. Peritrichous flagellation of *S. trueperi* EY4218^T is shown in Fig. BXII.α.90.

Colony characteristics Colonies on agar plating media suitable for each species are pinpoint in size after 48 h or more incubation at 25–30°C. Colonies are approximately 1 mm in diameter when fully grown, circular, domed, and smooth with entire margins. Colonies are pigmented at the beginning of their appearance on agar media. Members of the genus, except the type strain of *S. herbicidovorans*, do not produce water-soluble pigments. Pigmentation of colonies differs from species to species

TABLE BXII.α.83. Distribution of the five molecular species of sphingoglycolipid (SGL) among the members of *Sphingomonadaceae*[a]

SGL on TLC	Species	EY No.	Long-chain base(s)	Carbohydrate moiety(ies)	Hydroxy fatty acid(s)

[b]Nonhydroxy acid.

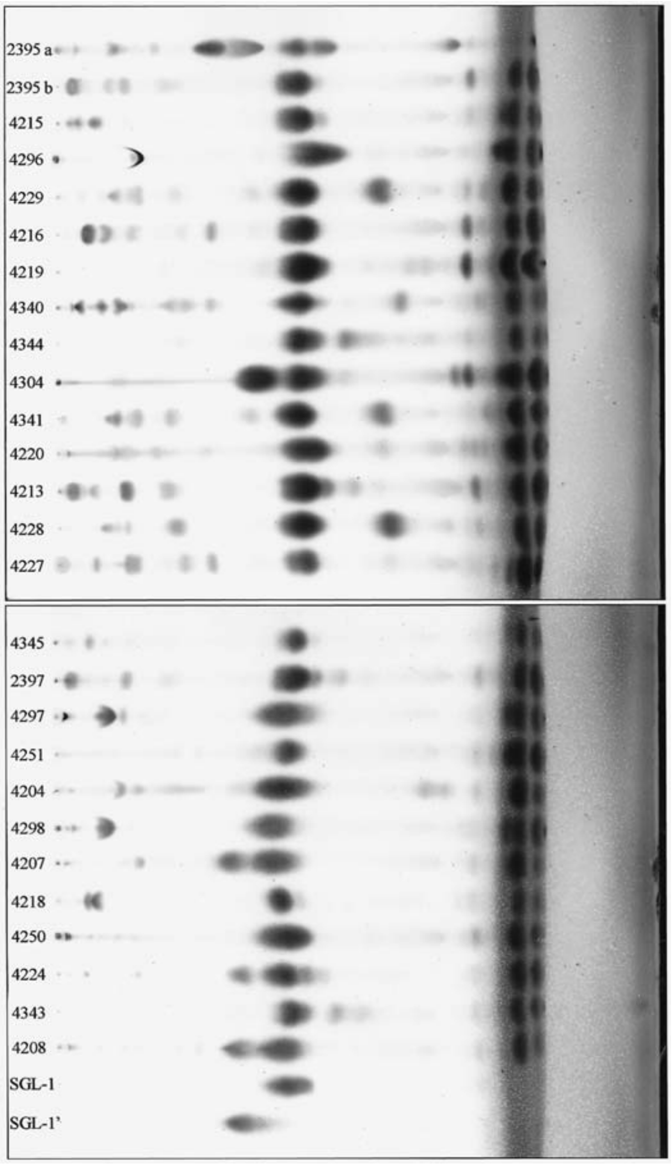

FIGURE BXII.α.85. Thin-layer chromatograms of alkali-stable lipids of type strains of 26 *Sphingomonas* species. EY strain number and species, from top to bottom: 2395^T, *S. paucimobilis* (*a* = crude lipids; *b* = alkali-stable lipids); 4215^T, *S. adhaesiva*; 4296^T, *S. aromaticivorans*; 4229^T, *S. asaccharolytica*; 4216^T, *S. capsulata*; 4219^T, *S. chlorophenolica*; 4340^T, *S. echinoides*; 4344^T, *S. herbicidovorans*; 4304^T, *S. macrogoltabidus*; 4341^T, *S. mali*; 4220^T, *S. natatoria*; 4213^T, *S. parapaucimobilis*; 4228^T, *S. pruni*; 4227^T, *S. rosa*; 4345, *S. roseiflava*; 2397, *S. sanguinis*; 4297^T, *S. stygia*; 4251^T, *S. subarctica*; 4204^T, *S. suberifaciens*; 4298^T, *S. subterranea*; 4207^T, *S. terrae*; 4218^T, *S. trueperi*; 4250^T, *S. ursincola*; 4224^T, *S. wittichii*; 4343^T, *S. xenophaga*; 4208^T, *S. yanoikuyae*; purified SGL-1, purified SGL-1′. Solvent system: chloroform/methanol/acetic acid/H_2O (100:20:12:5, by vol).

and may be influenced by the medium and time of incubation. A characteristic deep-yellow color is due to the carotenoid nostoxanthin (Jenkins et al., 1979), rather than the brominated arylpolyamine xanthomonadin that is produced by *Xanthomonas* sp. (Starr et al., 1977; Jenkins and Starr, 1985). Colonies of some initially nonpigmented strains such as *S. yanoikuyae* become lemon yellow after 3 days incubation at room temperature. The type strain of *S. herbicidovorans* produces the water-soluble brown pigment alcapton by accumulation of homogentisic acid in peptone media (Table BXII.α.85), as observed in the pyomelanogenic strain of *Pseudomonas aeruginosa* (Mann, 1969; Yabuuchi and Ohyama, 1972; Gessard, 1981). The type strain of *S. herbicidovorans* represents the second confirmed bacterium with a defective homogentisicase, which results in accumulation of homogentisic acid. The mechanism is similar to that in the human inborn error, alcaptonuria.

Sphingoglycolipids The presence of sphingolipids among the cells of eucaryotes and procaryotes is well known. Sphingolipids are divided into sphingophospholipids and sphingoglycolipids. The skeleton of sphingolipids is ceramide, which is composed of sphingosine (long chain base coupled with a fatty acid molecule by acidic amide linkage). Sphingomyelin is one of the most common mammalian sphingophospholipids. Sphingophospholipids are the characteristic component of the cellular lipids of *Sphingobacterium* spp. and *Prevotella* spp. Molecular species of sphingoglycolipids (SGLs) are differentiated according to their number (1 to 4) and kinds of carbohydrates (glucuronic acid, glucosamine, galactose, and mannose). These carbohydrates are linked to the alcoholic hydroxic base by a glycosidic bond. Both glucuronosyl-ceramide (SGL-1) (Yamamoto et al., 1978) and galacuturonosyl-ceramide (SGL-1′) (Naka et al., 2000) are novel sphingoglycolipids among procaryotes and eucaryotes. The chemical structure, function, and distribution of SGL of *Sphingomonas* species in *Proteobacteria* have been reported to replace lipopolysaccharide in the cell wall of Gram-negative rods (Kawahara et al., 1990, 1991, 1999, 2000; Kawasaki et al., 1994c).

A key enzyme in sphingolipid biosynthesis, serine palmitoyltransferase (SPT, EC 2.3.1.50), has been successfully purified. When the gene encoding 420 amino acid residues was overexpressed in *Escherichia coli*, the recombinant SPT was indistinguishable from the native enzyme, both catalytically and spectrophotometrically (Ikushiro et al., 2001). *Sphingomonas* SPT is recognized as a prototype of the eucaryotic enzyme, and an investigation of the sphingolipid biosynthetic enzymes of *Sphingomonas* would help to clarify sphingolipid biosynthesis of both procaryotes and higher organisms (Ikushiro et al., 2001).

Localization of SGL-4 of the type strain of *S. paucimobilis* has been visualized by gold-labeled immunoelectron microscopy (Fig. BXII.α.88), and a model of the outer membrane of *S. paucimobilis* is shown in Fig. BXII.α.89. Stimulation of phagocytosis and phagosome-lysosome fusion in human neutrophiles was reported (Miyazaki et al., 1995). Induction and release of monokine by SGL of type strain of *S. paucimobilis* by different mechanisms from those of LPS were reported (Tahara and Kawazu, 1994; Krziwon et al., 1995).

Cellular fatty acid composition The presence of 2-hydroxymyristic acid and the lack of 3-hydroxy acid of any kind in cellular lipid are important characteristics of members of *Sphingomonadaceae* (except the anaerobic species *Zymomonas mobilis*) (Fig. BXII.α.86). Minor components may change their concentration because of culture conditions and are not useful as differential characters among species.

The fatty acid α-hydroxylase of the type strain of *S. paucimobilis* was partially purified, and direct involvement of hydrogen peroxide in the α-hydroxylation was confirmed (Fig. BXII.α.91). Interestingly, molecular oxygen was not required for α-hydroxylation if hydrogen peroxide was present (Matsunaga et al., 1996). The nucleotide sequence of the fatty acid α-hydroxylase gene was deposited in DDBJ/EMBLE/GenBank with accession number AB006957 (Matsunaga et al., 1998), and the deduced amino acid sequence of the enzyme is shown in Fig. BXII.α.92. The

fatty acid α-hydroxylase gene was defined as a cytochrome P450 enzyme and overexpressed in *Escherichia coli* (Matsunaga et al., 1997).

Biodegradation of dibenzo-*p*-dioxin and related compounds Soil and water pollution by polychlorinated derivatives of dibenzo-*p*-dioxin (DD) has become a problem worldwide. In addition to the most toxic compound 2,3,7,8-tetrachloro-dibenzo-*p*-dioxin (TCDD), there are many possible congeners, as shown in Fig. BXII.α.93. Accordingly, numerous articles have been published concerning the aerobic degradation pathways (Fig. BXII.α.94) used by strain RW1 of *Sphingomonas wittichii*—the best-known metabolizer of DD and DF (dibenzofuran) (Wittich et al., 1992; Bünz and Cook, 1993; Bünz et al., 1993; Happe et al., 1993; Moore et al., 1993; Bertini et al., 1995; Thakur, 1996; Arfmann et al., 1997; Armengaud and Timmis, 1997, 1998; Megharaj et al., 1997; Armengaud et al., 1998, 1999; Keim et al., 1999; Leung et al., 1999; Vuilleumier et al., 2001). Bioremediation of environments polluted with halogenated DDs and DFs seems difficult because of inefficient attack on the highly halogenated congeners by the initial dioxygenase of RW1 and because of the lack of catabolic pathways for the mineralization of halogenated intermediates.

Other species of *Sphingomonas* are capable of degrading a huge range of recalcitrant compounds of environmental concern. *S. paucimobilis* can degrade biphenyl (Davison et al., 1996, 1999) and utilize the herbicide diclofop-methyl (Smith-Greenier and Adkins, 1996), γ-hexachlorocyclohexane (Miyauchi et al., 1998), and aromatic hydrocarbons (Shuttleworth et al., 2000). *S. yanoikuyae* can degrade (polycyclic) aromatic hydrocarbons (Klecka and Gibson, 1980; Eaton et al., 1996b; Khan et al., 1996a; Kim et al., 1997; Lloyd-Jones and Lau, 1997; Kim and Zylstra, 1999; Kazunga and Aitken, 2000; Shuttleworth et al., 2000). *S. subarctica* degrades chlorophenols (Nohynek et al., 1996a); *S. aromaticivorans*, *S. subterranea*, and *S. stygia* degrade aromatic hydrocarbons (Balkwill et al., 1997); *S. herbicidovorans* degrades Mecoprop (Zipper et al., 1996); *S. chlorophenolica* degrades pentachlorophenol (Nohynek et al., 1995, 1996a; McCarthy et al., 1997; Ohtsubo et al., 1999; Xu et al., 1999; Xun et al., 1999); and *S. xenophaga* degrades naphthalene sulfonic acids and *N,N*-dimethylaniline (Stolz et al., 2000).

Numerous *Sphingomonas* isolates are capable of degrading diphenyl ethers (Schmidt et al., 1992a, b, 1993), dibenzofuran, and substituted dibenzofurans (Fortnagel et al., 1990; Harms and Zehnder, 1994; Harms et al., 1995; Wittich et al., 1999), 2,4-D

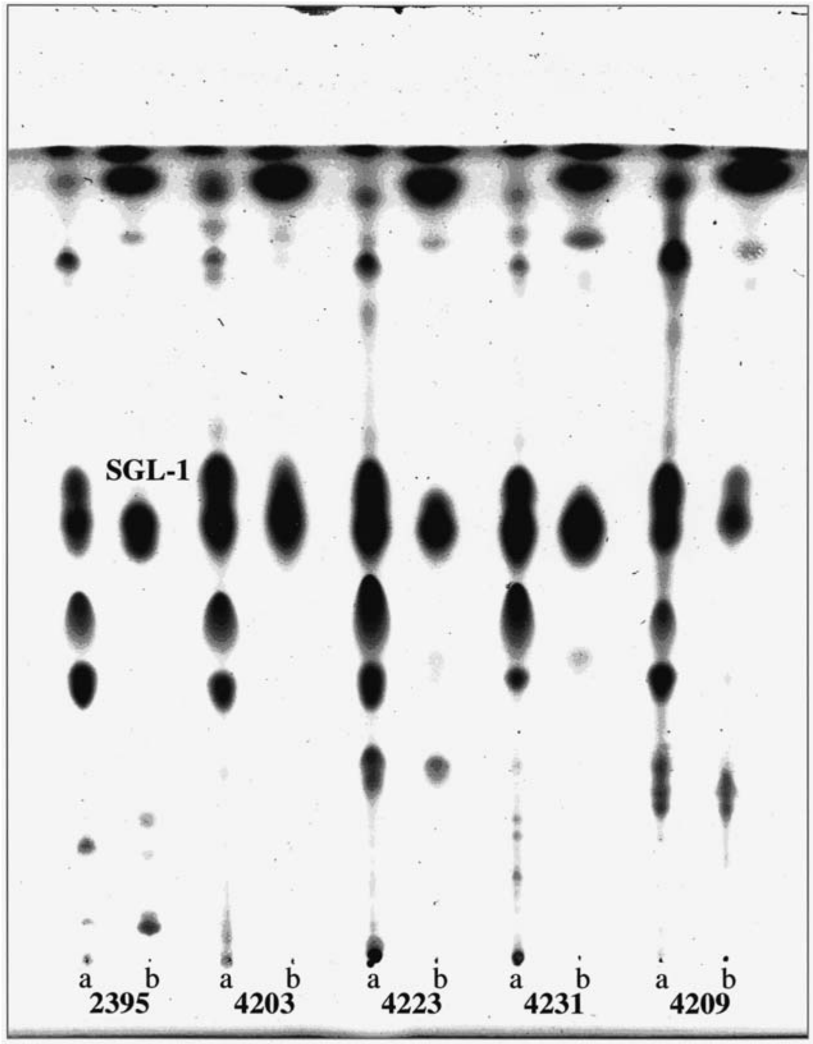

FIGURE BXII.α.87. Thin-layer chromatograms of cellular lipids and alkali-stable lipids of type strains in the family *Sphingomonadaceae*. EY strain number and species, from left to right: 2395^T = *S. paucimobilis*; 4203^T = *Erythrobacter longus*; 4223^T = *Erythromicrobium ramosum*; 4209 ^{T} = *Zymomonas mobilis*. Solvent system: chloroform/methanol/acetic acid/H_2O (100:20:12:5, by vol).

(Ka et al., 1994a, b, c), (polycyclic) aromatic hydrocarbons (Fredrickson et al., 1995; Dagher et al., 1997; Ederer et al., 1997; Harayama, 1997; Mueller et al., 1997), aromatics and chloroaromatics (Yrjala et al., 1998), pentachlorophenol (Karlson et al., 1995), gentisate (Werwath et al., 1998), 4-methylquinoline (Pfaller et al., 1999), and carbofuran (Ogram et al., 2000).

Strain RW1 previously adapted to DD- and DF-contaminated soil was found to survive better in DD- and DF-amended soil and biodegrade DD and DF more efficiently than bacteria that had not been pre-adapted (Megharaj et al., 1997). There are some other interesting reports on biodegradation of compounds of environmental concern in polluted soil by strains of this genus (Thomas et al., 2000) and utilization of herbicide dichlorofop-methyl by soil microorganism as the sole source of carbon and energy (Smith-Greenier and Adkins, 1996). The use of pentachlorophenol-degrading sphingomonads for environmental clean up was reported (Colores et al., 1995) and may be exploited in the future.

Extracellular heteropolysaccharide Production of agar-like polysaccharide by *Pseudomonas* species was reported by Kang et al. (1982). Gellan S-60 (Kang and Veeder, 1982a), welan S-130 (Kang and Veeder, 1982b), rhamsan, S-88 (Kang and Veder, 1985), S-198, and S-657 are members of a family of microbial polysaccharides (Moorhouse, 1987). The structure of these Gellan-related heteropolysaccharides was called "sphingan" by Pollock (1993), who recognized the producers as members of the genus *Sphingomonas*. The biochemical functions of the glycosyl transferase genes essential for biosynthesis of exopolysaccharides have been reported by Pollock et al. (1998). A heteropolysaccharide isolated from a culture of a *"Pseudomonas elodea"* strain is a repeating linear tetrasaccharide composed of D-glucose, D-glucuronic acid, and L-rhamnose in a ratio 2:1:1 (Jansson et al., 1983); side chains were not present. An α-rhamnosidase of *Sphingomonas* sp. R1 has been reported (Hashimoto and Murato, 1998). X-ray crystallographic analysis and genetic studies were reported for the alginate lyases of a strain of *Sphingomonas* sp.

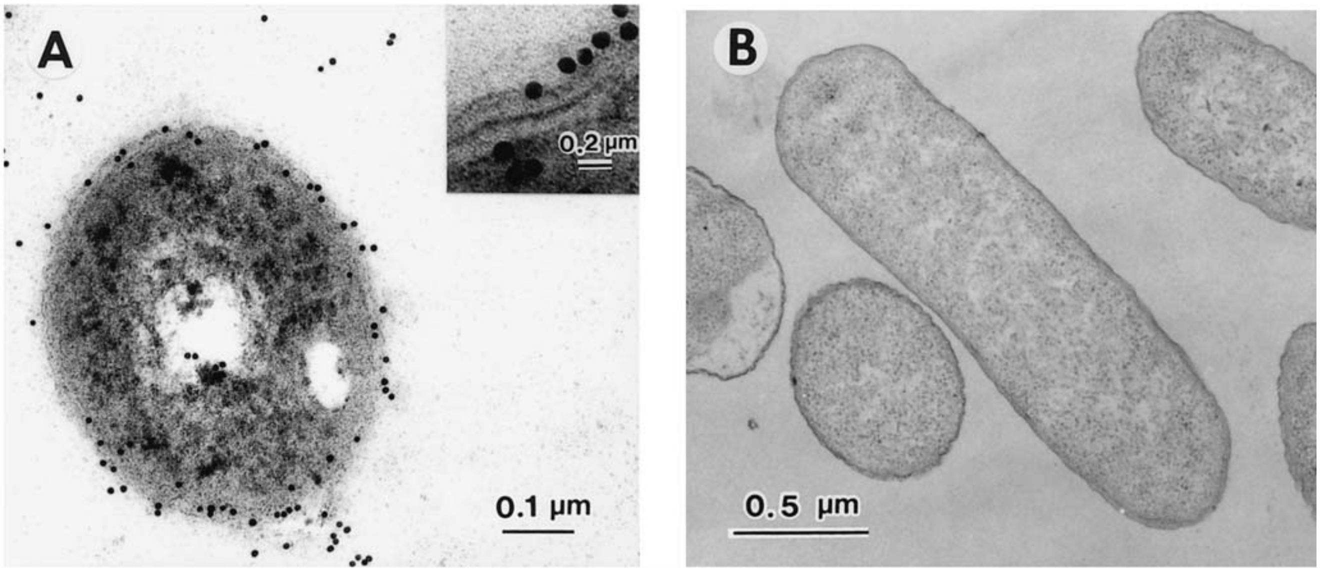

FIGURE BXII.α.88. Localization of sphingoglycolipid on the outer membrane of *Sphingomonas paucimobilis.* (A) *Sphingomonas paucimobilis* IAM 12576^{T}, immunogold-labeled soma after embedding. Ultrathin-sectioned cell was first treated with anti-SGL-4A antibody, and then stained with gold-labeled secondary antibody. Primary antibody recognized SGL-4A alone, not SGL-1. Gold particles observed on entire surface of the soma, but none on (B) *Escherichia coli* used as control. (Reproduced with permission from S. Kawasaki et al., Journal of Bacteriology *176:* 284–290, 1994, ©American Society for Microbiology.)

(Yoon et al., 2000a, b). A *pgmG* gene, which encodes a bifunctional enzyme in Gellan gum-producing *S. paucimobilis*, was reported by Videira et al. (2000).

Industrial usage of the heteropolysaccharides has been reported (Peik et al., 1983, 1985), and modified heteropolysaccharides might possibly be used for oil recovery (Robinson and Stipanovic, 1989).

Ecological features Sphingomonads are free living in natural and man-made environments. Yellow-pigmented aerobic Gram-negative rods have often been isolated from polluted and unpolluted environments and identified as members of the genus *Sphingomonas.* Furthermore, many yellow-colored isolates formerly assigned to the genus *Flavobacterium*, and others earlier classified as *Pseudomonas* and possibly *Moraxella*, might belong to the genus *Sphingomonas*, but they have not been reinvestigated to date.

Metabolic features The presence of either spermidine or homospermidine differs among species. Assimilation tests for selected organic compounds can serve to differentiate *Sphingomonas* species (Table BXII.α.86). Esculin is hydrolyzed, although

prolonged incubation may be needed for a positive reaction by some species. Additional information can be found in Nohynek et al. (1996a), Kämpfer et al. (1997), Denner et al. (1999), Stolz et al. (2000), and Denner et al. (2001).

Antibiotic sensitivity Of 33 type strains tested, 91–100% were susceptible to tetracyclines, amikacin, gentamicin, panipenem, and imipenem (Table BXII.α.87). Differences in susceptibilities to amoxicillin (67%) and amoxicillin/clavulanic acid (91%) suggest the presence of penicillinase in these species (Table BXII.α.87).

Pathogenicity *Sphingomonas* species can act as opportunistic pathogens (Decker et al., 1992) and have caused meningitis (Sakai et al., 1978; Hajiroussou et al., 1979), bacteremia (Calubiran et al., 1990), septicemia (Casadevall et al., 1992), peritonitis (Glupczynski et al., 1984), and neonatal infections in intensive care units. Their pathogenicity toward animals is not known. Induction of monokine production in human mononuclear cells (Flad and Ulmer, 1995) and stimulation of phagocytosis and phagosome–lysosome fusion in human neutrophils (Miyazaki et al., 1995) have been reported.

Differentiation of the genus *Sphingomonas* from other genera

Together with the results of phylogenetic analysis of 16S rDNA nucleotide sequence, the presence of glucuronosyl ceramide is the key characteristic that defines the genus *Sphingomonas* and the family *Sphingomonadaceae* (Figs. BXII.α.85, BXII.α.86, BXII.α.87, and BXII.α.88). Thus it is not enough to refer to the presence of sphingoglycolipid (correctly glucuronosyl ceramide) as "sphingolipid" or even "long chain bases" to define an organism as a member of the genus *Sphingomonas*. The presence of 2-OH myristic acid as the major hydroxy fatty acid and the absence of any kind of 3-hydroxy acid are also important characteristics throughout the family *Sphingomonadaceae*; however, nonpolar myristic acids are present instead of a 2-OH myristic acid in the facultative anaerobic species *Zymomonas mobilis* (Fig. BXII.α.86).

Taxonomic Comments

The genus *Sphingomonas** was so named by Yabuuchi et al. (1990a, b) because of the presence of a specific sphingoglycolipid (SGL-1) containing glucuronic acid as the carbohydrate moiety of its molecule (Yamamoto et al., 1978). SGL-1 was first found in the cellular lipids of the type strain of *Flavobacterium devorans* ATCC 10829. The species *Flavobacterium devorans* (Zimmermann 1890) Bergey et al. 1923b was cited in the Approved Lists of Bacterial Names (Skerman et al., 1980) and maintained its nomenclatural standing. However, ATCC strain 10829 was the only strain preserved in a culture collection and no other living cultures of the species were available. Furthermore, the history of the species revealed that ATCC 10829 was a misidentified later isolate and not the holotype strain of the species (Yabuuchi et al., 1979). Thus, when the strain was later classified as *Pseudomonas paucimobilis*, the priority of specific epithet *devorans* over *paucimobilis* could not be accepted (Yabuuchi et al., 1979). Owen and Jackman (1982) revealed the close relationship between the type strains of *Pseudomonas paucimobilis* and *F. devorans* by a high DNA–DNA hybridization ratio (93 ± 6%) and protein pattern similarity (87%).

Based on the results of a phylogenetic analysis of 16S rDNA and the presence of sphingoglycolipid in cellular lipids of the type strains, the following genera have been placed into the genus *Sphingomonas* by Yabuuchi et al. (1999b): *"Rhizomonas"* van Bruggen et al. 1990, 186; *Blastomonas* Sly and Cahill 1997, 567 emend. Hiraishi et al. 2000a; and *Erythromonas* Yurkov et al. 1997, 1177.

The 16S rDNA sequence similarity of type strains of 34 *Sphin-*

**Editorial Note:* Readers should be advised that there are conflicting opinions regarding the taxonomic status of the genus *Sphingomonas*. At this time, there is no strong phenotypic support for the genera *Novosphingobium*, *Sphingobium*, and *Sphingopyxis*, which are well defined in phylogenetic models based on 16S rDNA sequences. Therefore, Yabuuchi et al. (2002) regard these genera as junior objective synonyms of *Sphingomonas*.

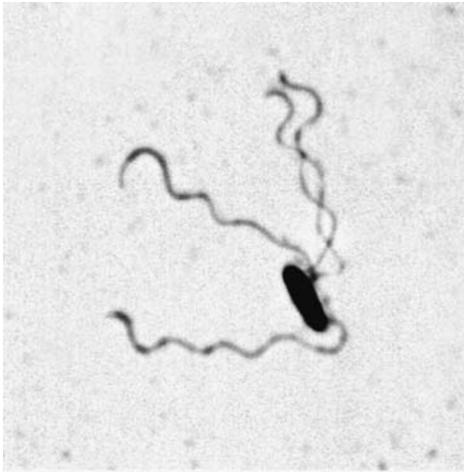

FIGURE BXII.α.90. Flagellar morphology of *Sphingomonas trueperi* EY 4218^T. Four flagella around the soma. Leifson flagella stain.

gomonas species to the type strain of *S. paucimobilis*—the type species of the genus—ranges from 98.1% to 91.0% (see Table BXII.α.80 in the description of the order *Sphingomonadales*). Because of the rapid increase in the number of species, the diversity of metabolic ability, and the wide distribution of organisms in various ecological niches, the definition of the genus *Sphingomonas* has been subjected to much taxonomic discussion chiefly based on the results of phylogenetic analysis of 16S rDNA nucleotide sequences (Takeuchi et al., 1994, 2001; Balkwill et al., 1997; Kämpfer et al., 1997; Hiraishi et al., 2000a; Stolz et al., 2000). Although there has been a proposal to split the genus *Sphingomonas* into four genera, *Sphingomonas*, *Sphingobium*, *Novosphingobium*, and *Sphingopyxis* (Takeuchi et al., 2001), on the basis of phylogenetic analysis of 16S rDNA sequences and polyamine profiles, from the practical aspect, it is essential that any genus not be delineated by phylogenetic analysis alone, but also be distinguished by a combination of phenotypic tests, which are easily performed in every microbiological laboratory. The phylogenetic tree derived from 16S rDNA sequence analysis seems likely to support splitting the genus, but an examination of the phenotypic characteristics of 27 type strains among the 33 species currently assigned to the genus *Sphingomonas* in relation to their phylogeny indicates that—as shown in Fig. BXII.α.95—there is no phenotypic evidence to support this proposal (Yabuuchi et al., 2002). We therefore concluded that *Sphingobium*, *Novosphingobium*, and *Sphingopyxis* are junior objective synonyms of *Sphingomonas*, and it is unreasonable to exclude *S. yanoikuyae*, *S. herbicidovorans*, *S. chlorophenolica*, *S. rosa*, *S. subarctica*, *S. stygia*, *S. subterranea*, *S. aromaticivorans*, *S. capsulata*, *S. macrogoltabidus*, and *S. terrae* from the genus *Sphingomonas*. A dendrogram showing the relationships among the 16S rDNA sequences of *Sphingomonas* species is given in Fig. BXII.α.96. Furthermore, Takeuchi et al. (2001) utilized the rejected generic name *"Rhizomonas"* in combination with the specific epithet *suberifaciens*. It is an obvious violation of the Code. *"Rhizomonas suberifaciens"* was transferred to the genus *Sphingomonas*, as *Sphingomonas suberifaciens* (Yabuuchi et al., 1999a).

Because of the detection of bacteriochlorophyll *a* and *puf* genes encoding the proteins related to photosynthetic activities from both *Blastomonas natatoria* and *Erythromonas ursincola*, together with phenotypic, chemoanalytic, and phylogenetic data, Hiraishi et al. (2000a) published an emended description of *Blastomonas natatoria* (Sly 1985) Sly and Cahill 1997 and a proposal of *Blastomonas ursincola* comb. nov. These two species had been assigned to the genus *Sphingomonas* as *Sphingomonas natatoria* (Sly 1985) Yabuuchi et al. 1999b and *Sphingomonas ursincola* (Yurkov et al. 1997) Yabuuchi et al. 1999b, based on the presence of glucuronosyl seramide (SGL-1) in their cellular lipids and the results of phylogenetic analysis of 16S rDNA sequences. In spite of the report and proposal by Hiraishi et al. (2000a), phototrophic ability is widely distributed among procaryotes, and its presence does not necessarily indicate a close phylogenetic relationship among these taxa (Kondratieva et al., 1992).

Differentiation of the species of the genus *Sphingomonas*

The differential features and other characteristics of the species of *Sphingomonas* are listed in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89. Data on members of the genera *Erythrobacter*, *Porphyrobacter*, *Sandaracinobacter*, and *Zymomonas* are provided for comparison in Tables BXII.α.84 (fatty acid composition), BXII.α.85 (morphological and biochemical characteristics), and BXII.α.88 (oxidative acid production).

List of species of the genus Sphingomonas

1. **Sphingomonas paucimobilis** (Holmes, Owen, Evans, Malnick and Wilcox 1977a) Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990b, 321^{VP} (Effective publication: Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990a, 116) (*Pseudomonas paucimobilis* Holmes, Owen, Evans, Malnick and Wilcox 1977a, 133.)
pau.ci.mo′ bi.lis. L. adj. *paucis* few; L. adj. *mobilis* mobile; M.L. fem. adj. *paucimobilis* intended to mean few motile cells.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Colonies are convex and deep yellow on ordinary peptone media. Soma size is 0.7 × 1.4 μm (Holmes et al., 1977a). A few cells are motile with single polar flagellum. Some cells form a rosette-like arrangement. In addition to SGL-1, SGLs-2, 3, and 4 are detected on TLC (Table BXII.α.83, Figs. BXII.α.85 and BXII.α.87). SGL induces monokine production in human mononuclear cells (Krziwon et al., 1995) and stimulates phagocytosis and phagosome-lysosome fusion in human neutrophil cells (Miyazaki et al., 1995). Major polyamine is homospermidine (Busse and Auling, 1988; Hamana and Matsuzaki, 1993; Segers et al., 1994; Takeuchi et al., 1995; Takeuchi et al., 2001); one strain was reported to produce trace amounts of spermidine (Segers et al., 1994). The structure and function of sphingan (Pollock, 1993; Lobas et al., 1994; Pollock et al., 1994; Sutherland, 1994) and lyases (Sutherland and Kennedy, 1996) have been reported. Human clinical cases of infection have been reported (Crane et al., 1981; Glupczynski et al., 1984; Calubiran et al., 1990; Casadevall et al., 1992; Decker et al., 1992; Lemaitre et al., 1996). Type strain was isolated from hospital respirators.

[b]Data from Lee et al. (2001). Blank space, no data available.

[c]Data from Yurkov et al. (1997). Blank space, no data available.

The mol% G + C of the DNA is: 62–64 (HPLC).

Type strain: ATCC 29837, DSM 1098, EY2395, GIFU 2395, IAM 12576,IFO 11385, JCM 7516, LMG 1227, NCTC 11030.

GenBank accession number (16S rRNA): U37337, X72722.

2. **Sphingomonas adhaesiva** Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990b, 321[VP] (Effective publication: Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990a, 116.)
ad.hae.si.va. L. *adhaerere* adhere; *adhaesiva* intended to mean sticking to agar medium.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Cells have polar monotrichous flagella. Circular and yellow-pigmented colonies stick to agar medium, but corrosion of the agar has not been observed. No growth occurs on Simmons' citrate medium. Acid production in OF medium from carbohydrates takes 4 or more days of incubation. Major long-chain bases are $C_{18:0}$ (39%) and $C_{21:1}$ (26%); major fatty acids are $C_{18:1\ cis}$ (46%) and $C_{14:0\ 2OH}$ (23%). Major polyamine is homospermidine (Hamana and Matsuzaki, 1993; Segers et al., 1994; Takeuchi et al., 1995). The type strain was isolated from ultraviolet-irradiated water at a surgical operation theater.

The mol% G + C of the DNA is: 67.2 (HPLC).

Type strain: ATCC 51229, CCUG 27290, DSM 7418, EY 4215, GIFU 11458, IFO 5099, JCM 7370, LMG 0922.

GenBank accession number (16S rRNA): D16146, X72720.

3. **Sphingomonas alaskensis** Vancanneyt, Schut, Snuwaert, Goris, Swings and Gottschal 2001, 78[VP]

a.las.ken′sis. M.L. adj. *alaskensis* pertaining to Alaska, the source of the type strain.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Motile small rod. Soma size 0.2–0.5 × 0.5–3.0 μm. Although isolated at low temperatures (4–8°C), the optimal growth temperature for the type strain is approximately 37°C. Growth occurs at 44–48°C. Does not grow in Bacto-OF medium. Acid is produced in Bacto-CTA medium from maltose and trehalose, but not from D-glucose (Table BXII.α.88). For results with the API 20NE and API 50CH systems, see Vancanneyt et al. (2001). Isolated from seawater from Alaska.

The mol% G + C of the DNA is: 65 (HPLC).

Type strain: DSM 13593, EY 4374, LMG 18877, RB 2256.

GenBank accession number (16S rRNA): AF145754.

4. **Sphingomonas aquatilis** Lee, Shin, Yoon, Takeuchi, Pyun and Park 2001, 1495[VP]

a.qua.til′is. L. fem. adj. *aquatilis* aquatic, growing in water.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.88, and BXII.α.89, with the following additional information. Motile by a single polar flagellum. Colonies are circular, entire, low convex, smooth, opaque and yellow. Gelatin is not liquefied. Esculin is not hydrolyzed. D-Melibiose, D-sucrose, glucose, malate, maltose, *N*-acetylglucosamine, rhamnose, and salicin are assimilated, but 2-ketogluconate, 5-ketogluconate, adipate, caprate, citrate, D-ribose, D-sorbitol, gluconate, glycogen, L-arabinose, mannose, and phenylacetate are not assimilated. Acid is weakly produced oxidatively from glucose and rhamnose, but not from glycerol. Isolated from natural mineral water in Taejon City, Korea.

The mol% G + C of the DNA is: 63 (HPLC).

Type strain: JSS7, KCTC 2881, KCCM 41067.

GenBank accession number (16S rRNA): AF131295.

Additional Remarks: Reference strain: EY 4383, JSS28, KCTC 2883, KCCM 41066.

5. **Sphingomonas aromaticivorans** Balkwill, Drake, Reeves,

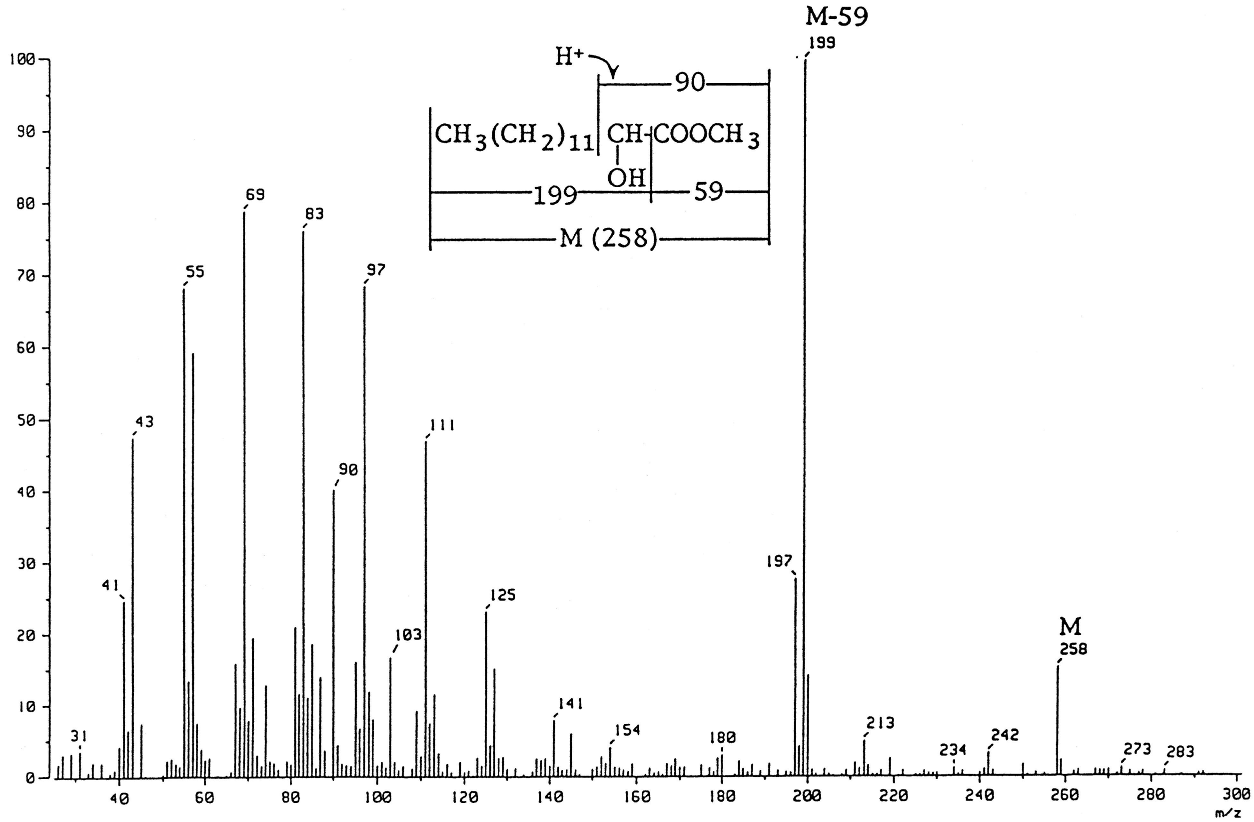

FIGURE BXII.α.91. Mass spectrum of the reaction product of H_2O_2-dependent α-hydroxylation of myristic acid. The mass spectrum of the methylated product gave ions of *m/z* 258 and 199, which were identical to those of methyl-2-hydroxcymyristic acid (*M*) and its characteristic fragment (*M-59*), respectively. (Reproduced with permission from I. Matsunaga et al., Federation of European Biochemical Societies Letters, *386:* 252–254, 1996, ©Elsevier Science B.V., Amsterdam.)

Fredreckson, White, Ringelberg, Chandler, Romine, Kennedy and Spadoni 1997, 199[VP]*

a.ro.ma.ti.ci′vo.rans. N.L. n. *aromaticus* aromatic compound; L. part. *vorans* eating; *aromaticivorans* eating aromatic compounds.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Nonmotile. Colonies are circular entire low convex smooth opaque and deep yellow. SGL-1 is present but not SGL-1′. In addition to $C_{14:0\ 2OH}$, $C_{15:0\ 2OH}$ is detected as a minor component. Major polyamine is spermidine (Busse et al., 1999; Takeuchi et al., 2001). Isolated from saturated Atlantic coastal plain terrestrial subsurface sediments.

The mol% G + C of the DNA is: 62.9–65.0 (HPLC).

Type strain: F199, DSM 12444, EY 4296, JCM 16084, SMCC F199.

GenBank accession number (16S rRNA): U20756.

Additional Remarks: Reference strains include strains B0522 (SMCC B0522) and B0695 (SMCC B0695).

6. **Sphingomonas asaccharolytica** Takeuchi, Sakane, Yanagi, Yamasato, Hamana and Yokota 1995, 341[VP]

a.sac.cha.ro.ly′ti.ca. Gr. pref. *a* not; Gr. n. *sacchar* sugar; Gr. adj. *lytica* able to loosen; M.L. fem. adj. *asaccharolytica* not digesting sugar.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Nonmotile because neither actively motile in wet mount preparation nor demonstrates any spreading growth on semisolid motility agar plate. Colonies are light yellow. In spite of the specific epithet, acid is produced oxidatively in OF basal medium from eight kinds of carbohydrates, including glucose and maltose (Table BXII.α.88). β-Galactosidase positive. 3-Ketolactose is produced and the major polyamine is homospermidine (Takeuchi et al., 1995; Takeuchi et al., 2001); Kämpfer et al. (1997) reported the production of minor amounts of spermidine in addition to homospermidine. Isolated from the roots of *Malus* spp. (apple) in Tsukuba City, Japan.

The mol% G + C of the DNA is: 64.8 (HPLC).

Type strain: Y-345, ATCC 51839, DSM 10564, EY 4229, IFO 15499, JCM 10279, LMG 17539.

GenBank accession number (16S rRNA): Y09639.

7. **Sphingomonas capsulata** (Leifson 1962) Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990b, 321[VP] (Effective publication: Yabuuchi, Yano, Oyaizu, Hashimoto,

Editorial Note: Novosphingobium aromaticivorans (Balkwill et al. 1997) Takeuchi et al. 2001, 1415 is a junior objective synonym of *S. aromaticivorans* (Yabuuchi et al., 2002).

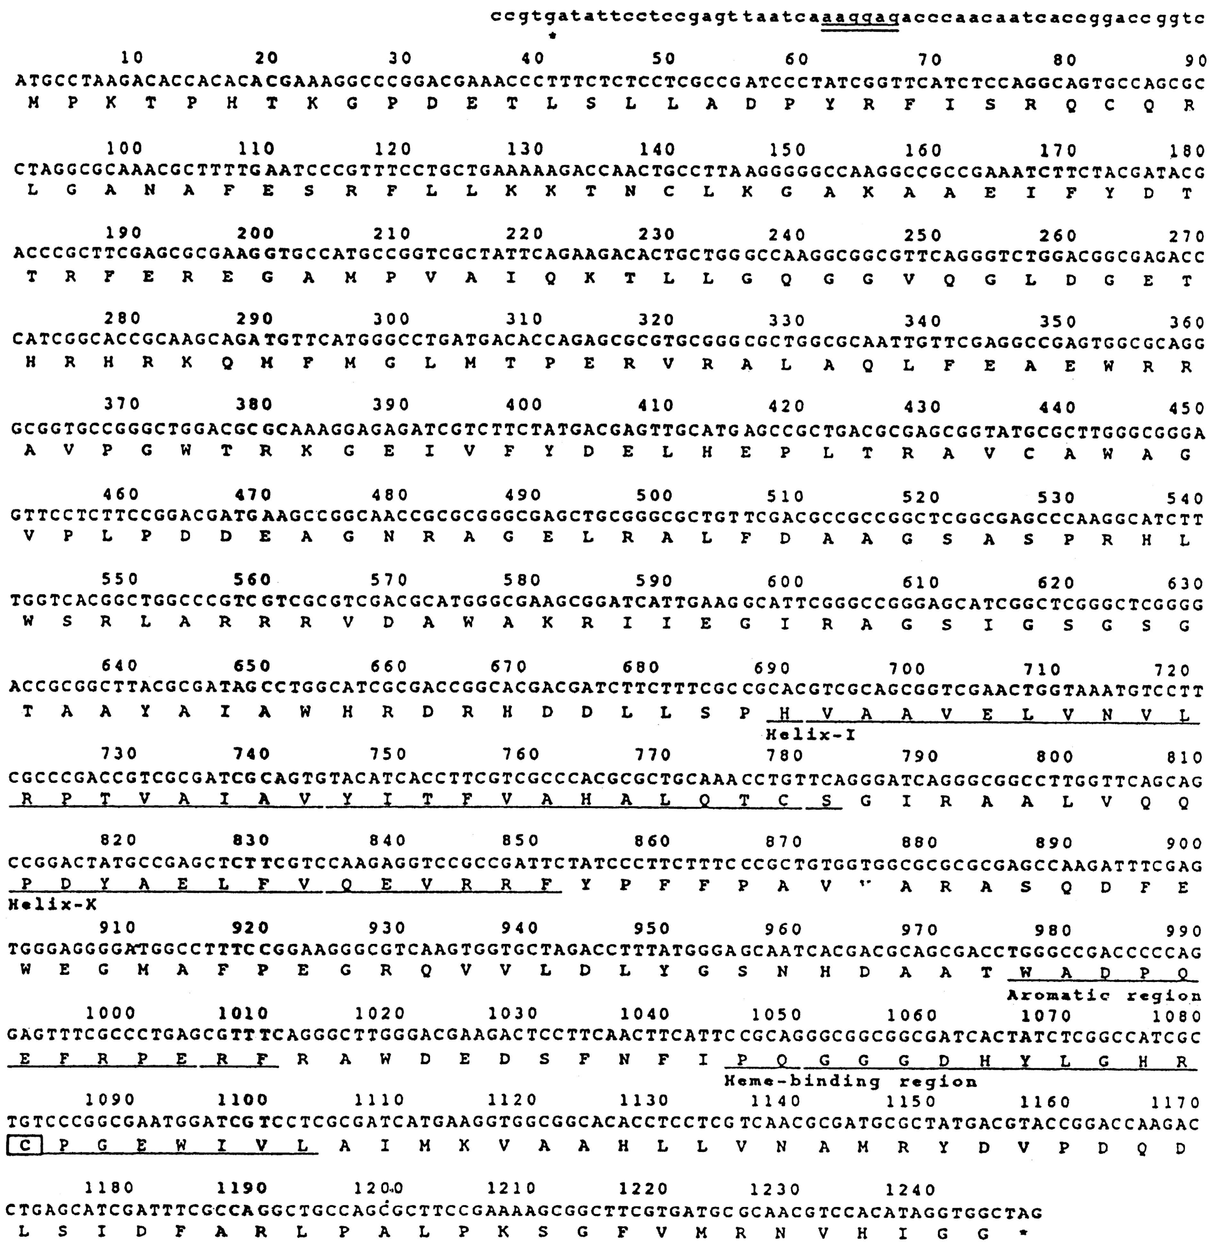

FIGURE BXII.α.92. Nucleotide sequence of 1.3-kb fragment containing the fatty acid α-hydroxylase gene and deduced amino acid sequence. The deduced amino acid sequence is represented under the nucleotide sequence by single-letter code. The asterisk and double underline indicate the termination codon and putative Shine-Dalgarno sequence, respectively. Helix-1, helix-K, aromatic region, and heme-binding region are underlined. Heme-binding cysteine is boxed. (Reproduced from I. Matsunaga et al., Journal of Biological Chemistry, *272:* 23592–23596, 1997, ©American Society for Biochemistry and Molecular Biology, Inc.)

Ezaki and Yamamoto 1990a, 117) (*Flavobacterium capsulatum* Leifson 1962, 161.)*

cap.su.la′ta. L. n. *capsula* a small chest, capsule; M.L. fem. adj. *capsulata* encapsulated.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Nonmotile without flagellum. Produces definitely yellow colonies. In spite of the specific epithet (Leifson, 1962), the organism lost its ability to produce capsule. Phenylalanine deaminase positive. Major polyamine reported as spermidine (Busse and Auling, 1988; Hamana and Matsuzaki, 1993; Segers et al., 1994; Takeuchi et al., 1995; Takeuchi et al., 2001). Isolated from distilled water.

The mol% G + C of the DNA is: 63.1 (HPLC).

Type strain: ATCC 14666, DSM 30916, EY 4216, GIFU 11526, IFO 12533, JCM 7508, LMG 2830, NCIMB 9890.

GenBank accession number (16S rRNA): D16147.

8. **Sphingomonas chlorophenolica** Nohynek, Suhonen, Nurmiaho-Lassila, Hantula and Salkinoja-Salonen 1996b, 625[VP]

*Editorial Note: *Novosphingobium capsulatum* (Leifson 1962) Takeuchi et al. 2001, 1415 is a junior objective synonym of *S. capsulata* (Yabuuchi et al., 2002).*

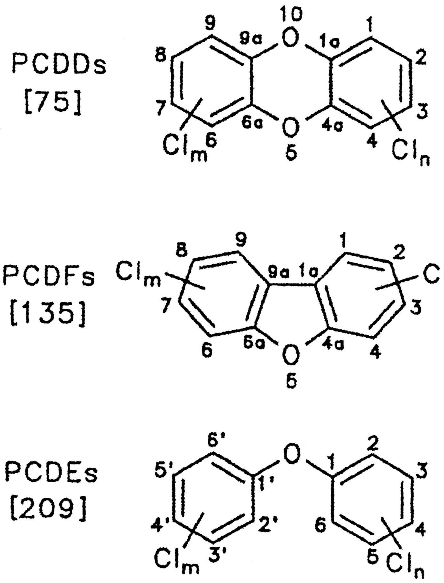

FIGURE BXII.α.93. Structure of polychlorinated dibenzo-*p*-dioxins (PCDDs), dibenzofurans (PCDFs), and diphenyl ethers (PCDEs). The number of possible congeners is given in brackets. (Reproduced from R.-M. Wittich. 1998. *In* Wittich (Editor) Biodegradation of Dioxins and Furans. Springer-Verlag, Berlin, and R.G. Landes Co., pp. 1–28.)

(Effective publication: Nohynek, Suhonen, Nurmiaho-Lassila, Hantula and Salkinoja 1995, 536.)*
chlor.o.phen.o′li.ca. L. fem. adj. *chloro* containing chlorine; N.L. n. *pheno* phenol; L. fem. adj. *chlorophenolica* relating to chlorophenols.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Rods vary in size, 0.3–0.7 × 1.0–3.5 µm. Acylamidase and DNase are positive, but hydrolysis of starch and Tween 80 are negative. Fimbriae or filaments may occur. Major polyamine is spermidine (Busse et al., 1999; Takeuchi et al., 2001).

Isolated from soil contaminated with wood preserving chlorophenols.

The mol% G + C of the DNA is: 63–67 (T_m).

Type strain: ATCC 33790, DSM 6284, EY4219, IFO 16172, JCM 10275, LMG 17554.

GenBank accession number (16S rRNA): U60171, X87161.

9. **Sphingomonas chungbukensis** Kim, Chun, Bae and Kim 2000a, 1646[VP]
chung.bu.ken′sis. M.L. adj. *chungbukensis* pertaining to Chungbuk National University.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Curved rods, 0.5–1 × 0.5–3.0 µm. Nonmotile. Colonies are smooth and yellow. Produce a great quantity of extracellular polysaccharide. Esculin and Tween 80 are not hydrolyzed. The major respiratory quinone is ubiquinone 10. Isolated from chemically contaminated freshwater sediment in Taejon, Republic of Korea.

The mol% G + C of the DNA is: 63 (T_m).

Type strain: DJ77, EY 4375, IMSNU 11152, JCM 11454, KCTC 2955.

GenBank accession number (16S rRNA): AF159257.

10. **Sphingomonas cloacae** Fujii, Urano, Ushio, Satomi and Kimura 2001, 608[VP]
clo.a′cae. L. n. *cloaca* sewer, the source of the organism.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Cells are 1.1–1.4 × 2.0–3.1 µm. Motile. Colonies are opaque and white. Unable to grow at 4° or 42°C. Both SGL-1 and SGL-1′ are present. The major isoprenoid quinone is ubiquinone Q-10. Isolated from wastewater of a sewage-treatment plant in Tokyo.

The mol% G + C of the DNA is: 63 (HPLC).

Type strain: S-3, EY 4361, IAM 14885, JCM 10874.

GenBank accession number (16S rRNA): AB040739.

11. **Sphingomonas echinoides** (Heumann 1962) Denner, Kämpfer, Busse, and Moore 1999, 1108[VP] (*Pseudomonas echinoides* Heumann 1962.)
e.chi.noi′des. Gr. adj. *echinos* spiny appearance; Gr. n. *eidus* form, shape; M.L. adj. *echinoides* spiny shaped.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Curved rods 0.8 × 1.9 µm, with sharp ends. Motile by polar flagella of 1.9 µm wavelength. Colonies are light yellow. Form cell aggregates (rosettes) both on solid and in liquid media. β-Galactosidase positive. For chromatogram of lipids, see Fig. BXII.α.85. Major polyamine is homospermidine (Denner et al., 1999; Takeuchi et al., 2001). Denner et al. (1999) also reported production of spermidine. Isolated as a laboratory contaminant on a nutrient agar plate.

The mol% G + C of the DNA is: 65.8 (T_m) (Owen and Jackman, 1982).

Type strain: ATCC 14820, DSM 1805, EY4340, ICBP 2835, IFO 15742, JCM 10637, NCIMB 9420.

GenBank accession number (16S rRNA): AB021370, AJ012461.

12. **Sphingomonas herbicidovorans** Zipper, Nickel, Angst, and Kohler 1997, 601[VP] (Effective publication: Zipper, Nickel, Angst and Kohler 1996, 4319.)**
herb.i.ci.do′vo.rans. L. n. *herba* an herb; *cido-cide* joint word to mean killing; L. v. *voro* to devour; M.L. fem. adj. *herbicidovorans* herbicide-devouring, referring to its ability to utilize herbicides as a sole source of carbon and energy.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. The type strain, strain MH (previously designated *Flavobacterium* sp. strain MH) was able to utilize the chiral herbicide (RS)-2-(4-chloro-2-methylphenoxy)propionic acid (mecoprop) as the sole carbon end en-

**Editorial Note: Sphingobium chlorophenolicum* (Nohynek et al. 1996a) Takeuchi et al. 2001, 1415 is a junior objective synonym of *S. chlorophenolica* (Yabuuchi et al., 2002).

***Editorial Note:* (Zipper et al. 1997) Takeuchi et al. 2001, 1415 is a junior objective synonym of *S. herbicidovorans* (Yabuuchi et al., 2002).

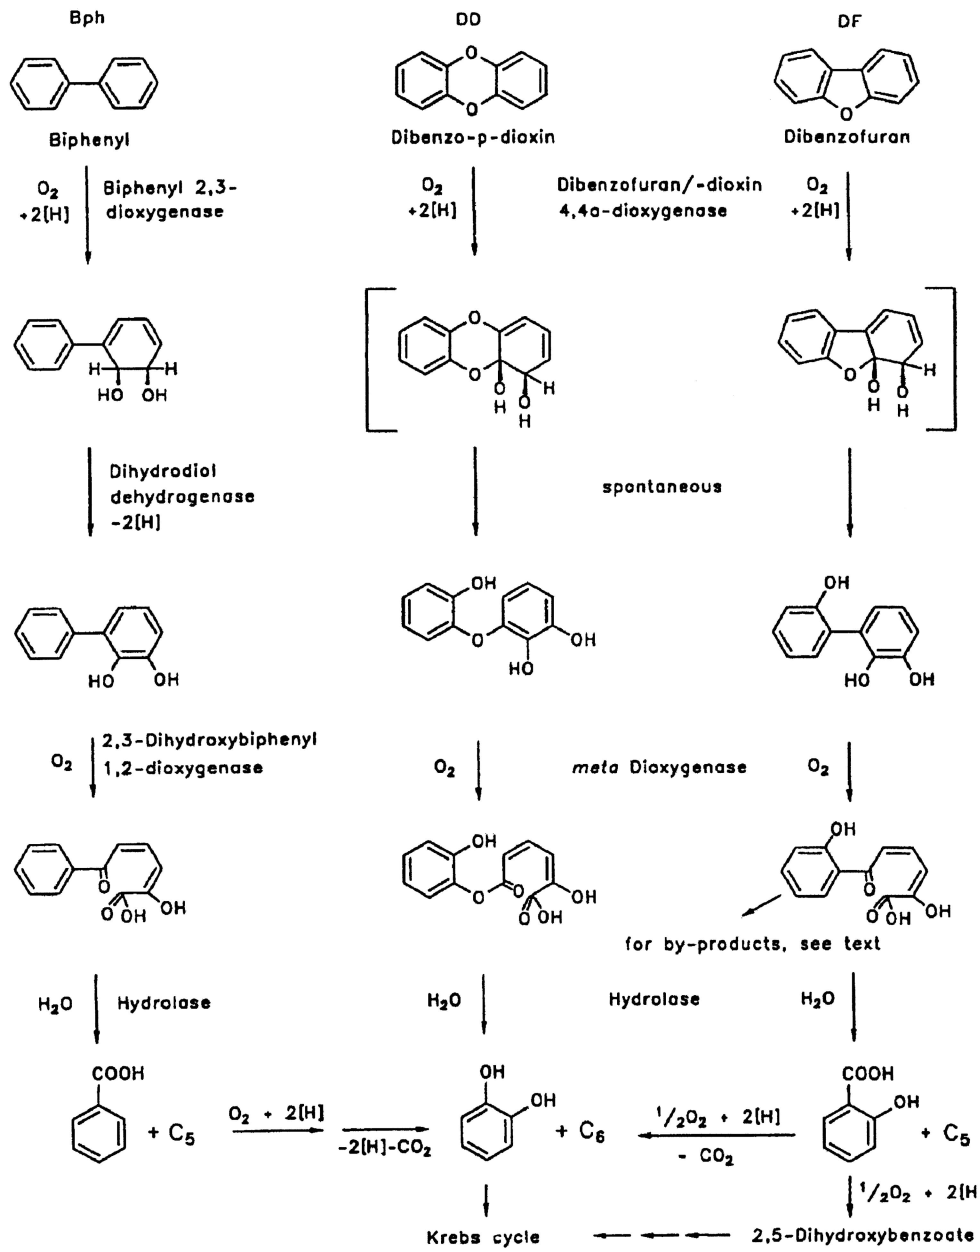

FIGURE BXII.α.94. Pathways for the complete aerobic degradation of biphenyl, dibenzo-*p*-dioxin, and dibenzofuran. (Reproduced from R.-M. Wittich. 1998. *In* Wittich (Editor) Biodegradation of Dioxins and Furans. Springer-Verlag, Berlin, and R.G. Landes Co., pp. 1–28.)

ergy source. Colonies are yellow. Produce the water-soluble brown pigment alkaptone due to accumulation of homogentisic acid by metabolic failure of phenylalanine or tyrosine. A chromatogram of SGL-1 is shown in Fig. BXII.α.85. Major polyamine is spermidine (Busse et al., 1999; Takeuchi et al., 2001). Isolated from soil.

The mol% G + C of the DNA is: 62.5 (HPLC).

Type strain: MH, ATCC 700291, CIP 106705, DSM 11019, EY 4344, LMG 18315.

GenBank accession number (16S rRNA): AB042233.

13. **Sphingomonas koreensis** Lee, Kook Shin, Yoon, Takeuchi, Pyun and Park 2001, 1496[VP]

ko.re.en'sis. N.L. fem. adj. *koreensis* pertaining to Korea, where the new organisms were isolated.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Motile rods with a single polar flagellum. Colonies are yellow. Acid is produced oxidatively in OF medium from 6 of 26 carbohydrates. The major isoprenoid quinone is ubiquinone Q-10. Isolated from natural mineral water in Taejon City, Korea.

The mol% G + C of the DNA is: 66 (HPLC).

Type strain: JSS26, EY 4376, JCM 11456, KCTC 2882, KCCM 41069.

GenBank accession number (16S rRNA): AF131296.

14. **Sphingomonas macrogoltabidus** Takeuchi, Kawai, Shimada, and Yokota 1993b, 864[VP] (Effective publication: Takeuchi, Kawai, Shimada and Yokota 1993a, 236.)*

[a]For symbols see standard definitions.

[b]The 17 substrates not assimilated by the 31 strains are dulcitol, L(+)-sorbose, D(+)-arabitol, L(−)-arabitol, D-sorbitol, adonitol, hydroxyquinoline-β-glucuronide, L(+)-tartrate, 3-phenylpropionate, *m*-coumarate, trigonelline, histamine, histidine, DL-α-amino-*n*-valerate, ethanolamine, malonate, and 3-*O*-methyl-D-glucopyranose.

mac.ro.gol.ta' bi.dus. M.L. fem. n. *macrogol* a trade name for a polyethylene glycol product; L. adj. *tabidus* dissolving; M.L. fem. adj. *macrogoltabida* polyethylene glycol dissolving.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Motile by a single polar flagellum. Colonies are grayish white. Polyethylene glycol 4000 is assimilated. Major polyamine is spermidine (Takeuchi et al., 1995; Takeuchi et al., 2001). Isolated from soil.

The mol% G + C of the DNA is: 63.2–65.0 (HPLC).

Type strain: CIP 104196, DSM 8826, EY 4304, IFO 15033, JCM 10192, LMG 17324.

GenBank accession number (16S rRNA): D13723.

15. **Sphingomonas mali** Takeuchi, Sakane, Yanagi, Yamasato, Hamana and Yokota 1995, 341[VP]

mal' i. M.L. gen. n. *mali* of *Malus*, the apple genus, the source of the organism.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Cells are motile. Colonies are light yellow. DNase positive, but does not hydrolyze gelatin and starch. Major polyamine is homospermidine (Takeuchi et al., 1995; Takeuchi et al., 2001). Isolated from the roots of *Malus* spp. (apple) in Tsukuba City, Japan.

The mol% G + C of the DNA is: 65.4–65.9 (HPLC).

Type strain: Y-547, ATCC 51480, DSM 10565, EY 4341, IFO 15500, JCM 10193, LMG 17331.

GenBank accession number (16S rRNA): Y09638.

16. **Sphingomonas melonis** Buonaurio, Stravato, Kosako, Fujiwara, Naka, Kobayashi, Cappelli and Yabuuchi 2002, 2086.

me.lo' nis. M.L. n. *melo* melon; L. gen. n. *melonis* of melon (*Cucumis melo* var. *inodorus*, Spanish melon), referring to the fruit of the plant for which the organism was pathogenic.

Editorial Note: Sphingopyxis macrogoltabida (Takeuchi et al. 1993a) Takeuchi et al. 2001, 1416 is a junior objective synonym of *S. macrogoltabidus* (Yabuuchi et al., 2002).

[a]For symbols see standard definitions.

[b]The 17 substrates not assimilated by the 31 strains are dulcitol, L(+)-sorbose, D(+)-arabitol, L(−)-arabitol, D-sorbitol, adonitol, hydroxyquinoline-β-glucuronide, L(+)-tartrate, 3-phenylpropionate, *m*-coumarate, trigonelline, histamine, histidine, DL-α-amino-*n*-valerate, ethanolamine, malonate, and 3-*O*-methyl-D-glucopyranose.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Nonmotile. Colonies are deep yellow. Isolated from fruits of yellow Spanish melons (*Cucunis melo* var. *inodorus*) in Almeria (Spain). Causal agent of brown spot of melon fruits. Organisms identified as strains of *Sphingomonas* sp., had previously been reported as a causative agent of melon fruit disease (Buonaurio et al., 2001).

The mol% G + C of the DNA is: 65 (HPLC).

Type strain: DAPP-PG 224, EY 4350, LMG 19484.

GenBank accession number (16S rRNA): AB055863.

17. **Sphingomonas natatoria** (Sly 1985) Yabuuchi, Kosako, Naka, Suzuki and Yano 1999b, 935[VP] (Effective publication: Yabuuchi, Kosako, Naka, Suzuki and Yano 1999a, 347) (*Blastobacter natatorius* Sly 1985, 40; *Blastomonas natatoria* (Sly 1985) Sly and Cahill 1997, 568.)*

na.ta.to′ri.a. M.L. fem. adj. *natatoria* of a swimming place (pool).

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Straight rod. Rosette-like arrangements of cells are seen. Unable to visualize either budding or asymmetric division of cells by optical microscopy. Though single polar flagellum was observed by electron microscopy (Sly, 1985), neither active motility in wet mount preparation nor diffuse spreading growth on semisolid motility agar plate was demonstrated. Colonies are orange pigmented. Aerobic and facultative photoorganotrophs, possessing bacteriochlorophyll *a*. Acid produced oxidatively from fructose and maltose but not from glucose. Isolated from a fresh water swimming pool. Major polyamine is spermidine (Busse et al., 1999; Takeuchi et al., 2001).

The mol% G + C of the DNA is: 64.5 (HPLC).

Type strain: ACM 2507, ATCC 35951, DSM 3183, EY4220, IFO15649, JCM 10396, LMG 17322, NCIMB 12085.

GenBank accession number (16S rRNA): Y13774.

18. **Sphingomonas parapaucimobilis** Yabuuchi, Yano, Oyaizu,

**Editorial Note: Blastomonas natatoria* (Sly 1985) Sly and Cahill 1997, 568 emend. Hiraishi, Kuraishi and Kawahara 2000a, 1117 is a junior objective synonym of *S. natatoria* (Yabuuchi et al., 2002).

Hashimoto, Ezaki and Yamamoto 1990b, 321[VP] (Effective publication: Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990a, 116.)
pa.ra.pau.ci.mo.bi'lis. Gr. prep. *para* alongside of, resembling; M.L. *paucimobilis* specific epithet of *Sphingomonas paucimobilis*; M.L. gen. n. *parapaucimobilis* intended to mean like the species of *S. paucimobilis*.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Cellular and colonial characteristics are similar to those of *S. paucimobilis*. Glucuronosyl ceramide (SGL-1) is present, but not galacturonosyl ceramide (SGL-1′) (Fig. BXII.α.85). Major component of polyamine is homospermidine (Hamana and Matsuzuki, 1993; Takeuchi et al., 1995; Takeuchi et al., 2001); Segers et al. (1994) reported production of spermidine. Isolated from human urine.

The mol% G + C of the DNA is: 64–65 (HPLC).

Type strain: ATCC 51231, CCUG 27291, DSM 7463, EY 4213, GIFU 11387, IFO 15100, JCM 7510, LMG 10923.

GenBank accession number (16S rRNA): X72721.

19. **Sphingomonas pituitosa** Denner, Paukner, Kämpfer, Moore, Abraham, Busse, Wanner and Lubitz 2001, 837[VP]
pi.tu.i.to'sa. L. fem. adj. *pituitosa* slimy.

[a]Abbreviations: PP, plant pathogenic; AMPC, amoxicillin; CVA, clavulanic acid; S, susceptible; IM, intermediate; R, resistant.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Cells are 0.4–0.75 × 1.0–3.0 μm. Motile by a single polar flagellum. Strictly aerobic. Colonies are deep yellow. Poly-β-hydroxybutyrate is accumulated (Denner et al., 2001). Glucuronosyl ceramide (SGL-1) is present. Major polyamine is homospermidine (Denner et al., 2001). Isolated from the water of a eutrophic fountain in Vienna, Austria, in which an algal bloom was observed.

The mol% G + C of the DNA is: 64.5 (HPLC).

Type strain: EDIV, CIP 106154, DSM 13101, EY 4370.

GenBank accession number (16S rRNA): AJ243751.

20. **Sphingomonas pruni** Takeuchi, Sakane, Yanagi, Yamasato, Hamana and Yokota 1995, 340[VP]

pru′ni. M.L. gen. n. *Prunus* genus of peach; L, gen. n. *pruni* of peach (*Prunus persica*), the source of the organism.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Neither active motility in wet mount preparation nor diffuse spreading growth on semisolid motility agar plate was observed. Colonies are grayish white. Glucuronosyl ceramide (SGL-1) is present, but not SGL-1′ (Fig. BXII.α.85). Major polyamine is homospermidine (Takeuchi

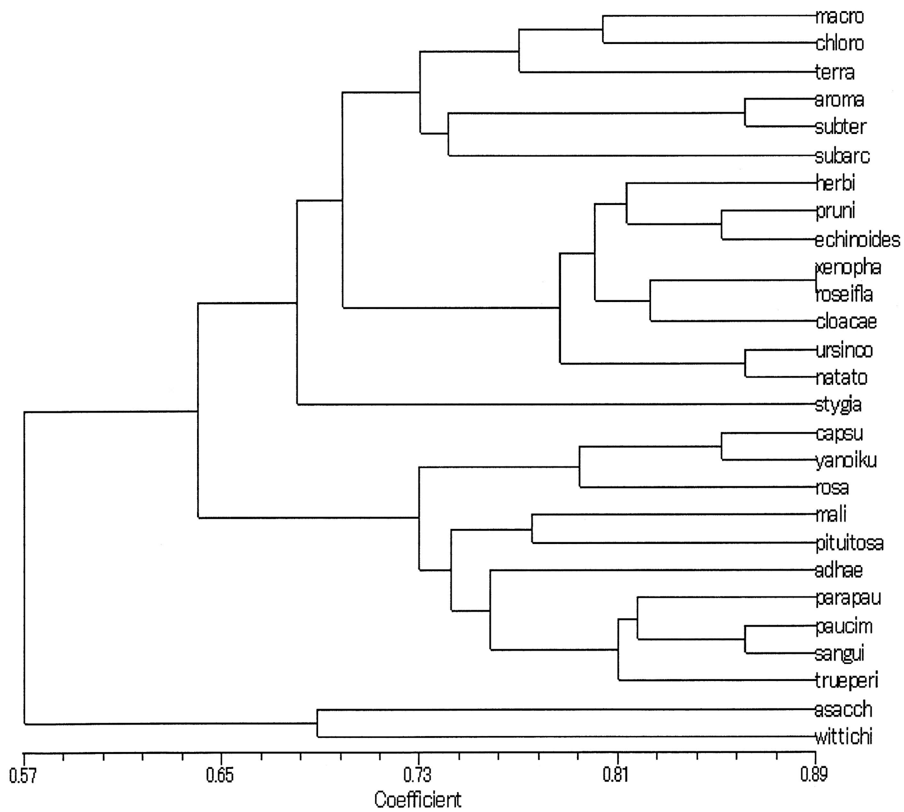

FIGURE BXII.α.95. Numerical analysis of 106 features of type strains of 27 *Sphingomonas* species. Numerical analysis was done by using NTSYS-pc Version 2 program package (Applied Biostatistics Inc. Setauket, NY). Coefficient was calculated by Simple Matching, and the dendrogram was drawn by UPGMA (Sneath and Sokal, 1973). Name of *Sphingomonas* species (new genus by Takeuchi et al., 2001): macro = *S. macrogoltabidus* (*Sphingopyxis*); chloro = *"S. chlororaphis"* (*Sphingobium*); terra = *S. terrae* (*Sphingopyxis*); aroma = *S. aromaticivorans* (*Sphingomonas*); subter = *S. subterranea* (*Sphingomonas*); subarc = *S. subarctica* (*Sphingomonas*); herbi = *S. herbicidovorans* (*Sphingobium*); pruni = *S. pruni* (*Sphingomonas*); echinoides = *S. echinoides* (*Sphingomonas*); xenopha = *S. xenophaga*; roseifla = *S. roseiflava* (*Sphingomonas*); cloacae = *S. cloacae*; ursincola = *S. ursincola* (*Blastomonas*); natato = *S. natatoria* (*Blastomonas*); stygia = *Sphingomonas stygia* (*Novosphingobium*); capsu = *S. capsulata* (*Novosphingobium*); yanoiku = *S. yanoikuyae* (*Sphingobium*); rosa = *S. rosa* (*Novosphingobium*); mali = *S. mali* (*Sphingomonas*); pituitosa = *S. pituitosa*; adhae = *S. adhaesiva* (*Sphingomonas*); parapau = *S. parapaucimobilis* (*Sphingomonas*); sangui = *S. sanguinis* (*Sphingomonas*); trueperi = *S. trueperi*; assach = *S. asaccharolytica* (*Sphingomonas*); wittichi = *S. wittichii*(*Sphingomonas*).

et al., 1995; Takeuchi et al., 2001). Isolated from the roots of *Prunus persica* (peach) in Tsukuba City, Japan.

The mol% G + C of the DNA is: 65.4 (HPLC).

Type strain: Y-250, DSM 10566, EY 4228, IFO 15498, JCM 10277, LMG 18380.

GenBank accession number (16S rRNA): D28568, Y09637.

21. **Sphingomonas rosa** Takeuchi, Sakane, Yanagi, Yamasato, Hamana and Yokota 1995, 340[VP]*

ro′sa. M.L. n. *rosa* rose, the source of the organism.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Neither active motility in wet mount preparation nor diffuse spreading growth on semisolid motility agar plate was observed. Colonies are light yellow. Glucuronosyl ceramide (SGL-1) is present, but not galacturonosyl ceramide (SGL-1′) (Fig. BXII.α.85). Major polyamine is spermidine (Takeuchi et al., 1995; Takeuchi et al., 2001). Isolated from the hairy roots of *Rosa* spp. (rose).

The mol% G + C of the DNA is: 64.7–65.0 (HPLC).

Type strain: ATCC 51837, DSM 7285, EY 4227, IFO 15208, JCM 10276, LMG 17328, NCPPB 2661.

GenBank accession number (16S rRNA): D13945.

22. **Sphingomonas roseiflava** Yun, Shin, Hwang, Kuraishi, Sugiyama and Kawahara 2000b, 1415[VP] (Effective publication: Yun, Shin, Hwang, Kuraishi, Sugiyama and Kawahara 2000a, 17) (*Sphingomonas roseoflava* (sic) Yun, Shin, Hwang, Kuraishi, Sugiyama and Kawahara 2000b, 1415.)

ro.se.i.fla′va. L. adj. *roseus* rose colored; L. adj. *flavus* yellow; N.L. fem. adj. *roseiflava* rose-yellow.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Nonmotile rod. Colonies are orange. Glucuronosyl ceramide (SGL-1) is present but not galacturonosyl ceramide (SGL-1′) (Fig. BXII.α.85). Two types of sphingoglycolipid are present: one contains glucuronic acid, and the other contains glucuronic acid, glucosamine, and hex-

*Editorial Note: *Novosphingobium rosa* (Takeuchi et al. 1995) Takeuchi et al. 2001, 1415 is a junior objective synonym of *S. rosa* (Yabuuchi et al., 2002).

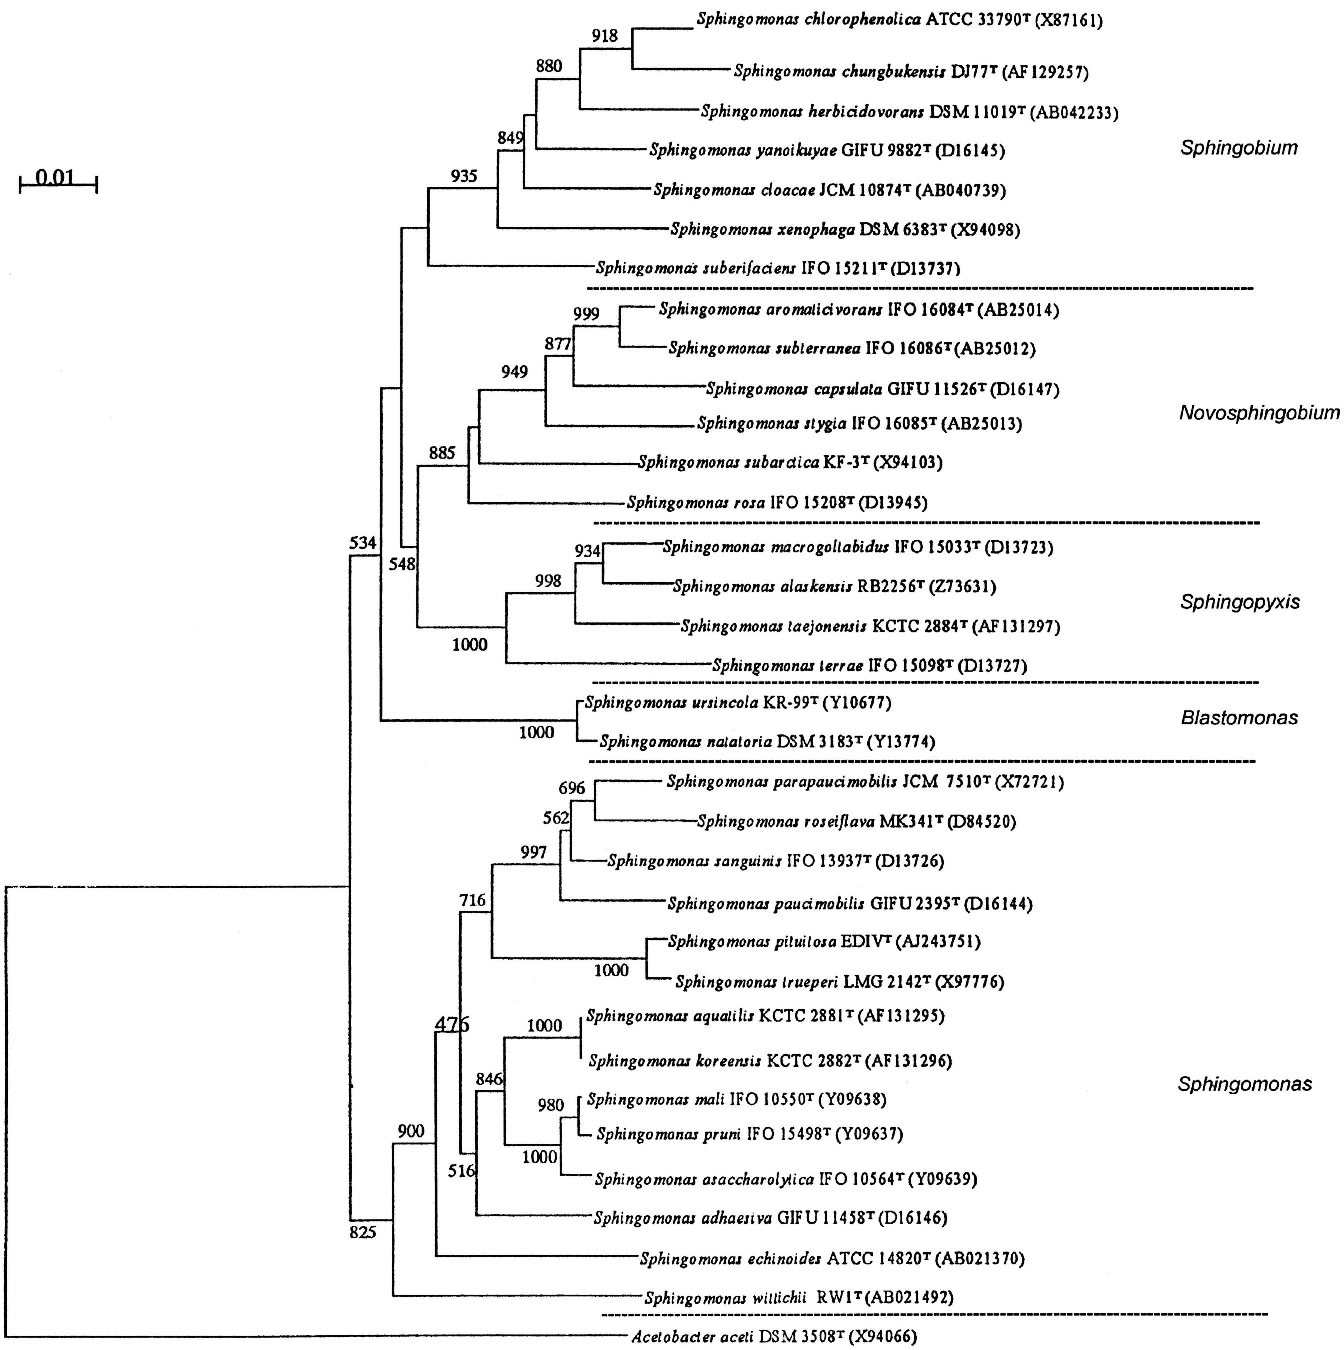

FIGURE BXII.α.96. Dendrogram based on the results of phylogenetic analysis of 16S rDNA sequence of type strains of 33 *Sphingomonas* species. Nucleotide substitution rates (K_{nuc}) (Kimura, 1980) were determined by using the CLUSTAL W program (Thompson et al., 1994). Neighbor-joining method (Saitou and Nei, 1987) was used to reconstruct a phylogenetic tree from the distance matrices by the NJPLOT written by Manolo Gouy (Laboratoire de Biometrie, Univ. Lyon, Villeurbanne, France). Alignment gaps and unidentified base positions were not taken into consideration for the calculations. To evaluate the topology of the phylogenetic tree, a bootstrap analysis was performed with 1000 bootstrapped trials. Bootstrap values are indicated at the branching points. Clusters containing *Sphingomonas* species assigned by Takeuchi et al., 2001 to the genera *Sphingobium*, *Sphingopyxis*, and *Novosphingobium* as well as the closely related *Blastomonas* species are indicated on the right.

oses (Yun et al., 2000a). Frequently isolated from the ear of the plant *Setaria viridis*.

The mol% G + C of the DNA is: 66–68 (HPLC).

Type strain: MK3412, EY 4345, IAM 14823.

GenBank accession number (16S rRNA): D84520.

23. **Sphingomonas sanguinis** Takeuchi, Kawai, Shimada and Yokota 1993b, 864[VP] (Effective publication: Takeuchi, Kawai, Shimada and Yokota 1993a, 237) (*Sphingomonas sanguis* (sic) Takeuchi, Kawai, Shimada, and Yokota 1993b, 864.)
san'gui.nis. L. gen. n. *sanguinis* of the blood.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87,

TABLE BXII.α.88. Oxidative acid production of the type strains of 38 species of *Sphingomonadaceae* in Bacto-Oxidation–Fermentation (OF), Cystine–tryptone agar, or Marine OF media[a,b]

[a] *Sphingomonas suberifaciens* EY 4202^{T} was omitted because of no growth on any of three media.

[b]Symbols: +, positive reaction within 4 d; −, negative reaction for 4 weeks; NG, no growth.

[c]EY, Eiko Yabuuchi.

[d](a) Bacto-Oxidation–Fermentation (OF) basal medium; (b) Bacto-Cystine–tryptone agar (CTA) medium; (c) Bacto-Marine Oxidation–Fermentation (MOF) medium.

[e]Data from Lee et al. (2001).

BXII.α.88, and BXII.α.89, with the following additional information. Rods. Motile by a single polar flagellum. Colonies are deep yellow. A thin-layer chromatogram of the alkali-stable lipids is shown in Fig. BXII.α.85. Major component of polyamine is homospermidine (Hamana and Matsuzaki, 1993; Segers et al., 1994; Takeuchi et al., 1995; Takeuchi et al., 2001); Segers et al. (1994) reported trace amounts of spermidine. PEG 4000 and PEG 6000 are not assimilated (Takeuchi et al., 1993a). Isolated from blood.

The mol% G + C of the DNA is: 61.8 (HPLC).

Type strain: ATCC 51382, CDC B4562, CIP 104197, DSM 13885, EY 2397, GIFU 2397, IFO 13937, JCM 7514, LMG 17325, NCTC 11032.

GenBank accession number (16S rRNA): D13726.

24. **Sphingomonas stygia** Balkwill, Drake, Reeves, Fredreckson, White, Ringelberg, Chandler, Romine, Kennedy and Spadoni 1997, 199[VP]*

sty′gi.a. L. masc. n. *Styx* underworld river in classical Greek mythology; L. fem. adj. *stygia* pertaining to the underworld, subterranean.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Nonmotile rods. Colonies are light yellow. Glucuronosyl ceramide (SGL-1) is present, but not galacturonosyl ceramide (SGL-1′) (Fig. BXII.α.85). Major component of polyamine is spermidine (Busse et al., 1999; Takeuchi et

al., 2001). Isolated from saturated Atlantic coastal plain terrestrial subsurface sediments.

The mol% G + C of the DNA is: 65.4 (HPLC).

Type strain: B0712, ATCC 700280, DSM 12425, EY 4297, JCM 16085, SMCC B0712.

GenBank accession number (16S rRNA): U20775.

25. **Sphingomonas subarctica** Nohynek, Nurmiaho-Lassila, Suhonen, Busse, Mohammadi, Hantula, Rainey and Salkinoja-Salonen 1996a, 1053VP*

sub.arc′ti.ca. M.L. adj. *subarcticus* below the arctic, because the organism was isolated from a subarctic area, Finland.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Though an electron micrograph of a cell with four flagella arranged peritrichously appeared (Nohynek et al., 1996a), neither active motility in wet mount preparation nor diffuse spreading growth on semisolid motility agar plate were observed. Colonies are light yellow. Glucuronosyl ceramide (SGL-1) is present, but not galacturonosyl ceramide (SGL-1′) (Fig. BXII.α.85). Strain KF1 degrades 2,4,6-tri- and 2,3,4,6-tetrachlorophenols but not pentachlorophenol. Major polyamine is spermidine (Nohynek et al., 1996a; Takeuchi et al., 2001). Isolated from the biofilm of an activated sludge reactor.

The mol% G + C of the DNA is: 65–67 (T_m).

Type strain: KF1, DSM 10700, EY 4251, HAMBI 2110, JCM 10398.

GenBank accession number (16S rRNA): X94102.

26. **Sphingomonas suberifaciens** (van Bruggen, Jochimsen and Brown 1990) Yabuuchi, Kosako, Naka, Suzuki and Yano

*Editorial Note: *Novosphingobium subarcticum* (Balkwill et al. 1997) Takeuchi et al. 2001, 1415 is a junior objective synonym of *S. subarctica* (Yabuuchi et al., 2002).

[b]All 26 strains positive for hydrolysis of esculin and Zinc dust test in negative NO_2 test. All 26 strains negative for NO_2 from NO_3, indole from tryptophan, acid from glucose, arginine dihydrolase activity, hydrolysis of urea and gelatin.

[c]Data from Lee et al. (2001).

[d]Positive reaction after more than 5 d.

1999b, 935[VP] (Effective publication: Yabuuchi, Kosako, Naka, Suzuki and Yano 1999a, 347) (*Rhizomonas suberifaciens* van Bruggen, Jochimsen and Brown 1990, 186.)*
su.be.ri.fa′ ci.ens. L. gen. n. *suberus* of cork, corky; L. part. adj. *faciens* making, producing; M.L. part. adj. *suberifaciens* corky making.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.87, and BXII.α.89, with the following additional information. Cells of the type strain are thin and short straight rods. Actively motile in wet mount preparation. Spreading growth occurs on semisolid (0.3%) agar medium. Colonies on agar plate of ATCC medium 1700 (*Rhizobium* medium) after 24 h at 26°C are colorless and translucent. Unable to determine acid production from carbohydrates, because neither OF nor CTA medium supports the growth of the organism. Glucuronosyl ceramide (SGL-1) is present but not galacturonosyl ceramide (SGL-1′) (Fig. BXII.α.85). Major polyamine is spermidine (Takeuchi et al., 1995; Takeuchi et al., 2001). Isolated from the corky roots of lettuce (*Lactuca sativa*).

The mol% G + C of the DNA is: 59.0 (HPLC).

Type strain: Ca1, ATCC 49355, DSM 7465, EY 4204, IFO 15211, JCM 8521, NCPPB 3629.

GenBank accession number (16S rRNA): D13737.

27. **Sphingomonas subterranea** Balkwill, Drake, Reeves, Fredreckson, White, Ringelberg, Chandler, Romine, Kennedy and Spadoni 1997, 199[VP]**
sub.ter.ra′ ne.a. L. fem., adj. *subterranea* underground, subterranean.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Colonies are deep yellow. Glucuronosyl ceramide (SGL-1) is present, but not galacturonosyl ceramide (SGL-1′) (Fig. BXII.α.85). Major component of polyamine is spermidine (Takeuchi et al., 2001). Isolated from saturated Atlantic coastal plain terrestrial subsurface sediments.

The mol% G + C of the DNA is: 60.0 (HPLC).

Type strain: B0478, ATCC 700279, DSM 12447, EY 4298, JCM 16086, SMCC B0478.

GenBank accession number (16S rRNA): U20773.

28. **Sphingomonas taejonensis** Lee, Kook Shin, Yoon, Takeuchi, Pyun and Park 2001, 1497[VP]
tae.jon.en′ sis. N.L. fem. adj. *taejonensis* of Taejon, Korea, the geographical origin of the species.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Motile by a single polar flagellum. Colonies are pale yellow. Sphingolipid is present, though no details have been reported. Isolated from natural mineral water from Taejon City, Korea.

The mol% G + C of the DNA is: 63 (HPLC).

Type strain: JSS54, EY 4377, JCM 11457, KCTC 2884, KCM 41068.

GenBank accession number (16S rRNA): AF131297.

**Editorial Note:* The generic name *Rhizomonas* Orla-Jensen 1909 has been placed on the List of Rejected Generic Names, Opinion 14 of the Judicial Commission, Lapage et al. (1992).

***Editorial Note: Novosphingobium subterraneum* (Balkwill et al. 1997) Takeuchi et al. 2001, 1415 is a junior objective synonym of *S. subterranea* (Yabuuchi et al., 2002).

[b]All 26 strains positive for hydrolysis of esculin and Zinc dust test in negative NO_2 test. All 26 strains negative for NO_2 from NO_3, indole from tryptophan, acid from glucose, arginine dihydrolase activity, hydrolysis of urea and gelatin.

[c]Data from Lee et al. (2001).

[d]Positive reaction after more than 5 d.

29. **Sphingomonas terrae** Takeuchi, Kawai, Shimada and Yokota 1993b, 864[VP] (Effective publication: Takeuchi, Kawai, Shimada and Yokota 1993a, 236.)*
ter′rae. L. n. *terra* earth; M.L. gen. n. *terrae* of the earth.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Rods with round ends. Motile by a single polar flagellum. Colonies are deep yellow. PEG 6000 is assimilated in a mixed culture. Both glucuronosyl ceramide (SGL-1) and galacturonosyl ceramide (SGL-1′) are present (Fig. BXII.α.85). Polyamines reported include spermidine alone (Takeuchi et al., 1995; Takeuchi et al., 2001) and homospermidine together with a trace of spermidine (Segers et al., 1994). Isolated from active sludge.

The mol% G + C of the DNA is: 63.0–64.9 (HPLC).

Type strain: E-1-A, ATCC 51381, CIP 104198, DSM 8831, EY 4207; IFO 15098, JCM 10195, LMG 17326.

GenBank accession number (16S rRNA): D13727.

30. **Sphingomonas trueperi** Kämpfer, Denner, Meyer, Moore and Busse 1997, 579[VP]
true′per.i. L. gen. n. *truepari* of Trüper; named in honor of the German microbiologist Hans G. Trüper in recognition of his numerous contributions to the taxonomy of the *Proteobacteria.*

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Motile with peritrichous flagella. Colonies are light yellow. Able to grow in the presence of the 10% sodium chloride and 0.02% sodium azide (Kämpfer et al., 1997). Reported polyamines include homospermidine together with spermidine (Busse and Auling, 1988) or homospermidine alone (Takeuchi et al., 2001). Glucuronosyl ceramide (SGL-1) present but not galacturonosyl ceramide (SGL-1′) (Fig. BXII.α.85). Isolated from soil.

The mol% G + C of the DNA is: 65.6 (T_m).

Type strain: ATCC 12417, DSM 7225, EY4218, JCM 10278, LMG 2141, NCIMB 9391.

GenBank accession number (16S rRNA): X97776.

31. **Sphingomonas ursincola** (Yurkov, Stackebrandt, Buss, Vermeglio, Gorlenko and Beatty 1997) Yabuuchi, Kosako Naka, Suzuki and Yano 1999b, 935[VP] (Effective publication: Yabuuchi, Kosako, Naka, Suzuki and Yano 1999a, 347) (*Erythromonas ursincola* Yurkov, Stackebrandt, Buss, Vermeglio, Gorlenko and Beatty 1997, 1177.)**
ur.sin′co.la. M.L. adj. *ursincola* neighbor or compatriot of bears.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Short rod or ovoid cells. Rosettes are not formed. In wet mount preparation, cells seem nonmotile and coccoid. No diffuse spreading growth on semisolid motility agar plate. Unable to visualize either budding or asymmetric division of cells by optical microscopy of Gram-

**Editorial Note: Sphingopyxis terrae* (Takeuchi et al. 1993a) Takeuchi et al. 2001, 1416 is a junior objective synonym of *S. terrae* (Yabuuchi et al., 2002).

***Editorial Note: Blastomonas ursincola* (Yurkov et al. 1997) Hiraishi et al. 2000a, 1117 is a junior objective synonym of *S. ursincola* (Yabuuchi et al., 2002).

stained preparations. Aerobic and facultative photoorganotrophic. Colonies are orange brown. Needs 5 d for esculin hydrolysis. Glucuronosyl ceramide (SGL-1) present but not galacturonosyl ceramide (SGL-1′). (Fig. BXII.α.85). Isolated from a freshwater cyanobacterial mat.

The mol% G + C of the DNA is: 64.8 (HPLC).

Type strain: KR-99, DSM 9006, EY 4250, JCM 10397.

GenBank accession number (16S rRNA): Y10677.

32. **Sphingomonas wittichii** Yabuuchi, Yamamoto Terakubo, Okamura, Naka, Fujiwara, Kobayashi, Kosako and Hiraishi 2001, 289[VP]
wi.tti′chi.i. M.L. gen. n. *wittichii* of Wittich, referring to Rolf-Michael Wittich, the German bacteriologist who first isolated this potent metabolizer of dibenzo-*p*-dioxin from the water of the river Elbe and described the metabolism of the compound by this organism.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Rods with rounded ends. Actively motile, with a single polar or subpolar flagellum. Colonies are grayish white and become faintly yellow after incubation for 3 d at 30°C. Both glucuronosyl ceramide (SGL-1) and galacturonosyl ceramide (SGL-1′) are present (Fig. BXII.α.85). Polyamines include homospermidine and smaller amounts of spermidine (Busse et al., 1999). Isolated from water of the River Elbe.

The mol% G + C of the DNA is: 67 (T_m).

Type strain: Wittich RW1, DSM 6014, EY 4224, JCM 10273, SMUM 2128.

GenBank accession number (16S rRNA): AB021492.

33. **Sphingomonas xenophaga** Stolz, Schmidt-Maag, Denner, Busse, Egli and Kämpfer 2000, 40[VP]
xe.no′pha.ga. Gr. adj. *xenos* foreign; Gr. n. *phagos* eater; M.L. fem. adj. *xenophaga* eating foreign (xenobiotic) compounds.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Motile by a polar flagellum. Colonies are deep yellow. Glucuronosyl ceramide (SGL-1) present, but not galacturonosyl ceramide (SGL-1′) (Fig. BXII.α.85). Major polyamine is spermidine (Stolz et al., 2000). The type strain was isolated from river water (River Elbe, Germany).

The mol% G + C of the DNA is: 62.1–63.3 (T_m).

Type strain: BN6, DSM 6383, EY 4343.

GenBank accession number (16S rRNA): X94098.

34. **Sphingomonas yanoikuyae** Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990b, 321[VP] (Effective publication: Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki and Yamamoto 1990a, 116.)*
ya.no.i.ku′yae. N.L. adj. *yanoikuyae* named in honor of Professor Ikuya Yano, the Japanese bacteriologist who first recognized the second major spot of alkaline-stable glycolipid (SGL-1′, now known as galacturonosyl ceramide) on TLC.

The characteristics are as described for the genus and in Tables BXII.α.84, BXII.α.85, BXII.α.86, BXII.α.87, BXII.α.88, and BXII.α.89, with the following additional information. Actively motile with a single polar or subpolar flagellum. Colonies are grayish white, never became definitely yellow after prolonged incubation at room temperature. Both glucuronosyl ceramide (SGL-1) and galacturonosyl ceramide (SGL-1′) are present (Fig. BXII.α.85). Major component of polyamine reported as spermidine (Hamana and Matsuzaki, 1993; Segers et al., 1994; Takeuchi et al., 1995; Busse et al., 1999; Takeuchi et al., 2001). Type strain isolated from a hospital specimen (Bruun, 1982); other strains from plant roots.

The mol% G + C of the DNA is: 61.7 (HPLC).

Type strain: ATCC 51230, CCUG 28380, DSM 7462, EY4208, GIFU 9882, IFO 15102, JCM 7371, LMG 11252.

GenBank accession number (16S rRNA): D16145.

Editorial Note: Sphingobium yanoikuyae (Yabuuchi et al. 1990b) Takeuchi et al. 2001, 1415 is a junior objective synonym of *S. yanoikuyae* (Yabuuchi et al., 2002).

Genus II. **Blastomonas** *Sly and Cahill 1997, 567[VP] emend. Hiraishi, Kuraishi and Kawahara 2000a, 1117*

Lindsay I. Sly and Philip Hugenholtz

Blas.to.mo′nas. Gr. n. *blastos* bud shoot; Gr. n. *monas* a unit, monad; M.L. fem. n. *Blastomonas* a budding monad.

Cells are ovoid or rod-shaped and reproduce by budding or asymmetric cell division. They occur singly or in pairs and **may form rosette-like aggregates**. No stalks and prosthecae are found. **Gram negative.** Nonsporeforming. **Motile by means of polar flagella. Strictly aerobic. Chemoorganotroph** and **facultative photoorganoheterotroph**. No growth occurs under anaerobic conditions in the light. **Produces BChl *a*.** Colonies and cell suspensions are **yellow to orange due to carotenoids**. **Mesophilic** and **neutrophilic**. **Catalase and oxidase positive.** Nitrate is not reduced. Acid is not produced in Hugh and Leifson's OF medium. The **major whole-cell fatty acid is $C_{18:1\ \omega9}$**. The **major hydroxy-fatty acid is $C_{14:0\ 2OH}$**. $C_{15:0\ 2OH}$ and $C_{16:0\ 2OH}$ are present as minor components. 3-OH fatty acids are absent. Monosaccharide-type glycosphingolipids are present. **Ubiquinone-10 is the major respiratory quinone.** Belongs to the *Alphaproteobacteria*. Habitat is fresh water.

The mol% G + C of the DNA is: 65.

Type species: **Blastomonas natatoria** (Sly 1985) Sly and Cahill 1997, 568 emend. Hiraishi, Kuraishi and Kawahara 2000a, 1117 (*Blastobacter natatorius* Sly 1985, 43.)

Further descriptive information

The cellular morphology of *Blastomonas* is shown in Fig. BXII.α.97. Some variation in cell shape and arrangement occurs. Cells are usually rod-shaped with straight sides, but may be swollen or wedge-shaped, or have a slightly curved axis (Sly, 1985). In *B. natatoria* each cell has a simple mucilaginous holdfast at its non-reproductive pole, by which it attaches to solid surfaces or other cells to form rosettes (Sly, 1985). Rosette formation in *B. ursincola* has not been reported. Further information on morphological and phenotypic characters may be found in publi-

(*B*) Electron micrograph of a daughter cell (bud) with a single polar flagellum. Bar = 1 µm. (*C*) Electron micrograph of budding cells in rosette formation. Bar = 1 µm. (*D*) and (*E*) Electron micrographs demonstrating different cell morphologies. Bar = 1 µm. (Reprinted with permission from L.I. Sly, International Journal of Systematic Bacteriology *35:* 40–45, 1985, ©International Union of Microbiological Societies.)

cations by Sly and Hargreaves (1984), Sly (1985), Sly and Cahill (1997), Yurkov et al. (1997), and Hiraishi et al. (2000a). Chemotaxonomic characteristics are described in Sittig and Hirsch (1992), Yurkov et al. (1997), and Hiraishi et al. (2000a).

Considerable research has been undertaken on the photosynthesis characteristics. Bacteriochlorophyll *a* has been detected in the type strains of both *B. natatoria* and *B. ursincola*, but the latter strain produces the photosynthetic pigment in higher amounts (Hiraishi et al., 2000a). *B. ursincola* was shown to have bacteriochlorophyll *a* incorporated into the photochemically active photosynthetic reaction center and core light harvesting (LH1) complexes (Yurkov et al., 1997, 1998a, b). The *puf* genes coding for proteins of the L and M subunits of the photosynthetic reaction center complex and of the LH1 complex have been detected in both species (Hiraishi et al., 2000a). *B. natatoria* and *B. ursincola* show 4–5% difference in their *pufL* and *pufM* gene sequences (Hiraishi et al., 2000a).

B. natatoria and *B. ursincola* contain carotenoid pigments in addition to the bacteriochlorophyll *a* pigment. Carotenoid pigments give three absorption peaks at 425–430, 453–458, and 481–485 nm (Yurkov et al., 1997; Hiraishi et al., 2000a) and together with bacteriochlorophyll *a* produce the colors of orange in young cultures and dark orange-brown in older cultures. In *B. ursincola* bacteriochlorophyll *a* is present in membrane-bound protein-pigment complexes, consisting of the reaction center with absorption peaks at 751, 801, and 853 nm and core LH1 absorbing at 867 nm (Yurkov et al., 1997). The reaction center contains tightly bound tetraheme cytochrome *c*.

Some information is available about the biochemistry of *B. ursincola*. The tricarboxylic acid cycle and the glyoxylate shunt are present, but the key enzyme of the Calvin cycle, ribulose biphosphate carboxylase, is not present (Yurkov et al., 1997). *B. ursincola* is very resistant to tellurite, growing in the presence of 2700 μg/ml in acetate-containing minimal medium (Yurkov et al., 1997). Tellurite is reduced and transformed into metallic tellurium accumulated as metal crystals in the cytoplasm (Yurkov et al., 1996).

Recently, Rickard et al. (2000) reported that strains of *B. natatoria* isolated from biofilms (Buswell et al., 1997) demonstrated intraspecies coaggregation between strains and intergeneric coaggregation with *Micrococcus luteus*. Coaggregation was maximal in the stationary phase of growth, and each member of a coaggregating pair carried either a heat- and protease-sensitive protein (lectin) adhesin or a saccharide receptor, as coaggregation was reversed by sugars.

Enrichment and Isolation Procedures

No enrichment media have been designed for the isolation of *Blastomonas*. The type strain of *B. natatoria* was isolated from a swimming pool using a Millipore *Pseudomonas* Count Water Tester (Sly and Hargreaves, 1984). However, *B. natatoria* may be grown on dilute media such as Staley's peptone yeast glucose medium (Staley, 1981b) on which the colonies appear pink (Sly, 1985). On nutrient agar and R2A agar (Reasoner and Geldreich, 1985) colonies are yellow (Sly, 1985; Rickard et al., 2000).

Maintenance Procedures

Cultures of *Blastomonas* grow well on dilute nutrient media. *B. natatoria* grows well on peptone, yeast extract, glucose (PYG) medium (Staley, 1981b), or R2A medium (Reasoner and Geldreich, 1985). Cultures may be preserved by cryogenic storage in liquid nitrogen when suspended in sucrose peptone broth containing 10% glycerol, and by freeze-drying in glucose peptone broth containing horse serum. Media for *B. ursincola* requires supplementation with 20 μg/l Vitamin B_{12} (Yurkov et al., 1997).

Differentiation of the genus *Blastomonas* from other genera

Budding of bacteria is widespread throughout the *Proteobacteria* and occurs in phylogenetically diverse genera with widely different physiological characteristics (Rothe et al., 1987; Hugenholtz et al., 1994; Sly and Cahill, 1997) including *Agromonas*, *Blastobacter*, *Blastomonas*, *Gemmobacter*, *Rhodopseudomonas*, *Methylosinus*, and *Nitrobacter*. Tables BXII.α.90 and BXII.α.91 give the characteristics that are useful in differentiating the species of heterotrophic Gram-negative rod-shaped budding bacteria.

Taxonomic Comments

The genus *Blastomonas* was described for the type species *Blastomonas natatoria* (Sly and Cahill, 1997), which was transferred from the genus *Blastobacter* in which it was originally placed (Sly, 1985). Phylogenetic analysis of the members of the genus *Blastobacter* revealed that the genus was polyphyletic and required taxonomic revision (Hugenholtz et al., 1994; Sly and Cahill, 1997). The second species of the genus, *Blastomonas ursincola*, was first described as an aerobic bacteriochlorophyll *a* containing organism and assigned to a new genus *Erythromonas*, as *Erythromonas ursincola*, by Yurkov et al. (1997), even though the type strains of *Blastomonas natatoria* and *Erythromonas ursincola* showed 99.8% 16S rRNA sequence similarity. This taxonomic decision was made with regard to their different physiologies and the important position of photosynthesis in bacterial taxonomy. However later, Hiraishi et al. (2000a) demonstrated that *Blastomonas natatoria* also synthesized bacteriochlorophyll *a* aerobically and contained *puf* genes for photosynthesis. Hiraishi et al. (2000a) consequently transferred *Erythromonas ursincola* to *Blastomonas* and emended the description of the genus to include aerobic bacteriochlorophyll-*a*-synthesizing bacteria.

The taxonomy of *Blastomonas* species continues to be subject to differences of opinion, in particular their relationship to the genus *Sphingomonas* in the family *Sphingomonadaceae*. Takeuchi et al. (2001) proposed that the genus *Sphingomonas* be split into four separate genera (*Sphingomonas sensu stricto*, *Sphingobium*, *Novosphingobium*, and *Sphingopyxis*), primarily on phylogenetic and chemotaxonomic evidence, and proposed that the genera *Blastomonas* and *"Rhizomonas"* be retained to avoid taxonomic confusion. Yabuuchi et al. (1999a), on the other hand, argue that all species in the *Sphingomonadaceae*, including the species of *Blastomonas* be combined into the genus *Sphingomonas*.

Phylogenetically, the genus *Blastomonas* belongs to the *Sphingomonadales*, a monophyletic group in the *Alphaproteobacteria* (Fig. BXII.α.98). *Blastomonas* comprises a monophyletic lineage, not robustly affiliated with any other lineage within the *Sphingomonadales* (including *"Rhizomonas"*, which is often shown branching with *Blastomonas*). There is no reproducible (robust) branching order of lineages within the *Sphingomonadales*, so it could be argued that all taxa in the *Sphingomonadales* shown in Fig. BXII.α.98 could be reclassified into the genus *Sphingomonas* to preserve phylogenetic coherence of the group if a "lumping" strategy was adopted. However, it could also be argued that all independent monophyletic lineages within the *Sphingomonadales* (currently there are 10) could be classified as separate genera, thus retaining *Blastomonas* as a distinct genus. Applying this criterion, several species of *Sphingomonas* in Fig. BXII.α.98 would need to be re-

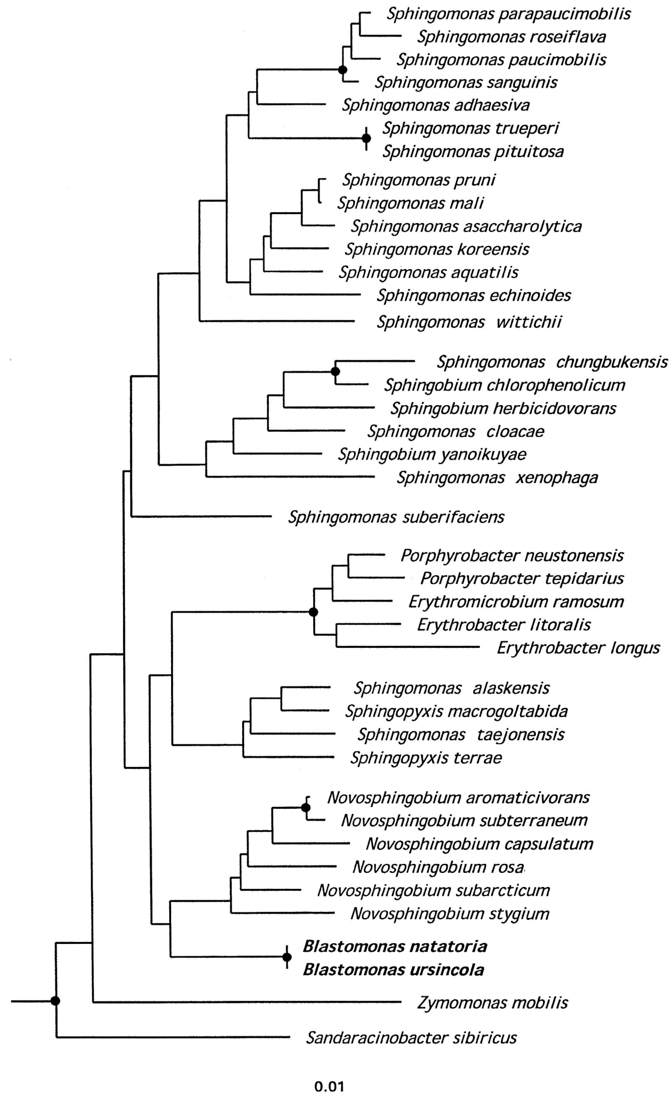

FIGURE BXII.α.98. 16S rRNA evolutionary distance tree of the *Sphingomonadales*. The outgroups used were *Rhodospirillum rubrum*, *Rhodobacter capsulatus*, and *Agrobacterium tumefaciens*. Robust internal nodes (>90 bootstrap confidence) are indicated by a solid circle on the node. The intra-order sequence divergence within the *Sphingomonadales* is 9%.

classified according to their generic affiliation, and *Erythrobacter*, *Erythromicrobium*, and *Porphyrobacter* may need to be reclassified into a single genus. Papers by Sly and Cahill (1997), Takeuchi et al. (2001), and Yurkov et al. (1997) argue on phylogenetic evidence that *Blastomonas* belongs to a deep separate lineage without a close relationship to the genus *Sphingomonas*. Hiraishi et al. (2000a) proposes that *Blastomonas* should be retained on phylogenetic and phenotypic evidence, particularly its budding morphology and photosynthesis capacity, which clearly separate it from *Sphingomonas*. On the other hand, Yabuuchi et al. (1999a) have proposed the transfer of *B. natatoria* and *B. ursincola* to the genus *Sphingomonas*.

On balance, the authors support the retention of the genus *Blastomonas* at this time to avoid taxonomic confusion. Based on budding morphology and aerobic bacteriochlorophyll *a* synthesis, *Blastomonas* can easily be differentiated from *Sphingomonas*. Hiraishi et al. (2000a) support the retention of the genus *Blastomonas* and note that whereas most species of the genus *Sphingomonas* contain monosaccharide- and oligosaccharide-type glycosphingolipids, *B. natatoria* and *B. ursincola* contain monosaccharide-type glycosphingolipids only.

List of species of the genus Blastomonas

1. **Blastomonas natatoria** (Sly 1985) Sly and Cahill 1997, 568[VP] emend. Hiraishi, Kuraishi and Kawahara 2000a, 1117 (*Blastobacter natatorius* Sly 1985, 43.)
na.ta.to′ri.a. M.L. masc. adj. *natatorius* of a swimming place [pool], the source of the water from which the organism was first isolated.

Cells are ovoid or rod-shaped, 0.6–0.9 × 1–2.5 µm, and reproduce by budding or asymmetric cell division. Colonies on complex media containing peptone and beef extract or yeast extract are circular, convex, smooth, and opaque and grow to 2 mm within 1 week of incubation. Color of colonies is yellow, orange, or brown, depending upon the composition of growth media and age of culture. Aerobic chemoorganotrophy is the preferred mode of growth. No chemolithotrophic growth with H_2, sulfide, or thiosulfate is found. Optimal temperature for growth is 30–35°C. Optimal pH is 7.0–7.5. Growth occurs in the presence of 3% NaCl. No growth factors are required. Esculin, starch, gelatin, Tween 80, and DNA are hydrolyzed. Chitin, cellulose, and casein are not hydrolyzed. Urease, phenylalanine deaminase, indole, and H_2S are not produced. Good growth occurs with D-xylose, maltose, pyruvate, glutamate, peptone, or yeast extract as sole carbon sources. Other usable carbon sources are L-arabinose, D-glucose, acetate, propionate, butyrate, succinate, fumarate, and Casamino acids. No or little growth occurs with D-fructose, D-mannose, cellobiose, lactose, mannitol, sorbitol, lactate, methanol, propanol, formate, citrate, malate, phenylacetate, benzoate, dichlorophenol, dibenzofuran, dibenzo-*p*-dioxin, or naphthalene. The major phospholipids are phosphatidylglycerol, phosphatidylethanolamine, phosphatidyldimethylethanolamine, and phosphatidylcholine. Inhabits freshwater environments. Isolated from a freshwater swimming pool.

The mol% G + C of the DNA is: 65 (HPLC).

Type strain: ACM 2507, ATCC 35951, DSM 3183, JCM 10396, NCIMB 12085, UQM 2507.

GenBank accession number (16S rRNA): AB024288.

2. **Blastomonas ursincola** (Yurkov, Stackebrandt, Buss, Vermeglio, Gorlenko and Beatty 1997) Hiraishi, Kuraishi and Kawahara 2000a, 1117[VP] (*Erythromonas ursincola* Yurkov, Stackebrandt, Buss, Vermeglio, Gorlenko and Beatty 1997, 1177.)
ur.sin' co.la. M.L. adj. *ursincola* neighbor or compatriot of bears.

Cells are 0.8–1.0 × 1.3–2.6 μm in size. No growth occurs in the presence of 3% NaCl. Growth factors are not required, but growth is stimulated significantly by vitamins. Starch, casein, Tween 80, and DNA are hydrolyzed. Esculin, chitin, cellulose, and gelatin are not hydrolyzed. Urease, phenylalanine deaminase, indole, and H_2S are not produced. Good growth occurs with maltose, pyruvate, glutamate, peptone, or yeast extract as sole carbon source. Other usable carbon sources are D-xylose, D-glucose, D-sorbitol, acetate, propionate, butyrate, succinate, fumarate, malate, and Casamino acids. No or little growth occurs with L-arabinose, D-fructose, D-mannose, cellobiose, lactose, D-mannitol, lactate, methanol, ethanol, propanol, formate, citrate, phenylacetate, benzoate, dichlorophenol, dibenzofuran, dibenzo-*p*-dioxin, or naphthalene. Inhabits freshwater environments. Isolated from a cyanobacterial mat of a thermal spring on Kamchatka Island (Russia).

The mol% G + C of the DNA is: 65 (HPLC).

Type strain: DSM 9006, KR-99.

GenBank accession number (16S rRNA): AB024289.

Genus III. **"Citromicrobium"** *Yurkov, Krieger, Stackebrandt and Beatty 1999, 4523*

Vladimir V. Yurkov

Ci.tro.mi.cro' bi.um. Gr. n. *citron* citron; Gr. adj. *micros* small; Gr. n. *bios* life; M.L. n. *Citromicrobium* citron-colored microbe.

Cells are pleomorphic, depending on the growth phase of cultures, coccoid to ovoid rods, often forming Y-cells. Motile by one polar or subpolar flagellum. **Gram negative, highly variable in its mode of multiplication.** Cultures are **intensely lemon-yellow colored because of carotenoid pigments, and contain bacteriochlorophyll *a*. Photosynthetic apparatus contains reaction center (RC) and light harvesting (LH) complexes. No growth occurs anaerobically in the light**. Incapable of autotrophic growth. **Obligately aerobic.** No dissimilatory denitrification activity detected. The habitat is marine.

The mol% G + C of the DNA is: 67.5.

Type species: **"Citromicrobium bathyomarinum"** Yurkov, Krieger, Stackebrandt and Beatty 1999, 4523.

Further descriptive information

"Citromicrobium bathyomarinum" is the only *"Citromicrobium"* species currently described. Phylogenetically, this species is closely related to other aerobic phototrophic bacteria and belongs to the *Alphaproteobacteria*.

On agar plates, *"C. bathyomarinum"* forms small (2–4 mm) lemon-yellow colonies with a smooth surface. With age, the color of the colonies turns intensely yellow. After growth aerobically in liquid media aerated by shaking, cultures are slightly aggregative, and bright yellow. The culture does not grow anaerobically in the light or under dark conditions. In agar (0.7%) deeps, growth occurs only at the surface (the aerobic and semiaerobic zones) of agar tubes. Light is not required for growth.

Cells of strain *"C. bathyomarinum"* grown in rich organic (RO) liquid medium that contains 0, 0.5, 1.0, 2.0, 3.0, or 5.0% NaCl, are similar morphologically and unusually pleomorphic. Depending on the growth phase of cultures, the morphology of cells ranges from almost coccoid (0.4–0.5 × 0.5–0.8 μm), through ovoid rods (0.4–0.5 × 1.0–1.2 μm), to thread-like formations of up to 5 cells. In RO medium with higher NaCl content (7% or 10%), bean shaped or wavy cells as well as long thread-like formations of up to 10 cells are found. Coccoid cells from young cultures are motile by one polar or subpolar flagellum (Yurkov and Beatty, 1998b; Yurkov et al., 1999).

"C. bathyomarinum" is variable in its mode of cell division. Budding, ternary fission, binary division, and symmetric and asymmetric constrictions were observed. This bacterium forms Y-cells, a rare type of bacterial multiplication, which results in the possibility of three daughter cells produced from one mother cell (Fig. BXII.α.99). Cells often remain attached after division, apparently by means of a membranous connective material of unknown nature, and are surrounded by a thin "bubbly" substance (Fig. BXII.α.99). Therefore, cells in liquid culture are slightly aggregative, such that many individual cells remain in contact after division.

Electron microscopic thin sections showed that *"C. bathyomarinum"* has a Gram-negative cell wall. The cytoplasmic membrane was visible, but no obvious intracytoplasmic membranes (ICMs) were detected. No inclusions indicative of storage materials were seen in cells harvested from RO medium.

The *in vivo* absorption spectrum of *"C. bathyomarinum"* has a major peak at 867 nm, indicating the presence of bacteriochlorophyll *a* incorporated into LH complex I (LHI). The small peak at 800 nm indicates the presence of the photosynthetic RC. The photosynthetic apparatus organization of an LH system associated with the RC (photosynthetic unit) in this species was indicated by isolation and purification of LHI-RC particles after lysis and treatment of cells with detergent, and sucrose gradient fractionation. In addition to the LHI-RC-enriched fraction, another fraction that contained a low amount of apparently an LHII complex (absorption peaks at 799 and 849 nm) was reported (Yurkov et al., 1999).

The above data indicate the presence of LHI, LHII, and RC complexes in cells of *"C. bathyomarinum"*, and the total number of photosynthetic units per cell is similar to the number of units determined from the spectra of other aerobic phototrophic bacteria. Cells contain 0.4–0.6 nmol of BChl/mg of protein. *"C. bathyomarinum"* produces BChl when grown aerobically in the dark, but production of this pigment is significantly repressed on rich media such as RO, or media containing yeast extract or Casamino acids. The most pronounced BChl synthesis was detected in a minimal medium containing acetate, glutamate, or butyrate as the sole source of carbon.

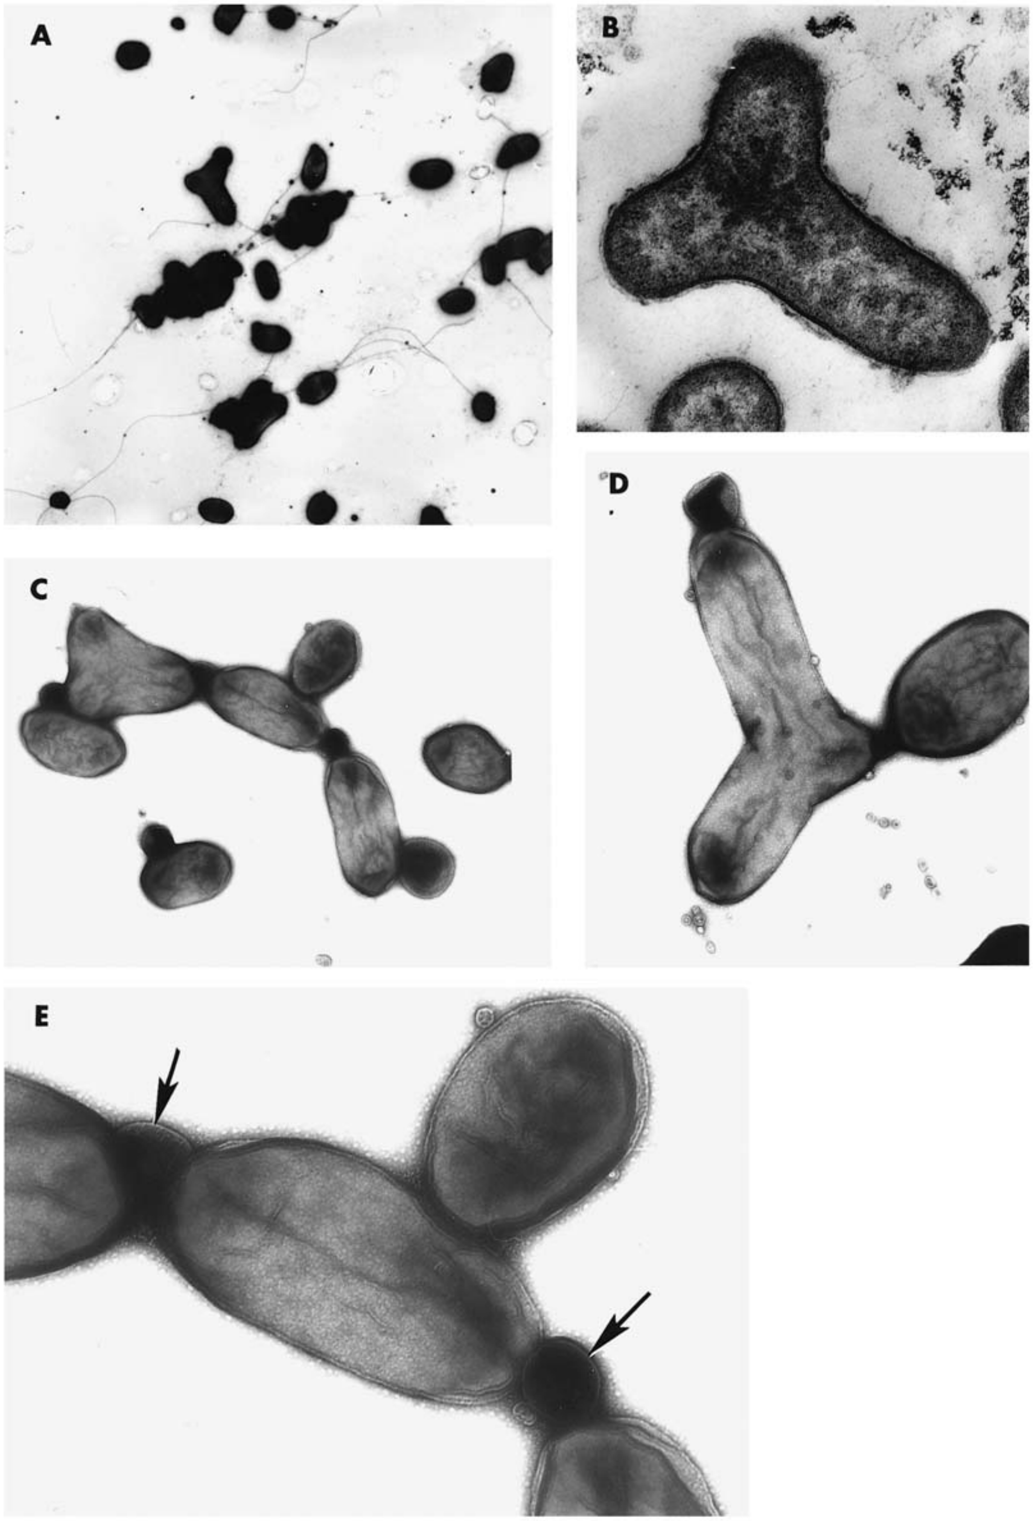

FIGURE BXII.α.99. Electron micrographs of negatively stained (A, C, D, E) and thin-sectioned (B) cells of *"Citromicrobium bathyomarinum"*. (*A*) Pleomorphism of cells, (*B*) Y-shaped form during early stage of cell division. The nucleoid is distributed in three directions, (*C* and *D*) Cells of different morphologies connected by an unknown material, (*E*) Enlarged fragment of panel *C*, showing membranous connective material (*arrows*).

The yellow color of cells and the three peaks at 433, 457, and 487 nm indicate the presence of carotenoids, apparently of the carotene type. The ratio of the absorbance at the LHI BChl absorption peak (867 nm) to that at the main carotenoid absorption peak (457 nm) is about 1:8. However, the ratio of carotenoids:BChl was much higher in intact cells than in partially purified photosynthetic complexes. It seems that most of these carotenoids were not intimately bound to the components of the photosynthetic apparatus (LH and RC). As noted above, ICM invaginations were not observed in the electron microscopic thin sections. Possibly the photosynthetic apparatus of *"C. bathyomarinum"* is restricted to the cytoplasmic membrane.

"C. bathyomarinum" is broadly tolerant to culture conditions such as salinity, temperature, and pH. Thus, growth occurs in a freshwater medium and a medium supplemented with 10% NaCl, at temperatures ranging from 4° to 45°C, and at pH values of 5.5–10.0. Therefore, *"C. bathyomarinum"* is a salt-, pH-, and thermotolerant strain.

"C. bathyomarinum" utilizes an unusually low number of substrates compared to other aerobic phototrophic bacteria. Glutamate, butyrate, and yeast extract are the best carbon sources, and acetate and glucose support weak growth. The substitution of nitrate for ammonia as a nitrogen source, and an increase or decrease in aeration did not affect the variety of organic substrates that supported growth. Gelatin is not hydrolyzed, but Tween 20, Tween 80, and starch are hydrolyzed, indicating the absence of gelatinase and the presence of lipolytic and amylolytic activities (Table BXII.α.92).

[a]For symbols see standard definitions; nd, not determined; w, weak growth.

As a good representative of the aerobic phototrophic bacteria, *"C. bathyomarinum"* is highly resistant to tellurite and reduces this compound to tellurium apparent as intracellular crystals with the minimal inhibitory concentration of tellurite shown to be 2000 μg/ml (Yurkov et al., 1999).

Enrichment and Isolation Procedures

"C. bathyomarinum" strain JF-1 was isolated from samples obtained from the vicinity of nonbuoyant regions of plumes emitted from hydrothermal vents on the Juan de Fuca Ridge (Northeastern Pacific Ocean; ~47°57′N, 129°05′W; about 2000 m beneath the ocean surface). Descriptions of the samples and bacterial heterotrophic population enumerated on the medium used are given in Yurkov and Beatty (1998b). The techniques used to isolate and cultivate *"C. bathyomarinum"* are similar to those described for *Erythromicrobium.*

Maintenance Procedures

"Citromicrobium" can be preserved by standard procedures in liquid nitrogen, by freezing at −70°C or below, or lyophilization (see chapter on *Erythromicrobium* for details).

Differentiation of the genus *Citromicrobium* from other genera

Genus *"Citromicrobium"* can be easily differentiated from other known genera of the aerobic phototrophic bacteria. On a phylogenetic tree based on 16S rDNA sequences, *"C. bathyomarinum"* represents an independent branch within the *Alphaproteobacteria.* This organism has a very characteristic lemon yellow color, which has been used to compose a taxonomic name for this species. *"C. bathyomarinum"* is very pleomorphic (Fig. BXII.α.99) and variable in its mode of reproduction. The Y-cell type of cellular division, a type rarely observed among bacteria, has been found as one of the ways *"C. bathyomarinum"* reproduces itself (Fig. BXII.α.99). Cells often remain attached after division, apparently by means of membranous connective material of unknown nature. This species is capable of growth over a broad range of NaCl concentrations, pH values, and temperatures. However, it seems to have quite limited metabolic possibilities, being able to grow on an unusually low (for this physiological group) number of substrates (Table BXII.α.92).

Taxonomic Comments

The 16S rDNA sequences of strain JF-1 showed that the phylogenetically closest relatives of the genus *"Citromicrobium"* were members of the genera *Sphingomonas*, *Sandaracinobacter*, *Erythrobacter*, *Erythromonas* (*Sphingomonas*), and *Porphyrobacter* (Fig. BXII.α.100). The phylogenetic position of *"C. bathyomarinum"* is as a branch between the genus *Erythromonas* (*Sphingomonas*) and the *Erythromicrobium–Porphyrobacter– Erythrobacter* cluster within the *Alphaproteobacteria.*

List of species of the genus "Citromicrobium"

1. **"Citromicrobium bathyomarinum"** Yurkov, Krieger, Stackebrandt and Beatty 1999, 4524.
ba.thy.o.ma.ri′ num. Gr. adj. *bathys* deep; L. adj. *marinum* oceanic; M.L. adj. *bathyomarinum* deeply oceanic.

Gram negative, lemon-yellow pigmented, pleomorphic. Cells may be almost coccoid (0.4–0.5 × 0.5–0.8 μm), ovoid rods (0.4–0.5 × 1.0–1.2 μm), or thread-like structures. Coccoid cells are motile by means of one polar or subpolar flagellum. Cells contain BChl *a* and carotenoid pigments. BChl *a* bound to proteins gives *in vivo* absorption peaks at 800 and 867 nm. Photosynthetic apparatus is organized in RC, LHI, and LHII complexes, as evidenced by partially purified preparations in which the LHI complex yields a peak at 866 nm and the LHII complex at 799 and 849 nm.

Aerobic, chemoorganotroph, and facultative photoheterotroph. The best growth substrates are L-glutamate, butyrate, and yeast extract; weak growth on minimal media containing acetate or D-glucose. No growth on pyruvate, citrate, malate, succinate, lactate, formate, D-fructose, methanol, or ethanol. Optimal temperature for growth 20–42°C. Capable of growth over a salinity range from 0% to 10% NaCl in RO medium with an optimum of 1–5%. The pH optimum is from 6.0 to 8.0. Exhibits oxidase, catalase, lipase, and amylase, but not gelatinase activities. No dissimilatory denitrification, or anaerobic growth in the presence of trimethylamine oxide (TMAO). Glucose is fermented to acid products without gas generation. Demonstrates a high level of resistance to tellurite (up to 2000 μg/ml in an acetate-glutamate minimal medium). Tellurite is reduced and transformed to metallic tellurium causing blackening of the culture. Resistant to penicillin and streptomycin; sensitive to chloramphenicol, fusidic acid, and polymixin B.

Habitat: the vicinity of nonbuoyant regions of plumes emitted from hydrothermal vents on the Juan de Fuca Ridge (northeastern Pacific Ocean).

The mol% G + C of the DNA is: 67.5 (HPLC).

Deposited strain: JF-1.

GenBank accession number (16S rRNA): Y16267.

Genus IV. **Erythrobacter** *Shiba and Simidu 1982, 215*[VP]

TSUNEO SHIBA AND JOHANNES F. IMHOFF

E.ryth' ro.bac.ter. Gr. adj. *erythros* red; M.L. masc. n. *bacter* rod; M.L. masc. n. *Erythrobacter* red rod.

Cells are ovoid to rod-shaped, 0.2–0.4 × 1.0–5.0 µm, multiply by binary fission, and are motile by means of polar or subpolar flagella. Gram negative and belong to the *Alphaproteobacteria*. Cell suspensions and colonies are orange or pink. **Bacteriochlorophyll *a*** is present. **The major respiratory quinone is ubiquinone-10.** The main cellular fatty acid is $C_{18:1}$.

Aerobic chemoorganoheterotrophic bacteria. Do not grow chemoautotrophically or under anoxic conditions in the light. Metabolism is predominantly respiratory. Under microoxic conditions, small amounts of acid are produced from carbohydrates. Oxidase and catalase positive. Tween 80 is hydrolyzed.

Mesophilic and neutrophilic bacteria from the marine environment. Optimum growth is at pH 7.0–8.0 and 25–30°C. Grow well at salt concentrations of 0.1–9.6%.

The mol% G + C of the DNA is: 57–67.

Type species: **Erythrobacter longus** Shiba and Simidu 1982, 216.

FURTHER DESCRIPTIVE INFORMATION

Erythrobacter belongs to the *Alphaproteobacteria*, together with *Porphyrobacter*, *Erythromicrobium*, "*Citromicrobium*," *Erythromonas*, *Sandaracinobacter*, *Sphingomonas*, and *Blastomonas*. Although *Erythrobacter* contains bacteriochlorophyll *a* (Bchl *a*), internal membrane systems are not present. The cellular level of Bchl is only around 2 nmol/mg of dry weight for *E. longus*, or 0.9–3.9 nmol/mg of protein for *E. litoralis*, and comparable to the level in heterotrophically grown cells of most purple nonsulfur bacteria (Harashima et al., 1978; Yurkov et al., 1994c). A reaction center–light-harvesting complex I (RC-LH I) is present, but not a light-harvesting complex II. In the near infrared region, the *in vivo* absorption spectrum of Bchl *a* reveals a minor maximum at 800–807 nm and a major one at 866–868 nm. *Erythrobacter* contains a large amount of polar carotenoids not included in the RC-LH l complex (Shimada et al., 1985) and not engaged in photosynthetic activities (Noguchi et al., 1992). Among about 20 different polar carotenoids, the most abundant are erythroxanthin sulfate and caloxanthin sulfate (Takaichi et al., 1991). The RC-LH I complex contains bacteriorubixanthinal, zeaxanthin, and hydroxyderivatives of β-carotene (Takaichi et al., 1988). Terminal oxidase in the respiratory system of *E. longus* is aa_3-type cytochrome oxidase (Fukumori et al., 1987).

The amine composition of *E. longus* is characteristic, in that only spermidine, but no appreciable amounts of putrescine, is found (Hamana et al., 1985). A high level of melatonin, *N*-acetyl-5-methoxytryptamine, which is known to offer protection against oxygen radicals, is found in *E. longus*. Cell homogenates of dark-grown, but not of light-grown, cells retain melatonin-producing enzyme activity (Tilden et al., 1997).

Erythrobacter grows as an aerobic chemoorganoheterotroph (Shiba and Simidu, 1982). Neither phototrophic growth nor light-dependent ATP synthesis are found, though an operative light-driven cyclic electron transfer system occurs (Harashima et al., 1982). The physiological function of Bchl *a* is not yet known. In contrast to anoxygenic phototrophic bacteria, Bchl synthesis is inhibited by light, but not suppressed at atmospheric oxygen tension (Harashima et al., 1980, 1987; Shiba, 1987). *E. litoralis* is quite resistant to tellurite (Yurkov et al., 1996).

E. litoralis was isolated from a cyanobacterial mat in a supralittoral zone of the North Sea, which is flooded approximately twice a month. Due to rainfall and evaporation induced by wind and sunlight, the salinity in the pore water may fluctuate greatly and reach high levels. Growth of *E. litoralis* at salt concentrations of 0.5–9.6% may reflect adaptation to these conditions (Yurkov et al., 1994c).

E. longus was isolated from the green seaweed *Enteromorpha linza* distributed in a high intertidal zone. This species can also grow in a wide salinity range of 0.1–7% (Sato et al., 1989; Shiba et al., 1991; Shiba, 1995).

ENRICHMENT AND ISOLATION PROCEDURES

Enrichment of *Erythrobacter* species has been achieved from marine beach sand, surface seawater, and several seaweeds. Samples were diluted 10-fold with seawater and spread on agar plates. The agar plates were incubated at 20°C. Characteristic pink or orange colonies were streaked out on further agar plates until pure cultures were obtained.

The culture medium used for *E. litoralis* contained per liter of distilled water: 1.0 g sodium acetate, 1.0 g yeast extract (Difco), 1.0 g Bacto Peptone (Difco), 15.0 g NaCl, 0.3 g KCl, 0.5 g of $MgSO_4 \cdot 7H_2O$, 0.05 g $CaCl_2 \cdot 2H_2O$, 0.3 g NH_4Cl, 0.3 g K_2HPO_4, 20 µg vitamin B_{12}, and 1 ml of a trace element solution (Drews, 1983). The pH is adjusted to 7.6–7.8.

For *E. longus*, the modified PPES-II medium (Shiba, 1989) was used, containing per liter: 2 g polypeptone (Nihon Pharmaceutical Co.), 1 g proteose–peptone (Difco no. 3), 1 g Bacto soytone (Difco), 1 g Bacto yeast extract (Difco), 0.1 g ferric citrate, 300 ml of distilled water, 700 ml artificial seawater (Lyman and Fleming, 1940), and 15 g agar.

MAINTENANCE PROCEDURES

Erythrobacter can be maintained at 20°C as stab cultures in media containing 0.4% agar (Difco). Cultures should be transferred monthly. Maintenance on agar slant cultures at room temperature is not recommended. The bacteria remain viable for 6 months when slant cultures are kept at −80°C. Cultures may also be preserved in liquid nitrogen or by lyophilization.

DIFFERENTIATION OF THE GENUS *ERYTHROBACTER* FROM OTHER GENERA

Erythrobacter differs from the genus *Sphingomonas* by the presence of Bchl *a* (Takeuchi et al., 1994). The color of cell suspensions and colonies of *Erythrobacter* is orange or pink, while those of *Sphingomonas* are yellow or white. The difference in colony color suggests differences in carotenoid composition. *Erythrobacter* also differs from the two genera in the presence of 3-hydroxy fatty acids (Urakami and Komagata, 1988; Takeuchi et al., 1993a).

Erythrobacter can be distinguished from *Erythromicrobium* by the composition of Bchl-protein complexes. *Erythrobacter* contains only a RC-LH I complex, while *Erythromicrobium* contains RC-LH I and LH II complexes. In addition to near infrared absorption maxima at 799 and 870 nm, *Erythromicrobium* has a maximum at 838 nm (Shimada et al., 1985; Yurkov et al., 1997).

Cell form and type of fission distinguish *Erythrobacter* from *Blastomonas*. *Erythrobacter* is rod shaped and reproduces by binary fission, while *Blastomonas* is ovoid and reproduces by budding. It does not contain 3-hydroxy fatty acids. *Erythrobacter* and *Sandaracinobacter* are distinguished by their color: colonies of *Erythro-*

bacter are orange or pink and show an *in vivo* absorption maximum at 470 nm, while those of *Sandaracinobacter* are yellow-orange and have maxima at 424, 450, and 474 nm (Shiba and Simidu, 1982; Yurkov et al., 1997).

Erythrobacter differ from *Porphyrobacter* in carotenoid composition. *Erythrobacter* contain erythroxanthin sulfate as a major polar carotenoid, while *Porphyrobacter* contain a carotenoid sulfate, the structure of which is not yet identified, but different from erythroxanthin sulfate. Zeaxanthin is a major non-polar carotenoid in *Erythrobacter*, whereas it is minor in *Porphyrobacter* (Takaichi et al., 1990 1991; Hanada et al., 1997). *Erythrobacter* species were isolated from marine environments and show a slight requirement for sodium ion, while *Porphyrobacter* species were isolated from terrestrial environments and do not have a requirement for sodium (Shiba and Simidu, 1982; Yurkov et al., 1994c). *Erythrobacter* are different from "*Citromicrobium*" in colony color and cell form. "*Citromicrobium*" is yellow-pigmented and pleomorphic.

Taxonomic Comments

The genus *Erythrobacter* contains two species. The strain OChll4, assigned to the genus *Erythrobacter*, was originally transferred to the genus *Roseobacter* as *Roseobacter denitrificans* (Shiba, 1991a). Based on 16S rDNA sequence analysis, *"Erythrobacter sibiricus"* has been removed from the genus (Yurkov and Gorlenko, 1990). After tentative assignment to the genus *Erythromicrobium*, this species is now included in a new genus as *Sandaracinobacter sibiricus* (Yurkov et al., 1997).

List of species of the genus Erythrobacter

1. **Erythrobacter longus** Shiba and Simidu 1982, 216^VP^
lon' gus. L. adj. *longus* long.

Cells are long rods, 0.3–0.4 × 1.0–5.0 µm, motile by means of subpolar flagella. The cells do not form internal membranes. Cell suspensions and colonies are orange, having *in vivo* absorption maxima at 807 (minor) and at 470 nm and 866–867 nm (major). Bacteriochlorophyll *a* esterified with phytol is present. Contain erythroxanthin sulfate and bacteriorubixanthinal as major carotenoids. Main cellular fatty acid is $C_{18:1}$. $C_{15:0\ 2OH}$ and $C_{14:0\ 2OH}$ are present.

Aerobic, chemoorganoheterotrophic, predominantly respiratory metabolism. Utilize glucose, acetate, pyruvate, glutamate, and butyrate as sole carbon sources. Methanol is not utilized. Some strains reduce nitrate to nitrite. Oxidase, catalase, and phosphatase positive. The Voges–Proskauer and methyl-red tests are negative. H_2S is not produced. Indole is produced. Tween 80 and gelatin are hydrolyzed. Some strains hydrolyze alginate. Biotin is required as growth factor.

Mesophilic and neutrophilic bacterium with optimal growth at pH 7.0–8.0 and 25–30°C. Good growth at salt concentrations of 0.1–7.0%.

Habitat: oxic marine environments, especially on seaweeds.

The mol% G + C of the DNA is: 57 (HPLC).

Type strain: OCh101, ATCC 33941, DSM 6997, IFO 14126.

GenBank accession number (16S rRNA): L01786, M96744, M59062.

2. **Erythrobacter litoralis** Yurkov, Stackebrandt, Holmes, Fuerst, Hugenholtz, Golecki, Gad' on, Gorlenko, Kompantseva and Drews 1994c, 432^VP^
li.to.ra' lis. L. gen. n. *litoris* of the seashore; M.L. masc. adj. *litoralis* belonging or pertaining to the seashore.

Cells are rod shaped, 0.2–0.3 × 1.0–1.3 µm, motile by means of polar or subpolar flagella. Short chains of up to five cells may occur. Internal membranes are not formed. Color of cell suspensions and colonies is pink or orange, but become red or brown in older cultures. Near-infrared absorption maxima are at 800 and 868 nm. Bchl *a* is present. The main carotenoids are bacteriorubixanthinal and erythroxanthin sulfate.

Aerobic chemoorganoheterotrophic metabolism. Growth occurs on glucose, fructose, butyrate, glutamate, acetate, and lactate, and weak growth on succinate. Methanol is not utilized. Nitrate is not reduced. Tween 80 is hydrolyzed; gelatin and starch are not. Catalase and oxidase positive. Susceptible to chloramphenicol, tetracycline, and fusidic acid. Resistant to penicillin, streptomycin, and polymyxin B.

Mesophilic and neutrophilic bacterium with optimal growth at pH 7.0–8.0 and 25–30°C. Good growth at salt concentrations of 0.5–9.6%.

Habitat: marine cyanobacterial mat in supralittoral zones.

The mol% G + C of the DNA is: 67 (T_m).

Type strain: T4, DSM 8509, IAM 14332.

GenBank accession number (16S rRNA): ABO13354.

Genus V. Erythromicrobium *Yurkov, Stackebrandt, Holmes, Fuerst, Hugenholtz, Golecki, Gad'on, Gorlenko, Kompantseva and Drews 1994c, 432^VP^*

Vladimir V. Yurkov

E.ry' thro.mi.cro' bi.um. Gr. adj. *erythrus* red; Gr. adj. *micros* small; Gr. n. *bios* life; M.L. n. *Erythromicrobium* red microbe.

Pleomorphic bacteria, **Gram negative**, and usually motile by means of flagella. Divide by binary or ternary fission. **Real branching may occur.** Colonies are red-orange. Cells **contain bacteriochlorophyll *a* and carotenoids**.

Aerobic. Cultures do not grow anaerobically in the light and do not grow chemoautotrophically. Ribulose diphosphate carboxylase is not detected. No fermentation and no denitrification activities occur.

The mol% G + C of the DNA is: 62.5–68.5.

Type species: **Erythromicrobium ramosum** Yurkov, Stackebrandt, Holmes, Fuerst, Hugenholtz, Golecki, Gad' on, Gorlenko, Kompantseva and Drews 1994c, 432.

Further descriptive information

Phylogenetically, the genus *Erythromicrobium* is associated with members of the *Alphaproteobacteria* and is closely related to *Ery-*

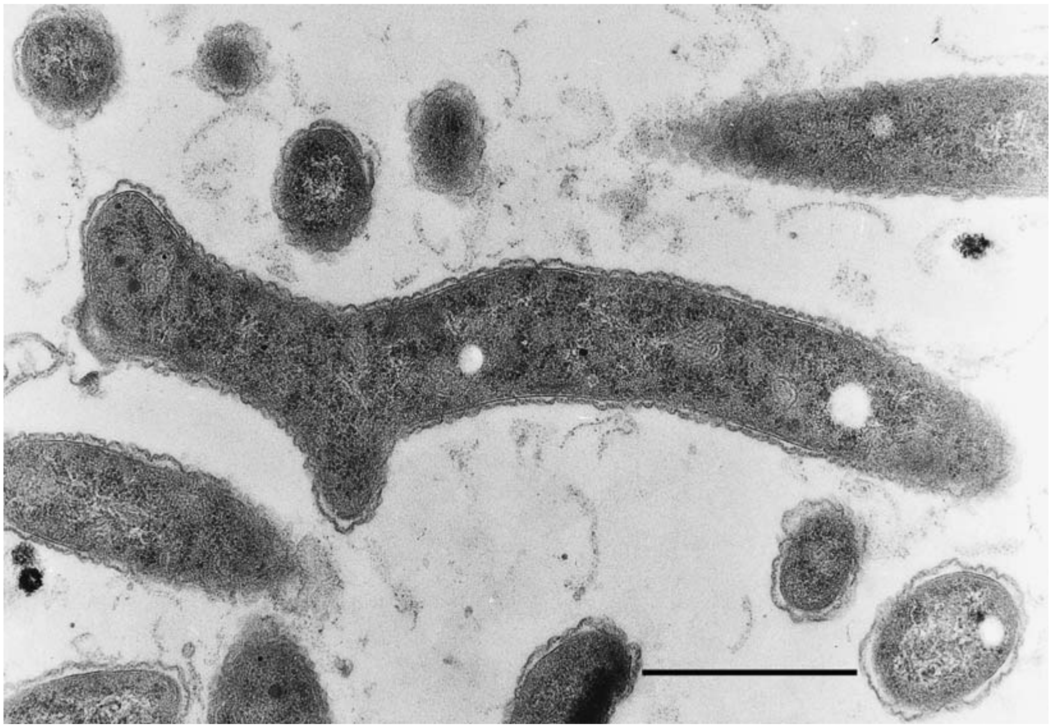

FIGURE BXII.α.101. *Erythromicrobium ramosum.* Ramifying thread-like cell showing true branching. Electron micrograph, ultrathin section. Bar = 0.5 μm. (Printed with permission from V. Yurkov.)

throbacter (level of 16S rDNA sequence similarity, 98%) (Yurkov et al., 1994c). The genera *Erythromicrobium*, *Erythrobacter*, and *Porphyrobacter* form a phylogenetic cluster in the *Alphaproteobacteria*. The genus *Sphingomonas* was shown to be the most closely related nonphotosynthetic genus within the *Alphaproteobacteria* (Yurkov et al., 1994c).

Three described species of *Erythromicrobium*—*E. ramosum*, *"E. ezovicum"*, and *"E. hydrolyticum"*—are very long rods and produce characteristic thread-like cells, dividing by symmetric or asymmetric constriction. For *E. ramosum* and *"E. hydrolyticum"* ternary fission and branching were demonstrated (Fig. BXII.α.101) (Yurkov and Gorlenko, 1992).

All *Erythromicrobium* species synthesize a large amount of carotenoid pigments that determine the color of the organism. *E. ramosum* was shown to produce at least 10 different kinds of carotenoids (Yurkov et al., 1993). The two predominant carotenoids, the orange erythroxanthin sulfate and the red bacteriorubixanthinal, are very polar. The *in vivo* absorption spectra of *"E. ezovicum"*, *"E. hydrolyticum"*, and *E. ramosum* all have major carotenoid peaks at 466 and 478 nm, indicating a similar carotenoid composition. The carotenoids impact an intense color in liquid cultures, red-orange (Yurkov et al., 1997).

The photosynthetic apparatus of *Erythromicrobium* contains a reaction center and two types of antenna complexes, LHI and LHII. Reaction centers do not possess reaction center-bound cytochrome *c*, and the photooxidized special pair (P^+) of the reaction center is directly reduced by a soluble cytochrome *c* (Yurkov et al., 1995, 1998a). LHI with absorption maximum at 871 nm is similar to that measured in many anaerobic phototrophic and other aerobic phototrophic bacteria. Isolated LHII showed bacteriochlorophyll absorption maxima at 798–800 and 832–833 nm, indicating the presence of new types of LHII in *Erythromicrobium* cells. The long-wavelength band of LHII at 832–833 nm is about 20 nm less than that usually observed in purple bacteria (Yurkov et al., 1997). Although it has some peculiarities, the photosynthetic apparatus of *Erythromicrobium* is functional in terms of a cyclic electron transfer system. The photoinduced cyclic electron transfer occurs only under relatively oxidized (aerobic) conditions, as elucidated by light-induced absorbance changes in intact cells. Under anaerobic conditions, no light-induced reaction center absorbance changes were observed. The lack of photochemistry under anaerobic conditions is consistent with the inability of these bacteria to grow by light-dependent photophosphorylation in the absence of oxygen (Yurkov et al., 1995, 1998a).

Erythromicrobium species possess ubiquinone Q-10 as the major quinone. No menaquinones or rhodoquinones have been detected. The ubiquinone Q-9 was detected as a minor quinone in addition to Q-10 in *E. ramosum*, *"E. ezovicum"*, and *"E. hydrolyticum"*. The quinone Q-10 of *"E. hydrolyticum"* and *E. ramosum* seems to exist as a methylated form (Gogotov and Gorlenko, 1995).

The genus *Erythromicrobium* demonstrated high-level resistance to tellurite and accumulation of metallic tellurium crystals due to tellurite reduction (Fig. BXII.α.102) (Yurkov et al., 1996). Tellurite resistance and tellurium accumulation depend on medium composition, particularly on organic carbon source (Table BXII.α.93).

The major determinative characteristics of the genus *Erythromicrobium* are summarized in Table BXII.α.94.

Enrichment and Isolation Procedures

Erythromicrobium species have been isolated from the samples of freshwater cyanobacterial mats that developed in alkaline warm springs (pH 9.5, 25°C) of the Bol' shaya River valley (Baykal Lake region in Russia). It was isolated by direct inoculation of a ho-

mogenized mat sample with dilutions on agar plates of rich organic (RO) medium (Yurkov et al., 1994c) containing (g/l): yeast extract, 1.0; Bacto peptone, 1.0; sodium acetate, 1.0; KCl, 0.3; $MgSO_4 \cdot 7H_2O$, 0.5; $CaCl \cdot 2H_2O$, 0.05; NH_4Cl, 0.3; K_2HPO_4, 0.3. The medium was supplemented with 20 mg/l of vitamin B_{12} and 1.0 ml/l of a trace element solution (Drews, 1983). The plates were cultivated in the dark at 30°C and pH 7.6–7.8. Characteristic red-orange colonies are streaked out on agar plates by the usual aerobic techniques. When a pure culture is obtained, a single colony is transferred into liquid RO medium and cultivated in an Erlenmeyer flask aerobically in the dark.

Maintenance Procedures

Erythromicrobium liquid cultures (taken from late logarithmic growth phase) and agar surface cultures remained viable after storage at 4°C for at least 2 months. Long-term preservation of *Erythromicrobium* species is possible by storage in liquid nitrogen or freezing at −70°C. For this purpose, heavy cell suspensions of liquid cultures (mid-logarithmic growth phase) are supplemented with glycerol (final concentration, 30%) as a protective agent. These cell suspensions are filled into 2-ml plastic screwcap tubes and freeze-stored. Lyophilization can also be used as a method for *Erythromicrobium* preservation.

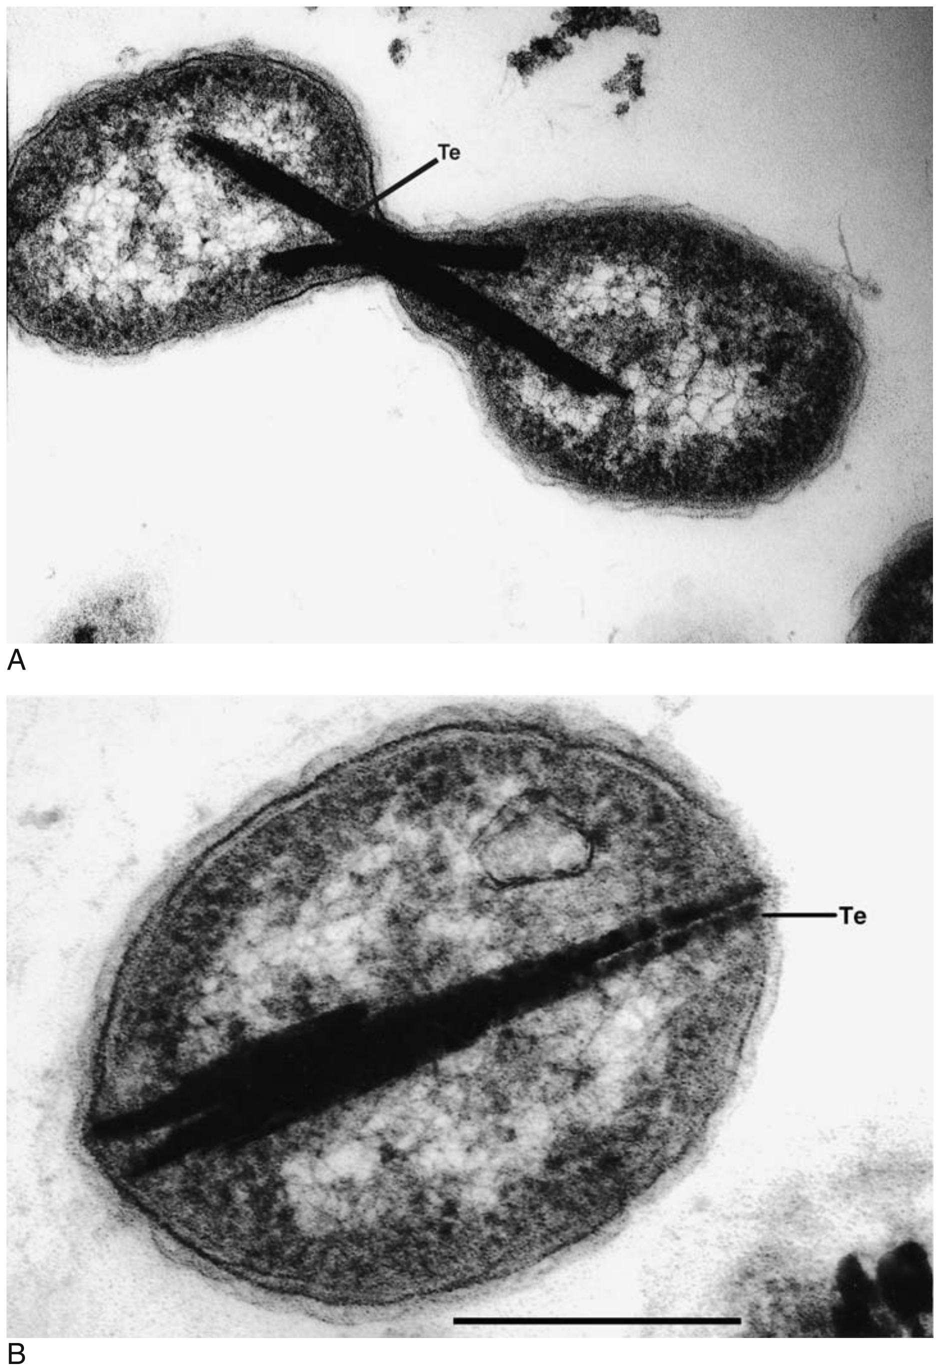

FIGURE BXII.α.102. Intracellular localization of accumulated tellurium (*Te*; indicated by *arrows*) by *Erythromicrobium ramosum.* (Printed with permission from V. Differentiation of the genus *Erythromicrobium* from other genera

Species of the genus *Erythromicrobium* are freshwater bacteria inhabiting cyanobacterial mats of warm springs. The cells of certain representatives exhibit morphological pleomorphism and the ability to divide by ternary fission because of real branching of the cells. *E. ramosum*, *"E. ezovicum"*, and *"E. hydrolyticum"* are very long rods that often produce characteristic thread-like cells (Figs. BXII.α.101 and BXII.α.103B). The specific carotenoid composition determines the major carotenoid absorption peaks of the intact cell absorption spectra at 466 and 478 nm, apparent as an intense red-orange color in liquid cultures (Yurkov et al., 1997). The photosynthetic apparatus of all *Erythromicrobium* species described so far is unique. In addition to the reaction center and light-harvesting complex I, it contains a new type of light-harvesting complex II, with absorption maxima at 798–800 nm and 832–833 nm. The presence of this light-harvesting complex II in *Erythromicrobium* distinguishes its *in vivo* absorption characteristics from the absorption spectra of other aerobic and anaerobic anoxygenic phototrophic genera.

Taxonomic Comments

The genus *Erythromicrobium* was introduced by Yurkov et al. (1992a) as a genus of freshwater obligately aerobic, facultatively photoheterotrophic bacteria that included five species: *E. ramosum*, *"E. ezovicum"*, *"E. hydrolyticum"*, *"E. sibiricum"*, and *"E. ursincola"*. The genus was validly published in 1994 with *E. ramosum* as the type strain (Yurkov et al., 1994c). In 1997, the genus *Erythromicrobium* was taxonomically reorganized, resulting in the exclusion of *"E. sibiricum"* and *"E. ursincola"* from the genus transfer to two new genera, *Sandaracinobacter* and *Erythromonas*, respectively (Yurkov et al., 1997).

Differentiation of the species of the genus *Erythromicrobium*

Although they resemble each other physiologically and morphologically, *Erythromicrobium* species have some distinguishing features (Table BXII.α.94). All described species differing from each other by the mol% DNA G + C content and lower levels of DNA similarity, determined using DNA–DNA hybridization (Yurkov et al., 1991a). *"E. hydrolyticum"* demonstrates specifically high hy-

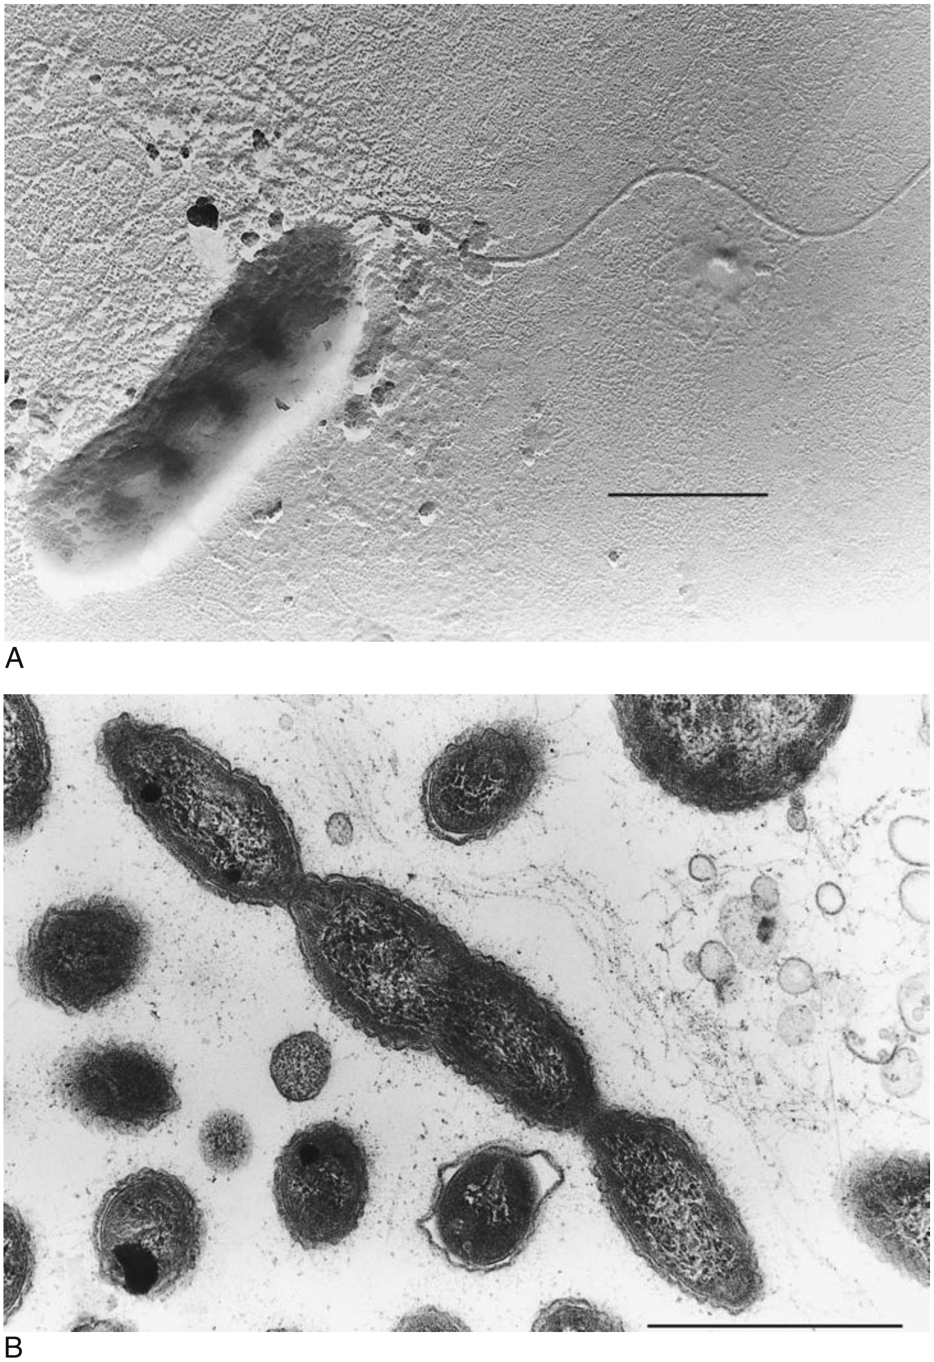

FIGURE BXII.α.103. *"Erythromicrobium ezovicum"*. Electron micrographs. (Printed with permission from V. Yurkov.) *A*, Scanning micrograph showing polar flagellum. *B*, Long thread-like formation of cells. Bars = 1.0 μm.

drolytic activities utilizing starch, gelatin, and Tween-80 as sole carbon sources. This species can oxidize thiosulfate to tetrathionate in aerobic energy metabolism as an addition to using organic energy sources. Representatives of *Erythromicrobium* are resistant to the toxic heavy metal oxide tellurite, reduce tellurite to tellurium, and accumulate metallic tellurium crystals inside the cells (Yurkov et al., 1996). However, the MIC (minimal inhibitory concentration) level of tellurite is species specific (Table BXII.α.93).

List of species of the genus Erythromicrobium

1. **Erythromicrobium ramosum** Yurkov, Stackebrandt, Holmes, Fuerst, Hugenholtz, Golecki, Gad'on, Gorlenko, Kompantseva and Drews 1994c, 432[VP]

ra.mo'sum. L. adj. *ramosum* ramifying, referring to the morphology of the cells.

Gram-negative, red-orange rods that are 0.6–1.0 × 1.3–

2.5 μm. Cells may branch (Fig. BXII.α.101). Multiplication occurs by binary or ternary fission. Motile by means of polar flagella. Bacteriochlorophyll *a* and carotenoids are present. The cytoplasmic membrane contains a reaction center and two light-harvesting complexes, LHI with an absorption maximum at 870 nm and unusual "blue shifted" LHII with absorption maxima at 798 and 832 nm. The major carotenoids are the very polar compound erythroxanthin sulfate and bacteriorubixanthinal. Optimal growth occurs at temperatures between 25 and 30°C and at pH values between 7.0 and 8.5.

The optimal substrates for growth are glucose, sucrose, maltose, acetate, pyruvate, butyrate, malate, succinate, fumarate, propionate, glutamate, casein hydrolysate, and yeast extract. Growth also occurs on fructose, citrate, lactate, tartrate, and ethanol. No growth occurs on ribose, arabinose, formate, benzoate, mannitol, glycerol, and glycolate. Methanol is not utilized. Starch, gelatin, and Tween-80 are not hydrolyzed. Oxidase and catalase positive. The tricarboxylic acid cycle operates. The glyoxylate shunt has been observed in strain E4(2), but not in strain E5.

Susceptible to the following antibiotics: tetracycline, polymyxin B, erythromycin, nalidixic acid, amikacin, gentamicin, nystatin, bacitracin, kanamycin, neomycin, aureomycin, vancomycin, novobiocin, chloramphenicol, and fusidic acid. Resistant to penicillin, ampicillin, streptomycin, and nystatin. The storage compounds are polysaccharides, poly-β-hydroxybutyric acid, and polyphosphates.

Resistant to heavy metal oxide tellurite. Reduction of tellurite results in the accumulation of elemental tellurium inside cells. Tellurite resistance and reduction depend on supplemented organic carbon source (Fig. BXII.α.102; Table BXII.α.93).

Habitat: cyanobacterial mat from an alkaline spring (pH 9.5; 25°C).

The mol% G + C of the DNA is: 64.2 (T_m).

Type strain: E5, ATCC 700003, CIP 106927, DSM 8510, JCM 10282.

GenBank accession number (16S rRNA): AB013355 and X72909.

2. **"Erythromicrobium ezovicum"** Yurkov and Gorlenko 1992, 248.

e.zo′vi.cum. M.L. adj. *ezovicum* referring to the Russian river name Ezovca, site of isolation.

Gram-negative, red-orange colored rods, 0.6–0.8 × 2.7–2.8 μm. Divide by symmetric or asymmetric constrictions. Nonbranching thread-like cells are characteristic. Motile by means of a polar flagellum (Fig. BXII.α.103). Cells produce bacteriochlorophyll *a* and carotenoids. *In vivo* absorption spectrum of bacteriochlorophyll *a* has maxima at 868 (light-harvesting complex I) and 798 nm, and a shoulder at 836 nm (light-harvesting complex II). Carotenoid acetone extracts have two peaks, at 466 and 478 nm.

Aerobic, chemoorganotrophic, facultative photoorganotrophic. No growth in the light under anaerobic conditions. Fermentation and denitrification activities not observed. The optimal temperature and pH are 25–30°C and 7.0–8.0, respectively.

Best growth in media containing glucose, sucrose, maltose, malate, succinate, casein hydrolyzate, and yeast extract. Good growth obtained on fructose, acetate, butyrate, citrate, lactate, fumarate, propionate, tartrate, ethanol, and glutamate. Ribose, arabinose, pyruvate, formate, benzoate, methanol, mannitol, glycerol, and glycolate are not utilized. Gelatin, starch, and Tween-80 are not hydrolyzed.

A closed tricarboxylic acid cycle and the glyoxalate shunt operate. Oxidase and catalase positive.

Sensitive to the following antibiotics: tetracycline, polymixin-B, amikacin, gentamicin, bacitracin, kanamycin, neomycin, aureomycin, vancomycin, chloramphenicol, and fusidic acid. Resistant to penicillin, ampicillin, streptomycin, erythromycin, nalidixic acid, lincomycin, mycostatin, and novobiocin.

High-level resistance to tellurite was established. However, unlike other species of *Erythromicrobium*, tellurite resistance of *"E. ezovicum"* is not always correlated with tellurite reduction to metallic tellurium (Table BXII.α.93). Other mechanisms, such as continuous tellurite efflux or tellurite complexing or methylation may play an important role in the resistance character. Tellurite is biotransformed to tellurium in glutamate-, succinate-, or malate-containing media (Yurkov et al., 1996).

Habitat: freshwater cyanobacterial mat that developed in alkaline spring (20–25°C; pH 9.5).

The mol% G + C of the DNA is: 62.5 (T_m).

Deposited strain: E-1.

3. **"Erythromicrobium hydrolyticum"** Yurkov and Gorlenko 1992, 249.

hyd.ro.ly′ti.cum. L. adj. *hydrolyticum* splitting water.

Gram-negative, red-orange rods 0.7–1.1 × 1.8–2.5 μm or more. Cells may branch. Multiply by binary or ternary fission. Motility not observed. Cells contain bacteriochlorophyll *a* and carotenoids. Bacteriochlorophyll *a* in intact cells has major peak at 868 nm (indicating the presence of light-harvesting complex I), a minor peak at 798 nm, and a shoulder at 836 nm (indicating the presence of "blue shifted" light-harvesting complex II). Carotenoid acetone extracts have peaks at 466 and 478 nm.

Aerobic, chemoorganotrophic, facultative photoorganotrophic. Thiosulfate may be utilized as an additional source of energy, being oxidized to tetrathionate. Anaerobic growth in the light does not occur. Fermentation and denitrification activities are not detected. Favorable growth temperature, 25–30°C. Optimal pH, 7.0–8.0.

Best growth occurs in the presence of glucose, maltose, pyruvate, malate, succinate, fumarate, casein hydrolyzate, and yeast extract. Fructose, acetate, citrate, tartrate, and ethanol support a good growth. Lactate supports weak growth. Ribose, arabinose, butyrate, formate, propionate, benzoate, methanol, mannitol, glycerol, and glycollate cannot be used as organic carbon sources. Starch, gelatin, and Tween 80 are hydrolyzed.

Tellurite resistant. Transform tellurite to metallic tellurium (Table BXII.α.93).

The closed tricarboxylic acid cycle and the glyoxalate shunt operate. Oxidase and catalase positive. Storage compounds: polysaccharides and polyphosphates.

Habitat: cyanobacterial mat from an alkaline spring (20–25°C; pH 9.5).

The mol% G + C of the DNA is: 65.2 (T_m).

Deposited strain: E4(1).

Genus VI. **Erythromonas*** *Yurkov, Stackebrandt, Buss, Vermeglio, Gorlenko and Beatty 1997, 1177*^{VP}

Vladimir V. Yurkov

E.ry.thro.mo′ nas. Gr. adj. *erythrus* red; Gr. n. *monas* a unit, monad; M.L. fem. n. *Erythromonas* red monad.

Ovoid, **Gram negative**, motile by means of polarly flagellated cells. Do not form chains. Reproduce by **budding** or asymmetric division. The cells are **orange-brown due to carotenoid pigments**. **Contain bacteriochlorophyll *a*. Aerobic, chemoorganotrophic, and facultatively photoheterotrophic. No photosynthetic growth occurs under anaerobic conditions.** NaCl is not required for growth.

The mol% G + C of the DNA is: 65.4.

Type species: **Erythromonas ursincola** Yurkov, Stackebrandt, Buss, Vermeglio, Gorlenko and Beatty 1997, 1177.

Further descriptive information

The monospecific genus *E. ursincola* is phylogenetically related to members of the *Alphaproteobacteria* that form a separate subline on the evolutionary tree of *Sphingomonas* with a 16S rDNA homology of 92.5% (Yurkov et al., 1997).

E. ursincola cells are ovoid (0.8–1.0 × 1.3–2.6 µm) and reproduce by budding or asymmetric division. The carotenoid composition of the species, apparent as absorption peaks at 430, 458, and 485 nm of the intact cell absorption spectra, produces the characteristic orange-brown color of *E. ursincola.* Bacteriochlorophyll *a* (BChl *a*) is incorporated into the photosynthetic apparatus that is organized in the reaction center with tightly bound tetraheme cytochrome *c* and light-harvesting complex I absorbing at 867 nm. Under anaerobic conditions, no light-induced absorbance changes can be observed in the photosynthetic apparatus of *E. ursincola.* In contrast, when cells were grown aerobically, typical photochemical reactions were revealed confirming aerobic photosynthetic functionality of the reaction center (Yurkov et al., 1995, 1998a).

E. ursincola has a complex soluble (three cytochromes *c* of 6.5, 9.0, and 14.0 kDa) and membrane-bound (four cytochromes *c* of 14.3, 21.0, 24.0, and 40.0 kDa) cytochrome population (Yurkov et al., 1997). Interestingly, *E. ursincola* contains an unusually small soluble cytochrome *c* of 6.5 kDa. Such a small cytochrome *c* is rare in bacteria and is present in *Hydrogenobacter thermophilus* (6.0 kDa), *Methylomonas* strain A4 (4.0 kDa), and an aerobic phototrophic species, *Roseococcus thiosulfatophilus* (4.0 and 6.5 kDa). The quinone composition of *E. ursincola* is represented by the only quinone Q-10 (Gogotov and Gorlenko, 1995).

Similarly to other aerobic phototrophic bacteria, *E. ursincola* is highly resistant to tellurite and reduces this compound to tellurium apparent as intracellular crystals. However, the minimal inhibitory concentration of tellurite (2700 µg/ml) for *E. ursincola* in acetate medium is significantly higher than that found in other species (Yurkov et al., 1996).

Enrichment and Isolation Procedures

Strain KR99 designated as *E. ursincola* was isolated from samples of a cyanobacterial mat that developed in freshwater thermal springs (pH 6.7–7.0 and temperature, 34–40°C). The Neskuchninskii spring is situated on Kunashir Island (Southern Kurily, Russia). The techniques used to isolate and cultivate *E. ursincola* are similar to those described for *Erythromicrobium.*

Maintenance Procedures

Erythromonas can be preserved by standard procedures in liquid nitrogen, by freezing at −70 to −80°C or by lyophilization.

Differentiation of the genus *Erythromonas* from other genera

The genus *Erythromonas* is separated from other genera of the aerobic anoxygenic phototrophic bacteria by its distinguishing morphological, physiological, as well as genetic properties. Its comparatively large cell size, ovoid form, budding, and characteristic absorption spectrum of the intact cells are distinctive phenotypic properties.

The major morphological and physiological differences between *Erythromonas* and its most closely related genera of freshwater aerobic phototrophic genera are shown in Table BXII.α.95.

Taxonomic Comments

Newly isolated in 1991, strain KR99 was initially assigned to the genus *Erythromicrobium* under the species name *"E. ursincola"* (Yurkov et al., 1991a). However, detailed phylogenetic investigation of 16S rDNA sequences and precise chemotaxonomic research performed on this bacterium later clearly revealed that a new genus named *Erythromonas* with *E. ursincola* as a type species should be created (Yurkov et al., 1997).

Phylogenetic comparisons of 16S rDNA sequences determined that *E. ursincola* clusters with *Blastomonas natatoria* (99.8% sequence identity) (Yurkov et al., 1997). However, significant phenotypic and physiological differences exist between *E. ursincola* and *B. natatoria* that preclude their assignment to the same genus. *B. natatoria* is a nonphotosynthetic species containing carotenoid pigments and lacking bacteriochlorophyll, whereas *E. ursincola* is physiologically related to obligately aerobic anoxygenic phototrophic bacteria producing carotenoids and BChl *a*. *E. ursincola* contains BChl *a* incorporated into a photochemically active reaction center and light-harvesting complexes, and contains specific electron transfer carriers of a cyclic photosynthetic pathway (such as cytochrome *c* bound to the reaction center, soluble cytochrome c_2, the reaction center Q_A primary electron acceptor, and the "special pair" P of the reaction center). High 16S rDNA sequence similarity between these two species indicates a close phylogenetic relationship and that they share a common ancestor; conceivably one is an evolutionary progenitor of the other. However, due to the occurrence of significant physiological differences (photosynthesis is a restricted mode of energy generation), they are not designated as members of the same genus for taxonomic purposes.

List of species of the genus Erythromonas

1. **Erythromonas ursincola** Yurkov, Stackebrandt, Buss, Vermeglio, Gorlenko and Beatty 1997, 1177[VP]
ur.sin' co.la. M.L. adj. *ursincola* neighbor or compatriot of bears.

Cells are Gram-negative and ovoid 0.8–1.0 × 1.3–2.6 μm. Long chains are not formed. Reproduce by budding or asymmetric division. Cells motile by means of a unique polar flagellum. Cells contain BChl *a* and carotenoid pigments. Carotenoids have three main absorption peaks at 430, 458, 485 nm *in vivo*, and in combination with BChl *a*, determine the culture color: orange in young culture and dark orange-brown in older liquid or young agar cultures. BChl *a* is present in membrane-bound, protein-pigment complexes, consisting of the reaction center with absorption peaks at 751, 801, and 853 nm and core light-harvesting complex I absorbing at 867 nm. Reaction center contains tightly bound tetraheme cytochrome *c* with a molecular weight of 40.0 kDa. Total cytochrome *c* composition of cells growing in the dark is very abundant and represented by soluble cytochrome *c* of 6.5, 9.0, and 14.0 kDa, and membrane-bound cytochrome *c* of 14.3, 21.0, and 24.0 kDa. In cells growing in the dark, only quinone Q-10 was determined.

Aerobic, chemoorganotrophic, facultatively photoorganoheterotrophic. Best growth is on media containing glucose, fructose, sucrose, maltose, acetate, glutamate, propionate, casein hydrolyzate, or yeast extract. Good growth on pyruvate, butyrate, malate, or succinate. Poor growth on media supplemented with arabinose, citrate, lactate, glycerol or mannitol. No growth detected in media containing ribose, formate, benzoate, tartrate, methanol, ethanol, or glycolate. The tricarboxylic acid cycle and glyoxylate shunt operate during growth on acetate containing medium. The key enzyme of the Calvin cycle, ribulose diphosphate carboxylase, is not found. No anaerobic growth in the light, fermentation, or denitrification is found.

Optimal growth temperature is 25–30°C. Freshwater organism, does not require NaCl for growth. Optimal pH is 7.0–8.0. Yeast extract and vitamin B_{12} satisfy the requirement for growth factors. Oxidase and catalase positive. Tween 80 is hydrolyzed. Lipase activity of 64.9 U/g of biomass. Starch and gelatin are not hydrolyzed. Sensitive to tetracycline, polymyxin B, amikacin, gentamicin, neomycin, aureomycin, vancomycin, novobiocin, chloramphenicol, and fusidic acid. Resistant to penicillin, ampicillin, streptomycin, erythromycin, nalidixic acid, lincomycin, mycostatin, bacitracin, and kanamycin. Very resistant to tellurite. Can grow in the presence of tellurite up to 2700 μg/ml in acetate-containing minimal medium. Resistance to tellurite depends on organic carbon source in the medium. Tellurite can be reduced and transformed into metallic tellurium, which is accumulated as metal crystals in the cell cytoplasm.

Storage compounds: polyphosphates.

Habitat: freshwater cyanobacterial mat developing in the thermal springs at pH 6.7–7.0 and temperature 34–40°C.

The mol% G + C of the DNA is: 65.4 (T_m).

Type strain: KR-99, EY 4250, CIP 106843, DSM 9006, JCM 10397.

GenBank accession number (16S rRNA): Y10677, AB024289.

Genus VII. **Porphyrobacter** *Fuerst, Hawkins, Holms, Sly, Moore and Stackebrandt 1993, 132[VP]*

Akira Hiraishi and Johannes F. Imhoff

Por.phy.ro.bac' ter. Gr. adj. *porphyreos* purple; M.L. masc. n. *bacter* equivalent of Gr. neut. n. *bacterion* a rod; M.L. masc. n. *Porphyrobacter* porphyrin-producing rod.

Cells are straight, pleomorphic, ovoid-to-short rods, or cocci, 0.5–1.0 × 0.8–2.0 μm. Spores and capsules are not formed. Multiply by budding or binary fission. Gram negative. Members of the *Alphaproteobacteria*. Motile or nonmotile. Do not form any type of internal membranes. **Synthesize bacteriochlorophyll *a* esterified with phytol and carotenoids** as photosynthetic pigments only under aerobic conditions in the dark.

Strictly aerobic, chemoorganoheterotrophic bacteria containing bacteriochlorophyll. Do not grow phototrophically under anoxic conditions in the light. Simple organic compounds, peptone, and yeast extract used as electron donors and carbon sources. Produce acid but not gas from glucose. Catalase positive and oxidase negative. Some strains may require vitamins for growth.

Mesophilic to moderately thermophilic, neutrophilic freshwater bacteria.

Straight-chain octadecenoic acid ($C_{18:1}$) is the major cellular fatty acid. 2-Hydroxy fatty acids and sphingoglycolipids are present. 3-Hydroxy fatty acids are absent. Ubiquinone-10 is the major quinone.

The mol% G + C of the DNA is: 65.0–66.4.

Type species: **Porphyrobacter neustonensis** Fuerst, Hawkins, Holms, Sly, Moore and Stackebrandt 1993, 132.

Further descriptive information

Based on 16S rDNA sequence analysis, *Porphyrobacter* species belong to the *Alphaproteobacteria*, with *Erythrobacter* and *Erythromicrobium* species as phylogenetic neighbors. The nearest phylogenetic neighbor is *Erythromicrobium ramosum*, with 98% 16S rDNA sequence identity to *Porphyrobacter neustonensis*.

Cell morphology of *Porphyrobacter* varies depending upon the species. The type species, *P. neustonensis*, contains rod-shaped and pleomorphic cells and in some cases exhibits coccoid forms (Fig. BXII.α.104). The cells reproduce by polar growth and budding, and this mode of cell division is similar to a division type found in *Planctomycetales*, in which the daughter cell appears as a small spherical bud. Cells produce multifibrillar stalk-like fascicle structures and crateriform structures on the cell surface. Cells of *P. neustonensis* are motile by means of subpolar or peritrichous flagella (Fig. BXII.α.105). Cells of *P. tepidarius* are ovoid-to-short rods, nonmotile, and multiply by binary fission (Fig. BXII.α.106). Thin-section electron microscopy shows that *Porphyrobacter* species do not contain internal membranes (Fig. BXII.α.107). Thin-sections of *P. neustonensis* indicated the presence of an electron-dense cell wall layer in the mother cell but the absence of such a layer in the bud (Fig. BXII.α.108). Analyses of crude cell wall material of *P. neustonensis* showed that muramic acid and diaminopimelic acid were present in the cell wall (Fuerst et al., 1993).

A group of highly polar carotenoids, including carotenoid sulfates and bacteriorubixanthin, are major components (Hanada et al., 1997). Nostaxanthin is also present in *P. tepidarius*. Unlike *Erythromicrobium* and *Erythrobacter* species, *Porphyrobacter* species lack zeaxanthin. Absorption spectra of living cells or membrane preparations have a low absorption maximum at

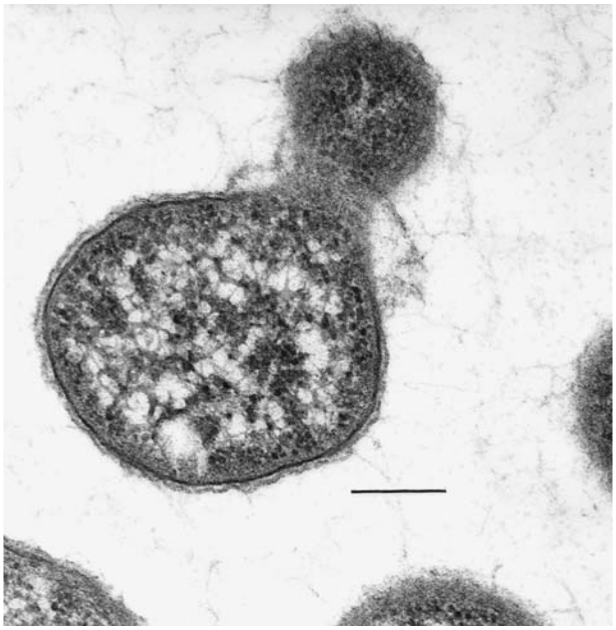

FIGURE BXII.α.108. Thin-section electron photomicrograph showing the ultrastructure of *Porphyrobacter neustonensis*. Bar = 0.2 μm. (Reproduced with permission from J.A. Fuerst et al., International Journal of Systematic Bacteriology, *43:* 125–134, 1993 ©International Union of Microbiological Societies.)

around 800 nm and a high absorption maximum at 868–871 nm. These spectral patterns in the near-infrared region indicate that the cells contain the core light-harvesting (LH) complex (B870), together with the photosynthetic reaction center, and lack the peripheral light-harvesting complex LHII, as is the case in other aerobic bacteriochlorophyll-containing bacteria of the *Alphaproteobacteria*.

Like many other aerobic photosynthetic bacteria, *Porphyrobacter* produces BChl *a* only under aerobic growth conditions in darkness. The amount of BChl *a* produced by *P. neustonensis* ACM 2844 is maximal in gently stirred dark broth cultures (J.A. Fuerst, personal communication). Standing broth cultures produce 0.08 ± 0.05 nmol/mg dry wt of BChl *a*, whereas stirred cultures produce 1.04 ± 0.09 nmol/mg dry wt and shaken cultures 0.65 ± 0.10 nmol/mg dry wt. The maximum BChl *a* content of *P. neustonensis* is somewhat lower than, or comparable to, the BChl *a* content reported for the phylogenetic neighbor *Erythrobacter longus* (Harashima et al., 1982). Due to the presence of carotenoids, liquid cultures and colonies on agar media are orange to red. The intensity of pigmentation depends upon the growth medium. For *P. neustonensis*, casitone–yeast extract agar is best for pigment production (Fuerst et al., 1993).

Porphyrobacter species are aerobic chemoheterotrophic bacteria that grow well under aerobic dark conditions but not anaerobically in the light. They do not grow by anaerobic respiration with nitrate, dimethyl sulfoxide, or trimethylamine *N*-oxide as the terminal electron acceptor. Most strains exhibit a doubling time of 2–4 h under optimal growth conditions. Simple organic compounds such as glucose are used as electron donors and carbon sources for growth. Peptone and yeast extract are also good substrates. Hydrolytic activities against starch, chitin, gelatin, and DNA are absent, whereas Tween 80 hydrolysis is positive in all strains.

The lipid composition of *Porphyrobacter* has not yet been studied in detail, but some information on fatty acid profiles is available. The major cellular fatty acid is straight-chain octadecenoic acid ($C_{18:1}$). Some strains of *P. neustonensis* contain either $C_{17:1}$ or $C_{18:2}$ as a second major component. Characteristic for *Porphyrobacter* is the production of 2-OH fatty acid components and glycosphingolipids (A. Hiraishi, unpublished data). These properties are found in other genera of the *Alphaproteobacteria*, such as *Erythrobacter* and the obligately chemotrophic relative *Sphingomonas*. All *Porphyrobacter* species contain ubiquinone-10 as their sole respiratory quinones.

The natural habitats of *Porphyrobacter* are freshwater environments. *P. neustonensis* strains have been isolated from the air-water interface of freshwater bodies (Fuerst et al., 1993). *P. tepidarius* was isolated from cyanobacterial mats developing in the Usami hot spring (Shizuoka Prefecture, Japan), which contains brackish water (Hanada et al., 1997).

Enrichment and Isolation Procedures

Growth media and cultural conditions commonly used for the isolation of freshwater aerobic bacteria can be used for the isolation of *P. neustonensis*. The surface water of freshwater environments is a possible source of this organism. As an isolation medium, casitone–yeast extract agar medium can be used (Fuerst et al., 1993).

The medium used for isolation of *P. tepidarius* is PE agar medium (Hanada et al., 1995, 1997), which includes acetate, succinate, glutamate, yeast extract, and Casamino acids as carbon sources. The medium is inoculated with water samples from thermal environments at 40–50°C and incubated at pH 5–8 and 45°C in darkness. After several days of incubation, orange colonies may appear on the agar medium.

Maintenance Procedures

Cultures are well preserved in liquid nitrogen or by lyophilization. Preservation in an electric freezer at −80°C is also possible.

Differentiation of the genus *Porphyrobacter* from other genera

Differential characteristics of the genus *Porphyrobacter* and the phylogenetically and phenotypically related genera *Erythromicrobium* and *Erythrobacter* are shown in Table BXII.α.96.

Taxonomic Comments

Porphyrobacter neustonensis is the first organism described as a budding species of aerobic bacteriochlorophyll-containing bacteria (Fuerst et al., 1993). Phylogenetically and physiologically, *P. neustonensis* is closely related to *Erythromicrobium* and *Erythrobacter*, but differences in morphological properties and in natural habitats led to the proposal of a new genus for this species. Based on phylogenetic evidence, *P. tepidarius* and *P. neustonensis* are closely related species, although cell morphology and temperature relations distinguish the two (Hanada et al., 1997).

Intensive studies on the isolation and phylogenetic analysis of aerobic BChl-containing bacteria in freshwater and marine environments have yielded new budding strains in both the genera *Porphyrobacter* and *Erythrobacter* (A. Hiraishi, unpublished data; M. Suzuki, personal communication). In addition, the marine bacterium *"Agrobacterium sanguineum"* (Ahrens and Rheinheimer, 1967) has been shown to belong to the genus *Porphyrobacter* phylogenetically (A. Hiraishi, unpublished). In view of these observations and the close phylogenetic relationship of *Porphyrobacter*

TABLE BXII.α.96. Differential characteristics of the genus *Porphyrobacter* and related aerobic bacteria containing bacteriochlorophyll[a]

Characteristic	*Porphyrobacter*	*Erythromicrobium*	*Erythrobacter*

The authors are indebted to J.A. Fuerst and S. Hanada for their contribution of figures, unpublished information, and helpful discussion.

DIFFERENTIATION OF THE SPECIES OF THE GENUS *PORPHYROBACTER*

General and differential characteristics of the two species *P. neustonensis* and *P. tepidarius* are included in Table BXII.α.97. The average level of genomic DNA–DNA hybridization between *P. neustonensis* and *P. tepidarius* is 30%. The two species also show 99% 16S rDNA sequence similarity.

[b]Substrates tested but not utilized by *P. neustonensis*: L-arabinose, D-ribose, L-rhamnose, inulin, adonitol, dulcitol, erythritol, sorbitol, caproate, caprylate, glycolate, tartrate, phtalate, leucine, lysine, methionine, phenylalanine, tyrosine, and valine.

List of species of the genus Porphyrobacter

1. **Porphyrobacter neustonensis** Fuerst, Hawkins, Holms, Sly, Moore and Stackebrandt 1993, 132[VP]
neu.sto.nen′sis. Gr. n. *neustos* swimming, floating; M.L. masc. adj. *neustonensis* occurring at the air–water interface layer.

Cells are pleomorphic rods or cocci, 0.5–1.0 × 0.8–2 μm and multiply by polar growth or budding. Produce multifibrillar, stalk-like, fascicle structures and crater-form structures on the cell surface. Motile by means of subpolar or peritrichous flagella. The absorption spectrum of living cells has maxima at 460, 494, 799–806, and 868–871 nm. Contain a group of highly polar carotenoids and bacteriorubixanthinal as the major components.

Obligately aerobic, chemoorganoheterotrophic bacterium. No phototrophic growth anaerobically in the light. Good growth occurs with xylose, glucose, galactose, mannose, maltose, sucrose, pyruvate, proline, and yeast extract. Methanol, ethanol, formate, acetate, lactate, and malate are not used. Tween 80, but not starch or gelatin, is hydrolyzed. Susceptible to penicillin G and chloramphenicol, but resistant to streptomycin. No vitamins required as growth factors.

Mesophilic freshwater bacterium. Optimal growth is at 28–30°C; growth range is 10–37°C. No growth in the presence of 1.3% NaCl.

Habitat: air–water interface of freshwater subtropical ponds.

The mol% G + C of the DNA is: 65.0–66.4 (HPLC).

Type strain: ACM 2844, DSM 9434.

GenBank accession number (16S rRNA): AB03327, L01785, M96745.

2. **Porphyrobacter tepidarius** Hanada, Kawase, Hiraishi, Takaichi, Matsuura, Shimada and Nagashima 1997, 413[VP]
tep.i.dar′ius. L. n. *tepidarium* a warm bath; M.L. adj. *tepidarius* warm bathing.

Cells are ovoid to rod-shaped, 0.5–0.7 × 0.8–1.4 μm, nonmotile and multiply by binary fission. Internal membranes may be absent. Colonies and liquid cultures are orange due to the presence of carotenoids and bacteriochlorophyll *a*. The *in vivo* absorption spectra show maxima at 460, 494, 596, 800, and 870 nm. The main carotenoids are OH-β-carotene sulfate derivatives, nostoxanthin, and bacteriorubixanthinal.

Obligately aerobic, chemoorganoheterotrophic bacterium. No phototrophic growth anaerobically in the light. Good growth occurs with glucose, acetate, butyrate, glutamate, Casamino acids, and yeast extract as sole energy sources. Methanol, ethanol, pyruvate, malate, and succinate are not used. Starch and Tween 80, but not gelatin, are hydrolyzed. Susceptible to penicillin and chloramphenicol, but resistant to streptomycin. Biotin required as growth factor.

Moderately thermophilic freshwater bacterium, able to tolerate up to 1.3% NaCl. Optimal growth is at 40–48°C; growth range is 30–50°C. No growth in the presence of 2% NaCl.

Habitat: cyanobacterial mats in brackish water of hot springs (Shizuoka, Japan).

The mol% G + C of the DNA is: 65.0 (HPLC).

Type strain: OT3, DSM 10594.

GenBank accession number (16S rRNA): AB033328, D84429.

Genus VIII. **Sandaracinobacter** *Yurkov, Stackebrandt, Buss, Vermeglio, Gorlenko and Beatty* 1997, 1177*[VP]

Vladimir V. Yurkov

San.da.ra.ci′no.bac′ter. Gr. adj. *sandaracinos* orange-colored; Gr. n. *bacter* rod; M.L. masc. n. *Sandaracinobacter* orange-colored rod.

Cells are thin, long rods, forming chains. Motile by means of subpolar flagella. **Gram negative.** Divide by binary division. Cultures are **intensely yellow-orange because of carotenoid pigments**. **Contain bacteriochlorophyll *a*.**

Aerobic chemoorganotrophic and facultative photoheterotrophic metabolisms. No growth occurs anaerobically in light. Ribulose diphosphate carboxylase is not detected. No fermentation or denitrification activities observed. The habitat is fresh water. Not halophilic.

The mol% G + C of the DNA is: 68.5.

Type species: **Sandaracinobacter sibiricus** Yurkov, Stackebrandt, Buss, Vermeglio, Gorlenko and Beatty 1997, 1177.

Further descriptive information

Currently the genus *Sandaracinobacter* is represented by a single species, *S. sibiricus.* On the 16S rDNA tree, *Sandaracinobacter* forms a single subline of descent within the *Alphaproteobacteria* (Yurkov et al., 1997).

Thin, long (0.3–0.5 × 1.5–2.5 μm), rod-shaped cells of *S. sibiricus* are intensely yellow-orange colored due to their high carotenoid content. The carotenoid composition, or at least the major pigments, of *S. sibiricus* (absorption at 424, 450, and 474 nm) are different from those detected for other aerobic phototrophic species and determine its unusual color. The cells of *S. sibiricus* often produce long chains (sometimes up to 10 cells) and reproduce by binary division. Budding and branching have not been observed. The cells are enclosed in a thin capsule. *S. sibiricus* is a nonhalophilic species, salt concentrations above 1% NaCl strongly inhibit bacterial growth.

S. sibiricus utilizes a variety of sugars such as glucose, fructose, sucrose, and maltose (Yurkov and Gorlenko, 1990). The catabolism of glucose by *S. sibiricus* occurs mainly via the Entner–Doudoroff pathway. The species possesses glucose-6-phosphate dehydrogenase and 2-keto-3-deoxygluconate-aldolase, two main enzymes of this pathway. Low activity of the key enzyme of the Embden–Meyerhof pathway, fructose-diphosphate-aldolase, was also detected in the cells growing in glucose-supplemented medium. It was concluded that this enzyme functions in biosynthesis. No 6-phosphogluconate dehydrogenase was detected in *S. sibiri-*

**Editorial Note:* Readers are advised that *Sandaracinobacter* and *Sandaracinobacter sibiricus* may be illegitimate names as the type material was not available from any public culture collection at the time this volume went to press.

cus, suggesting that the pentose monophosphate pathway does not function in this bacterium (Yurkov et al., 1992b).

The photosynthetic apparatus of *Sandaracinobacter* consists of a reaction center and one type of light-harvesting complex I (LHI), which absorbs maximally at 867 nm (Yurkov et al., 1997). The very fast cytochrome photooxidation observed after flash excitation in the cells of *S. sibiricus* indicates that the immediate electron donor to the reaction center in this species is a reaction center-bound cytochrome *c* (44.0 kDa) (Yurkov et al., 1995). Recently, reaction centers were purified from *S. sibiricus* membranes, confirming a typical overall organization of the reaction center (Yurkov et al., 1998a). The photochemical activity of the *S. sibiricus* photosynthetic apparatus was found to exist only under aerobic conditions (Yurkov et al., 1995, 1998a). Quinones Q-9 and Q-10 are the quinones of *S. sibiricus* (Gogotov and Gorlenko, 1995).

S. sibiricus demonstrated high-level resistance to toxic tellurite and accumulation of metallic tellurium crystals inside the cells. The level of tellurite resistance is strongly dependent on the organic carbon source used for growth. The highest resistance was found in yeast extract (sole carbon source)-containing medium and reached 1200 μg of tellurite per ml of medium (Yurkov et al., 1996).

S. sibiricus accumulates polyphosphates that provide a reserve of inorganic phosphate (Yurkov et al., 1991b). Osmium-stained granules of polyphosphates are found under nearly all experimental conditions studied—in the light and the dark, with high and low aeration. The highest amount of polyphosphate was accumulated in a growth medium supplemented with sucrose. Under such conditions, polyphosphate granules occupied about 30–40% of the total cell volume (Fig. BXII.α.109). Another inclusion body found in *S. sibiricus* consists of polyhydroxyalkanoate compound (a lipid-like compound that is formed from β-hydroxybutyric acid units) revealed as electron-transparent granules on electron micrographs (Yurkov et al., 1991b). Polyhydroxyalkanoate formation occurs when cells grow in media unbalanced for nitrogen (urea as a nitrogen source), as well as during incubation in a medium lacking fixed nitrogen. Replacement of ammonium with nitrate as the source of nitrogen also results in pronounced formation of polyhydroxyalkanoates with large granules occupying 40–50% of the total cell volume (Fig. BXII.α.110).

Enrichment and Isolation Procedures

S. sibiricus was isolated from thin microbial mats that developed around the underwater hydrothermal vents of the Bol' shaya river bottom. The mats were formed by cyanobacteria *Oscillatoria subcapitata*, diatoms, and the purple bacteria *Thiocapsa roseopersicina* and *Rhodopseudomonas palustris*. The mats were situated at the boundary of the anaerobic and aerobic zones at pH 8.9–9.4, temperature 9–33°C, and hydrogen sulfide and oxygen concentrations of 0.6–4.5 mg/l and 10.4–4.1 mg/l, respectively. The water redox potential was high, E_h = 230–330 mV. Thus, despite the presence of sulfide, the mat surface was washed by water with a high oxygen content (Yurkov and Gorlenko, 1990). Isolation procedures are identical to those described for the genus *Erythromicrobium*.

Maintenance Procedures

S. sibiricus can be readily maintained under short- and long-term storage following procedures described for the genus *Erythromicrobium*.

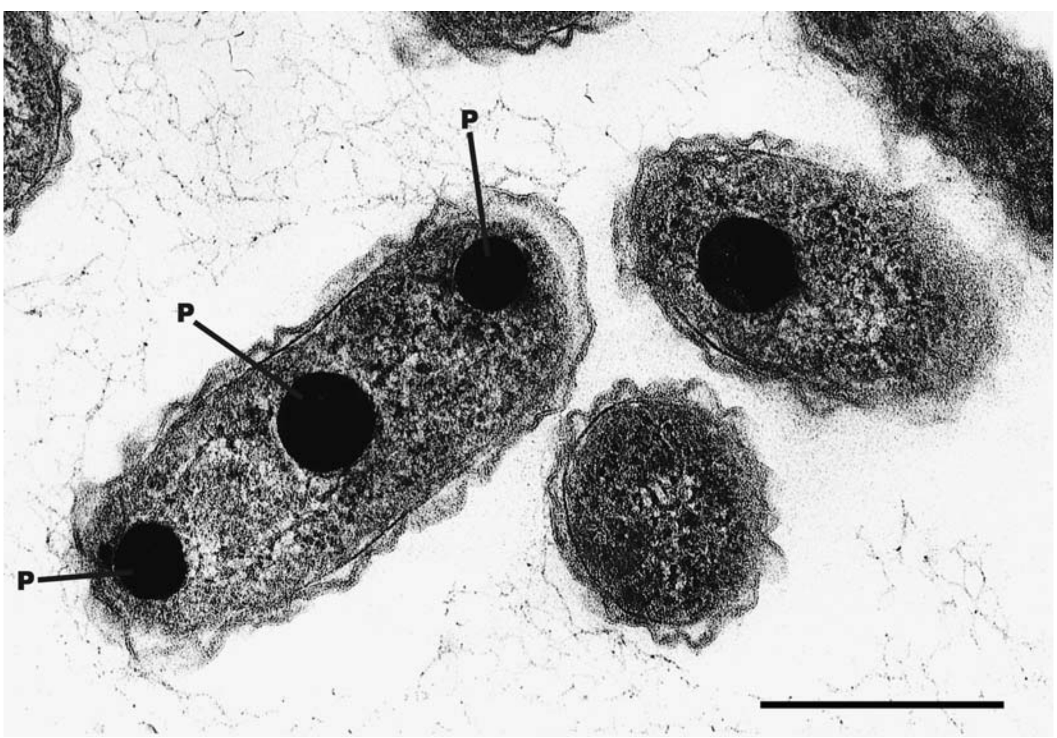

FIGURE BXII.α.109. Intracytoplasmic components of *S. sibiricus* revealed by electron microscopy of ultrathin sections. Electron dense granules of polyphosphates (*P* indicated by arrows). Bar = 0.5 μm. (Printed with permission from V. Yurkov).

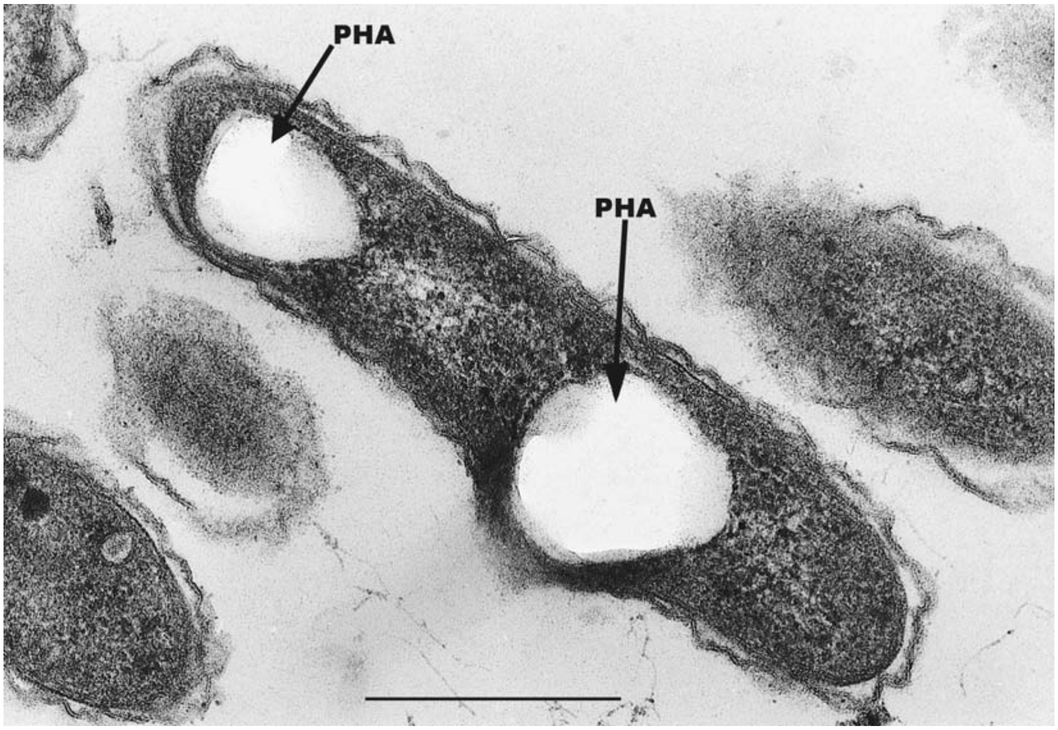

FIGURE BXII.α.110. *S. sibiricus.* Big electron clear granules of polyhydroxyalkanoate (*PHA*; indicated by *arrows*) often occupied up to 40–50% of the total cell volume. Note cell shape distortion by some granules. Bar = 0.5 μm. (Printed with permission from V. Yurkov.)

Differentiation of the genus *Sandaracinobacter* from other genera

Genomic difference of *Sandaracinobacter* from other genera of aerobic anoxygenic phototrophic bacteria was revealed by the DNA composition, DNA–DNA hybridization, and 16S rDNA sequence analyses. As determined by thermal denaturation, the mol% G + C content of *S. sibiricus* is 68.5. According to DNA–DNA hybridization, this species has a low level of DNA similarity with other species investigated. The highest level of DNA similarity (20–27%) was found with *Erythromonas ursincola* (formerly described as *"Erythromicrobium ursincola"*) (Yurkov et al., 1991a). Based on the 16S rDNA sequence data, *Sandaracinobacter* branches independently from its most closely related aerobic phototrophic genus *Erythromonas*, and nonphotosynthetic genera *Blastomonas*, *"Rhizomonas"*, and *Sphingomonas* (Yurkov et al., 1997).

The major morphological and physiological features of *Sandaracinobacter* that distinguish it from its closest relatives of freshwater aerobic phototrophic bacteria are shown in Table BXII.α.95 of the chapter describing genus *Erythromonas*.

Taxonomic Comments

The first representative of a freshwater aerobic bacteriochlorophyll *a* (BChl *a*)-containing bacterium (strain RB16-17), isolated from thin microbial mats, was ascribed to the marine genus *Erythrobacter* and named *"Erythrobacter sibiricus"* (Yurkov and Gorlenko, 1990). This assignment was made based on bacteriochlorophyll *a* production and strict aerobiosis. However, since that time *"E. sibiricus"* was reclassified into the genus *Erythromicrobium*, a new genus for freshwater aerobic anoxygenic phototrophic bacteria (Yurkov and Gorlenko, 1992; Yurkov et al., 1991a, 1992a). Based on phenotypic similarities, the five species—*"E. sibiricus"*, *"E. ursincola"*, *"E. ezovicum"*, *"E. hydrolyticum"*, and *E. ramosum*—were included in the same genus, *Erythromicrobium* (Yurkov et al., 1991a). However, DNA–DNA hybridization data showed that DNA from the species *"E. sibiricus"* and *"E. ursincola"* had very low relatedness (11–27%) to the other three species of this genus. It was proposed that additional physiological, biochemical, and DNA sequence analyses might demonstrate clear differences between *"E. sibiricus"* and *"E. ursincola"* on the one hand, and the other orange freshwater bacteria, on the other hand (Yurkov et al., 1991a). In agreement with this proposal, an analysis of 5S rRNA sequences confirmed the genetic heterogeneity of the genus *Erythromicrobium* (Turova et al., 1995).

Recent results on the morphology, physiology, pigment composition, light-harvesting antenna, reaction center organization, and electron carriers of five *Erythromicrobium* representatives led to excluding *"E. sibiricus"* from the genus *Erythromicrobium* and, based on its unique phylogenetic position, describing this microorganism as the type species of a new genus, *Sandaracinobacter* (Yurkov et al., 1997).

List of species of the genus Sandaracinobacter

1. **Sandaracinobacter sibiricus** Yurkov, Stackebrandt, Buss, Vermeglio, Gorlenko and Beatty 1997, 1177[VP]
si.bi'ri.cus. L. adj. *sibiricus* isolated in Siberia.

Gram-negative, yellow-orange pigmented thin, long rods, 0.3–0.5 × 1.5–2.5 µm or more. Motile by means of subpolar flagella (up to three). Cells contain BChl *a* and carotenoid pigments. Carotenoids have major absorption peaks at 424, 450, and 474 nm *in vivo*. The cytoplasmic membranes contain a reaction center (RC) and light-harvesting complex I (LHI) with absorption peaks at 750, 799, 857 nm for RC, and 867 nm for LHI. Tetraheme cytochrome *c* of 44.0 kDa is tightly bound to RC and is its immediate electron donor. Additionally contain soluble cytochrome *c* of 14.0 kDa and membrane-bound cytochrome *c* of 30.0 kDa (cytochrome of bc_1 complex). Contain quinones Q-9 and Q-10. Menaquinone is not found.

Aerobic chemoorganotroph and facultative photoheterotroph. The best growth substrates are butyrate, sucrose, casein hydrolysate, and yeast extract. Good growth is observed on acetate and maltose; weak growth on media containing glucose, fructose, pyruvate, propionate, or glycerol. No utilization of ribose, sorbitol, benzoate, fumarate, formate, succinate, citrate, malate, methanol, or ethanol.

Optimal temperature for growth is 25–30°C. Freshwater bacteria; salinity above 1.0% of NaCl in media strongly inhibits growth. The pH optimum is 7.5–8.5. The bacteria exhibit oxidase activity and lack catalase activity. Hydrolyze Tween 60 and do not hydrolyze gelatin or starch.

Resistant to chloramphenicol, fusidic acid, streptomycin, amikacin, bacitracin, kanamycin, neomycin, and novobiocin. Sensitive to penicillin, ampicillin, tetracycline, polymyxin-B, erythromycin, nalidixic acid, lincomycin, mycostatin, aureomycin, and vancomycin.

Demonstrate a high level of resistance to tellurite. Tellurite resistance depends on medium composition, particularly on organic carbon source. The highest tellurite concentration tolerated is 1200 µg/ml in media containing acetate or yeast extract as a sole organic source. Tellurite can be reduced and transformed into metallic tellurium accumulated inside of cells.

Storage compounds: polyphosphates, polysaccharide, and polyhydroxyalkanoate.

Habitat: freshwater algobacterial mat near hydrothermal sulfide-containing vents along the river bottom.

The mol% G + C of the DNA is: 68.5 (T_m).

Type strain: RB16-17.

GenBank accession number (16S rRNA): Y10678.

Genus IX. **Zymomonas** *Kluyver and van Niel 1936, 399*[AL]

GEORG A. SPRENGER AND JEAN SWINGS

Zy.mo'mo.nas or Zy.mo.mo'nas. Gr. n. *zyme* leaven, ferment; Gr. n. *monas* a unit, monad; M.L. fem. n. *Zymomonas* fermenting monad.

Rod-shaped cells with rounded ends, occasionally ellipsoidal, usually in pairs, 2–6 × 1.0–1.4 µm. Gram negative. **Usually nonmotile; if motile, they possess one to four polar flagella.** Motility may be lost spontaneously. **Facultatively anaerobic; some strains are obligately anaerobic.** Optimum temperature 25–30°C. Colonies on the standard medium[1] are glistening, regularly edged, white to cream colored, 1–2 mm in diameter after 2 d at 30°C. Oxidase negative. Chemoorganotrophic, growing on and **fermenting 1 mol of glucose or fructose to almost 2 mol of ethanol, 2 mol of CO_2, and some organic acids such as lactic acid**. Some strains may also utilize sucrose, but other carbon sources are not used. Gluconate can be degraded but does not serve as sole carbon or energy source (Strohdeicher et al., 1988). Sorbitol and gluconolactone are formed when grown on sucrose or mixtures of glucose and fructose by a so far unique enzyme, glucose-fructose oxidoreductase. **Membranes contain pentacyclic triterpenoids of the hopane series** (Sahm et al., 1993). Gelatinase negative. Nitrates are not reduced and indole is not produced. ***Zymomonas* tolerates 5% ethanol and is acid tolerant, growing at pH 3.5–7.5.** Good growth is obtained only when a mixture of amino acids is present in the medium, but no one amino acid is essential. All strains require biotin and pantothenate. ***Zymomonas* occurs as a spoiler in beers, ciders, and perries; as fermenting agents in** *Agave* sap, palm sap, and sugarcane juice; and on honeybees and in ripening honey.

The mol% G + C of the DNA is: 47.5–49.5.

Type species: **Zymomonas mobilis** (Lindner 1928a) Kluyver and van Niel 1936, 399 (*Thermobacterium mobile* Lindner 1928b, 253; *Zymomonas anaerobia* Kluyver 1957, 199.)

FURTHER DESCRIPTIVE INFORMATION

Morphology *Zymomonas* cells are mostly straight rods with rounded or ovoid ends, occurring singly or in pairs. *Zymomonas* cells form no spores, and contain no detectable intracellular lipids, glycogen, or poly-β-hydroxybutyrate. Some individual strains form rosette-like cell aggregations, cell chains, curved or U-shaped cells, or filamentous cells. Most strains are nonmotile.

Oxygen relationships Although *Zymomonas* has a fermentative type of metabolism, it is able to grow aerobically, and therefore should be qualified as a facultative anaerobe. Strains deficient in alcohol dehydrogenase are obligate aerobes (Wecker and Zall, 1987). An electron transport chain is present in the cytoplasmic membrane (Strohdeicher et al., 1990; Kalnenieks et al., 1993; Kim et al., 1995) but no oxidative phosphorylation occurs in the presence of glucose (Kalnenieks et al., 1993).

Cultural characteristics Deep colonies in solid standard me-

1. The standard medium (SM) has the following composition (g/l distilled water): D-glucose, 20; and yeast extract, 5. Another medium (RM) was introduced by Bringer et al. (1985) (g/l distilled water): D-glucose, 20; yeast extract, 10; KH_2PO_4, 1.0; $(NH_4)_2SO_4$, 1.0; and $MgSO_4{\cdot}7H_2O$, 0.5. A defined medium (Fein et al., 1983) consists of (g/l distilled water): glucose, 20; KH_2PO_4, 3.5; $(NH_4)_2SO_4$, 2.0; $MgSO_4{\cdot}7H_2O$, 1.0; $FeSO_4{\cdot}7H_2O$, 0.01; and 2-[*N*-Morpholino]ethanesulfonate (MES), 19.52. The medium is adjusted to pH 5.5 and autoclaved. A sterile solution of biotin and Ca-pantothenate is added after autoclaving to a final concentration of 0.001 g/l each.

dium are lenticular, regular, entire edged, butyrous, white or cream colored, and 1–2 mm in diameter after 2–4 d at 30°C. Anaerobic surface colonies are spreading, entire edged, convex or umbonate, and 1–4 mm in diameter after 2–7 d at 30°C (Swings and De Ley, 1977). When incubated aerobically, colonies reach a maximum diameter of 1.5 mm or appear as microcolonies (Swings et al., 1977).

Most (90%) of the *Zymomonas* strains are able to grow between pH 3.85 and pH 7.55. At pH 3.5, 43% of the strains develop, indicating a high acid tolerance (Swings and De Ley, 1977). This feature is not at all surprising as the natural niche of the genus is in acid palm wines, ciders, and beers at pH 4 or below. *Zymomonas* cannot grow in liquid standard medium at pH 3.05.

Zymomonas grows best between 25°C and 30°C. At 38°C, 74% of the strains grow, but at 40°C, growth is rare (De Ley and Swings, 1976; Swings and De Ley, 1977). *Zymomonas* slowly develops at 15°C (Millis, 1951; Dadds et al., 1973) but not at 4°C. Growth at 36°C is the best phenotypic test to differentiate *Z. mobilis* subsp. *mobilis* (+) from *Z. mobilis* subsp. *pomacii* (−) (Swings et al., 1977). *Zymomonas* is killed by exposure to 60°C for 5 min.

Glucose metabolism *Zymomonas* grows easily in liquid media containing either D-glucose or D-fructose; a dense turbidity accompanied by abundant CO_2 formation develops after 1–2 d at 30°C. The final pH in the standard medium after 3 d at 30°C is 4.8–5.2. The acidification of the medium is more pronounced upon incubation at higher temperatures. Strain-specific flocculent or compact cell deposits are formed. Half of the strains grow in glucose concentrations up to 40% (Swings and De Ley, 1977).

Zymomonas is an unusual bacterium in that it ferments glucose anaerobically by the Entner–Doudoroff pathway (for references, see Conway, 1992), followed by a pyruvate decarboxylation and reduction of acetaldehyde, according to the following general fermentation balance:

1 glucose → (1.58–1.93) ethanol + (1.7–1.9) CO_2 + (0.02–0.2) lactate or other organic acid + (0.011) cell material [CH_2O].

Small amounts of acetaldehyde, acetyl methyl carbinol, and glycerol are also formed. During the dissimilation of glucose under aerobic conditions, ethanol, acetaldehyde, and acetate are formed. In the presence of oxygen, NADH (from fermentation) is used by a membrane-bound NADH oxidase to reduce oxygen to water. Consequently, less NADH is available for the reduction of acetaldehyde to ethanol, and the accumulating acetaldehyde is growth inhibiting (Bringer et al., 1984; Pankova et al., 1985). Some acetate is formed from acetaldehyde through an NADP-dependent acetaldehyde dehydrogenase, with highest activity after aerobic growth (Barthel et al., 1989). Strains deficient in alcohol dehydrogenase are obligate aerobes (Wecker and Zall, 1987). A membrane-bound glucose dehydrogenase containing pyrroloquinoline-quinone as a prosthetic group (Strohdeicher et al., 1988), feeds the electrons derived from glucose into the respiratory chain, which contains ubiquinone-10 (Strohdeicher et al., 1990; Kalnenieks et al., 1993). A membrane-associated F_0F_1-ATPase has been purified (Reyes and Scopes, 1991), and ATP yields via oxidative phosphorylation have been shown with aerated cells using ethanol or acetaldehyde as substrates, but not with glucose (Kalnenieks et al., 1993). All enzymes from the Entner–Doudoroff pathway, including pyruvate decarboxylase and alcohol dehydrogenases, of *Z. mobilis* have been purified, the respective genes have been cloned, and the sequences thereof have been established (Scopes et al., 1985; Pawluk et al., 1986; Aldrich et al., 1992; Conway, 1992; Sprenger et al., 1993)

Only a truncated tricarboxylic acid cycle is functional in *Zymomonas.* Malate and oxaloacetate are provided by action of a phosphoenolpyruvate carboxylase and a malic enzyme (Dawes et al., 1970; Bringer-Meyer and Sahm, 1989). From the pentose-phosphate pathway enzymes, transaldolase is missing (Feldmann et al., 1992; Zhang et al., 1995). Acetyl-CoA for anabolism is provided by an anaerobically active pyruvate dehydrogenase complex (Bringer-Meyer and Sahm, 1993; Neveling et al., 1998).

Only 2% of the glucose is incorporated in the cells, producing 48% of the cellular carbon (Belaïch and Senez, 1965); the rest of the carbon is derived from yeast extract components. The growth yield coefficients ($Y_{glucose}$ = 3.88–9.32, as determined by several authors) indicate that the growth of these organisms is not very efficient.

Sucrose metabolism Sucrose is fermented and used for growth by many *Zymomonas* strains (for references, see Preziosi et al., 1990; Sprenger, 1996). This property is lost occasionally upon subculturing on D-glucose (Shimwell, 1950). Sucrose fermentation is inducible (Kluyver and Hoppenbrouwers, 1931; Dadds et al. 1973; Richards and Corbey, 1974) and can lead to capsule formation (Kirk et al., 1994): 35g/l of levan is formed from 150 g/l of sucrose (Yoshida et al., 1990). Other by-products of sucrose fermentation are fructo-oligosaccharides, sorbitol, and gluconate (Leigh et al., 1984; Viikari, 1984). Sorbitol and gluconolactone are formed by an intermolecular oxidation-reduction catalyzed by a periplasmic NADP-containing glucose-fructose oxidoreductase that so far has been detected only in *Zymomonas* (Zachariou and Scopes, 1986; Loos et al. 1991; G. A. Sprenger, unpublished results). Sorbitol is used as compatible solute and is accumulated intracellularly at high osmotic stress conditions (Loos et al., 1994). Sucrose is split extracellularly by action of levansucrase or invertase.

Glucose and fructose are taken up by facilitated diffusion through a transport protein that prefers glucose to fructose. *Zymomonas* appears to be the only known bacterium that relies solely on such a uniport type for sugar uptake (DiMarco and Romano, 1985 Parker et al. 1995; Weisser et al. 1995, 1996). Some strains form mannitol from fructose (Viikari, 1984). Dihydroxyacetone and glycerol are excreted after growth under suboptimal conditions with high fructose in the medium (Viikari, 1984) by the subsequent action of a dihydroxyacetone phosphate phosphatase and dihydroxyacetone reductase (Horbach et al., 1994).

Nitrogen sources The nitrogen source for growth can be supplied as peptone, yeast extract, nutrient broth, beer, palm juice, or apple juice or a mixture of 20 amino acids. (Groups of amino acids, individual amino acids, NH_4Cl, or $(NH_4)_2SO_4$ can also serve as nitrogen sources, but this has not been verified for every *Zymomonas* strain.) In synthetic media, the growth yield is lower and the generation time longer than in complex media, but the ethanol yield remains constant (Belaïch and Senez, 1965).

Growth factors *Zymomonas* strains require biotin and pantothenate as growth factors. No strain requires nicotinic acid. Only six strains need additional growth factors. The most exacting strain (VP3) requires additional vitamin B_2, lipoic acid, riboflavin, and folic acid (Van Pee et al., 1974).

Ethanol tolerance *Zymomonas* grows in the presence of 5% ethanol, and many strains grow at even higher concentrations

(Swings and De Ley, 1977; Bringer-Meyer and Sahm, 1988). The organism can produce high concentrations of ethanol, up to 13% (w/v) in batch cultures (Rogers et al., 1982), making it an attractive organism for industrial ethanol production. The main targets for detrimental action of ethanol are the cell membrane (Carey and Ingram, 1983) and fermentative activity; at an ethanol concentration of 10%, 3-phosphoglycerate is accumulated intracellularly concomitant with a decrease in fermentative activity (Strohhäcker et al., 1993). High ethanol levels or heat stress induces a characteristic protein pattern in the cells (Michel and Starka, 1986). A major protective function against ethanol can be ascribed to the hopanoids, pentacyclic triterpenoids, which occur in large amounts (up to 3% of membrane dry weight or 40–50% of total lipid content) in the membrane (Bringer et al., 1985; Flesch and Rohmer, 1989; Hermans et al., 1991; Sahm et al., 1993). Isoprenoids are synthesized exclusively via the pyruvate/glyceraldehyde-3-phosphate pathway (Rohmer et al., 1993). Other major membrane constituents are vaccenic acid (up to 70% of fatty acids; Tornabene et al., 1982; Carey and Ingram, 1983), sphingolipids as the precursor 3-oxosphinganine (Sutter, 1991) or free ceramide (*N*-palmitoyl-dihydroxyhexadecane; Tahara and Kawazu, 1990), and the newly discovered dialkylcyclohexadiene-carbinol (Koukkou et al., 1998). No evidence for ketodeoxyoctulosonic acid, heptoses, or hydroxy fatty acids has been found (Tornabene et al., 1982).

Other physiological features The following physiological tests are positive for the genus: catalase and superoxide dismutase (Bringer et al., 1984; Pankova et al., 1985; Shvinka et al., 1989); reduction of methylene blue, thionin, and 2,3,5-triphenyltetrazolium chloride; formation of traces of acetyl methyl carbinol and the production of a characteristic fruity odor. The following tests are negative: growth in 0.5% yeast extract, nutrient broth, or 1% peptone broth, in liquid standard medium + 2% NaCl; indole production, nitrate reduction, hydrolysis of gelatin, hydrolysis of Tween 60 and Tween 80, and oxidase.

Pathogenicity *Zymomonas* is not known to be pathogenic for humans, animals, or plants. Lindner (1929, 1931) recommended the use of *Zymomonas* in human nutrition as a kind of yogurt. Antagonistic effects of *Zymomonas* against bacteria and fungi *in vitro*, and the therapeutic use of *Zymomonas* in cases of chronic enteric and gynecological infections, have been reported (Swings and De Ley, 1977; Falcao de Morais et al., 1993).

Ecology In sweet English ciders, *Zymomonas* is the causative agent of a secondary fermentation, known as "cider sickness". The first description of this phenomenon was given by Barker and Hillier (1912). Cider sickness is recognized by frothing and abundant gas formation, a typical change in the aroma and flavor, reduction of sweetness, and marked turbidity forming a heavy deposit afterward (Barker, 1948; Millis, 1951; Carr and Passmore, 1971). A cider disorder known as framboise, or "framboisement" in France, is also attributed to *Zymomonas*. Millis (1951) also isolated *Zymomonas* from "sick" perries. Lindner (1928b) discovered that *Zymomonas* is the fermentative agent that transforms the sugary *Agave* sap (aguamiel) to pulque in Mexico. *Zymomonas* is a serious beer contaminant, particularly in English cask beers, producing a heavy turbidity and an unpleasant odor due to acetaldehyde and H_2S. Dennis and Young (1982) isolated five strains of *Zymomonas* from an ale brewery using an isolation medium containing actidione and Schiff's reagent as a dye to detect acetaldehyde production. *Zymomonas* has not been reported in lager beers. Palm wines are prepared in the Far East and in Africa from the sap of *Arenga*, *Raphia*, and *Elaeis* palms and are known to harbor *Zymomonas* as a fermentative agent. *Zymomonas* is also present in fermenting sugarcane juice in Brazil, and on bees and ripening honey in Spain.

Plasmids Indigenous plasmids in a size range of 1.5 kb to >40 kb of DNA have been described. Some antibiotic or heavy metal resistance features have been ascribed to the presence of these plasmids (for references, see Sprenger et al., 1993). Indigenous plasmids have been used to construct shuttle vectors for the expression of homologous and heterologous genes in *Z. mobilis* for metabolic engineering (Conway et al. 1987; Sprenger et al., 1993).

Potential for industrial applications and metabolic engineering *Zymomonas* may be important as an industrial ethanol producer and it offers advantages over traditional yeast fermentation: it has higher specific rates of glucose uptake and ethanol production; it gives higher ethanol yield and lower biomass; it grows anaerobically; and it has a high ethanol tolerance. Some authors have studied extensively the kinetics of ethanol fermentation in both batch and continuous cultures at high glucose concentrations (Lee et al., 1979; Rogers et al., 1982). Attempts to broaden the narrow substrate and product spectrum of *Z. mobilis* have yielded strains that can utilize carbon sources such as mannitol (Buchholz et al., 1988) after chemical mutagenesis. Introduction of heterologous genes from various microorganisms has led to strains that can utilize D-xylose (Feldmann et al., 1992; Zhang et al., 1995), D-mannose (Weisser et al., 1996), L-arabinose (Deanda et al., 1996), β-glucosides, or lactose (Sprenger, 1993). Similarly, strains that produce L-alanine (Uhlenbusch et al., 1991) or carotenoids (Misawa et al., 1991) have been described. Several reviews discuss the use of *Zymomonas* in the production of bioethanol from renewable carbon sources (Buchholz et al., 1987; Ingram et al., 1989; Johns et al., 1992; Sahm et al., 1992; Doelle et al., 1993; Sprenger, 1993, 1996; Sprenger et al., 1993).

Enrichment and Isolation Procedures

The following medium, originally designed as a detection medium for *Zymomonas* in breweries (Dadds, 1971), can be recommended for enrichment and has the following composition (g/l distilled water): malt extract, 3; yeast extract, 3; D-glucose, 20; peptone, 5; and actidione, 0.02. The pH is adjusted to 4.0. Ethanol is added to a final concentration of 3% (v/v). The presence of *Zymomonas* is indicated by abundant gas production after 2–6 d incubation at 30°C.

Maintenance Procedures

Zymomonas cultures held in the standard medium at room temperature are transferred every 2–3 weeks. *Zymomonas* survives the ordinary lyophilization procedure for many years. Cell viability is rapidly lost in ionic dilution buffers as sodium citrate, sodium chloride, or sodium phosphate. A 10 mM Tris buffer (pH 8) containing 33 mM $MgCl_2$ should be used for serial dilutions at low temperatures (Buchholz and Eveleigh, 1989).

Differentiation of the genus *Zymomonas* from other genera

Table BXII.α.98 indicates the most salient features that differentiate *Zymomonas* from other genera. *Zymomonas* can be differentiated from *Sphingomonas* by the absence of the fatty acid

$C_{14:0\ 2OH}$, which is typically present in all *Sphingomonas* species (Yabuuchi et al., 1990a; Takeuchi et al., 1993a; Balkwill et al., 1997), and also by the much lower mol% G + C of its DNA. *Zymomonas* is phenotypically and genotypically well defined and is easily recognized. Its most outstanding feature is the quantitative fermentation of glucose or fructose (and to a lesser extent of sucrose)—but no other sugars—to equimolar amounts of ethanol and CO_2. This feature makes *Zymomonas* a unique ethanol-producing bacterium.

Zymomonas is excluded from the *Enterobacteriaceae* based on polar flagellation, inability to reduce nitrates, growth at pH 4, and growth in the presence of 5% ethanol.

Genetically, phenotypically, and ecologically, *Zymomonas* is distantly related to the acetic acid bacteria: they both occur in acid, sugary, and alcoholized niches such as tropical plant juices and beer. They are ecologically complementary in that *Zymomonas* produces ethanol, which is further oxidized by the acetic acid and bacteria. The acetic acid bacteria are differentiated from *Zymomonas* by their strictly aerobic growth requirements and the mol% G + C values of their DNA.

Taxonomic Comments

The genus *Zymomonas* belongs to the family *Sphingomonadaceae* based on phylogenetic analysis of 16S rRNA gene sequences (Balkwill et al., 1997). The genus *Zymomonas* contains only one species: *Zymomonas mobilis*. Strains ATCC 29192, NCIB 8777, and 10565 are almost identical and are united in *Zymomonas mobilis* subsp. *pomacii* (Swings et al., 1977). All the other strains belong in *Zymomonas mobilis* subsp. *mobilis*.

All *Zymomonas* strains have mol% G + C values for their DNA within the narrow range of 47.5–49.5. The tightness of the genus *Zymomonas* is also reflected in the high phenotypic similarity (S_{sm} ≥88%) between the strains (De Ley and Swings, 1976). DNA–DNA hybridizations show a nucleotide sequence similarity of >76%; only one strain, ATCC 29192, is aberrant with less than 32% DNA duplexing (Swings and De Ley, 1975). Because of the high phenotypic similarity, the authors refrained from proposing the subspecies *Zymomonas mobilis* subsp. *pomacii* as a separate species, although the DNA–DNA hybridization with reference strain 5.3 was very low (i.e., 32%), so low a value that it would have allowed the creation of two separate species. However, no additional strains and hybridization values were available to further support the separation. The homogeneity of the genus *Zymomonas* is further demonstrated by the computer-assisted comparison of electropherograms of the soluble cell proteins. The genome size has been determined to be in the range of 1.4–1.5 × 10^9 Da (Swings and De Ley, 1975; Kang and Kang, 1998).

Plasmid profiles from both *Z. mobilis* subspecies have been described and have been used to discriminate laboratory strains (Tonomura et al., 1982; Stokes et al., 1983; Skotnicki et al., 1984; Walia et al., 1984; Scordaki and Drainas, 1987; Yablonsky et al., 1988; Misawa and Nakamura, 1989; Degli-Innocenti et al. 1990).

List of species of the genus Zymomonas

1. **Zymomonas mobilis** (Lindner 1928a) Kluyver and van Niel 1936, 399[AL] (*Thermobacterium mobile* Lindner 1928b, 253; *Zymomonas anaerobia* Kluyver 1957, 199.)
mo' bi.lis. L. adj. *mobilis* movable, motile.

The description of the species is as for the genus and as listed in Tables BXII.α.98 and BXII.α.99. The differentiation of its two subspecies is indicated in Table BXII.α.100.

The mol% G + C of the DNA is: 47.5–49.5 (T_m).

Type strain: ATCC 10988, DSMZ 424.

Additional Remarks: phenotypic centrotype ATCC 29191.

a. **Zymomonas mobilis** *subsp.* **mobilis** (Lindner 1928a) De Ley and Swings 1976, 156[AL] (*Zymomonas mobilis* biovar anaerobia Richards and Corbey 1974, 243; *Zymomonas mobilis* biovar recifensis Gonçalves de Lima, De Araújo, Schumacher and Cavalcanti Da Silva 1970, 3; *Zymomonas anaerobia* biovar anaerobia (Shimwell 1937) Carr 1974, 353; *Saccharomonas anaerobia* biovar immobilis Shimwell 1950, 182; *Zymomonas anaerobia* biovar immobilis (Shimwell 1937) Carr 1974, 353.)
mo' bi.lis. L. adj. *mobilis* movable, motile.

Methylene blue reduction	+
Thionin reduction	+
Triphenyltetrazolium reduction	+
Indole	−
Hydrolysis of gelatin, Tween 60, Tween 80	−
L-ornithine, L-arginine, and L-lysine decarboxylases	d
Antimicrobial agents (amount per disk):	
Chloramphenicol, 30 μg; fusidic acid, 10 μg; sulfafurazole, 500 μg; tetracycline, 10 μg	S
Ampicillin, 10 μg; cephaloridine, 10 μg; erythromycin, 10 μg; vancomycin, 10 μg	d
Bacitracin, 5 U; gentamicin, 10 μg; kanamycin, 10 μg; lincomycin, 10 μg; methicillin, 10 μg; nalidixic acid, 30 μg; neomycin, 10 μg; novobiocin, 30 μg; penicillin, 5 U; polymyxin, 300 U; streptomycin, 10 μg	R
Actidione, 0.01%	R

[a]For symbols see standard definitions; R, resistant; S, susceptible; and W, weak.

See Table BXII.α.100 for differentiation of this subspecies from the subsp. *pomacii.*

Isolated from bees, from ripening honey in Spain, from the fermenting sap of *Agave americana* (*atrovirens*) in Mexico, from fermenting palm juice (*Arenga pinnata*) in Indonesia, from sugarcane juice in Queensland, Australia, and the Fiji Islands (Warr et al., 1984), from *Elaeis guineensis* and *Raphia uinifera* in Zaire and Nigeria, and from fermenting sugarcane juice or molasses in Brazil. It has also been isolated in England from beer, from the surface of brewery yards, and from the brushes of cask-washing machines.

The mol% G + C of the DNA is: 47.5–49.5 (T_m).

Type strain: ATCC 10988, DSMZ 424.

Additional Remarks: phenotypic centrotype ATCC 29191.

b. **Zymomonas mobilis** *subsp.* **pomacii** (Millis 1956) De Ley and Swings 1976, 156[AL] (*Zymomonas anaerobia* subsp. *pomaceae* (sic) Millis 1956, 527; *Zymomonas mobilis* subsp. *pomaceae* (sic) (Millis 1956); De Ley and Swings 1976, 156.) *pom.a' ci.i.* V.L. n. *pomacium* cider; M.V.L. gen. n. *pomacii* of cider.

See Table BXII.α.100 for differentiation of this subspecies from the subspecies *mobilis.*

Isolated in England from sick cider and from apple pulp.

The mol% G + C of the DNA is: unknown.

Type strain: ATCC 29192, NCIB 11200.

Reference strains NCIB 8777 and NCIB 10565.

TABLE BXII.α.100. Differentiation between subspecies of *Zymomonas mobilis*[a]

Characteristics	*Z. mobilis* subsp. *mobilis*	*Z. mobilis* subsp. *pomacii*
Colony diameter after aerobic growth on SM for 7 d at 30°C	*1.5 mm*	*<1.0 mm*
Growth in SM at 36°C	+	−

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Cau' lo.bac.ter.a' ce.ae. M.L. masc. n. *Caulobacter* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Caulobacteraceae* the *Caulobacter* family.

The family *Caulobacteraceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA gene sequences; the family contains the genera *Caulobacter* (type genus), *Asticcacaulis*, *Brevundimonas*, and *Phenylobacterium*.

Oligotrophic and chemoorganotrophic, with a strictly aerobic respiratory metabolism. *Caulobacter*, *Asticcacaulis*, and some species of *Brevundimonas* produce prosthecae; *Phenylobacterium* does not.

Type genus: **Caulobacter** Henrici and Johnson 1935b, 83 emend. Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1070.

Genus I. **Caulobacter** *Henrici and Johnson 1935b, 83[AL] emend. Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1070*

JEANNE S. POINDEXTER

Cau' lo.bac' ter. L. n. *caulis* stalk; M.L. masc. *bacter* form of Gr. neut. n. *bactrum* rod; M.L. masc. n. *Caulobacter* stalk(ed) rod.

Cells single, unbranched, with tapered poles; long axis typically distinctly curved, conferring a **vibrioid** shape, but may be straight in some isolates and the cell shape **fusiform**; 0.4–0.6 × 1–2 µm during growth in most media. The younger pole of the dividing cell bears a **single flagellum**, and the older pole bears a prostheca (the **stalk**) developed by outgrowth of the cell envelope. The stalk includes outer membrane, peptidoglycan, cell membrane, and a core sometimes observed to be occupied in part by membranes but not in any case by any other discernible cytoplasmic components. Stalk diameter is constant along its length, varying from 0.11 to 0.18 µm among isolates; the stalk possesses at least one **stalk band** as a substructure after the cell has matured and completed at least one cell cycle. Binary fission is constrictive and is completed without formation of a septum. The stalk-bearing progeny cell grows and eventually repeats the **asymmetric cell division**. The flagellum-bearing progeny cell, after a period of motility, releases the flagellum and develops its stalk at the previously flagellated site as it grows and proceeds to its **asymmetric cell division**. At the base of the flagellum and at the outer tip of the stalk is a small mass of adhesive material, the **holdfast**, which confers adhesiveness on each of the progeny.

Gram negative. Strictly **respiratory** and **aerobic**; O_2 serves as the only terminal electron acceptor for growth, although nitrate may be reduced to nitrite. The principal respiratory quinone is ubiquinone-10. Colonies are circular, convex, and glistening, with smooth margins; butyrous in texture; may be colorless or yellow; upon aging, colorless colonies tend to become light brown. In static liquid cultures, cells accumulate as a **surface film** or pellicle and develop as a ring of growth on the vessel wall at or just below the air-liquid interface. Growth in agitated liquid cultures is evenly dispersed.

Chemoorganotrophic and **oligotrophic**; grow optimally in media such as peptone–yeast extract containing 0.05–0.3% (w/v) organic solutes, but not in standard nutrient broth with 0.8% (w/v) organic solutes or richer media such as tryptic soy broth. Do not produce acid or gas from sugars during growth. Optimal temperature for growth 25–30°C; tolerated range for growth 10–35°C. Optimal pH near neutrality; pH 6–9 tolerated. Typically do not grow in media containing 2% (w/v) NaCl. Maximum specific rates of exponential growth 0.17–0.46 h^{-1}. Isolates are diverse in their nutritional requirements. Isolates of one species grow in defined media with glucose or glutamic acid and minerals, other isolates are distinctly stimulated by riboflavin or cyanocobalamin, and some require unidentified growth factors available in peptone. Glucose and glutamic acid are the most widely utilized carbon sources.

Sequences of 16S rDNA are consistent with placement of *Caulobacter* among the *Alphaproteobacteria*. The positions of the 44 sequences grouped as *Caulobacter* in Fig. BXII.α.111 (see "Taxonomic Comments") are represented in Fig. BXII.α.112 by 12 nonredundant sequences which are grouped in Fig. BXII.α.113 and in Fig. BXII.α.114; their strain identities and GenBank accession numbers are displayed in Fig. BXII.α.112. These 12 sequences represent 11 isolates known to exhibit *Caulobacter* phenotypes as well as *Mycoplana segnis*, which is phenotypically distinguishable from *Caulobacter* species. (See "Taxonomic Comments" for descriptions of these trees and for further comments.)

Sources: isolated from distilled, tap and commercial bottled

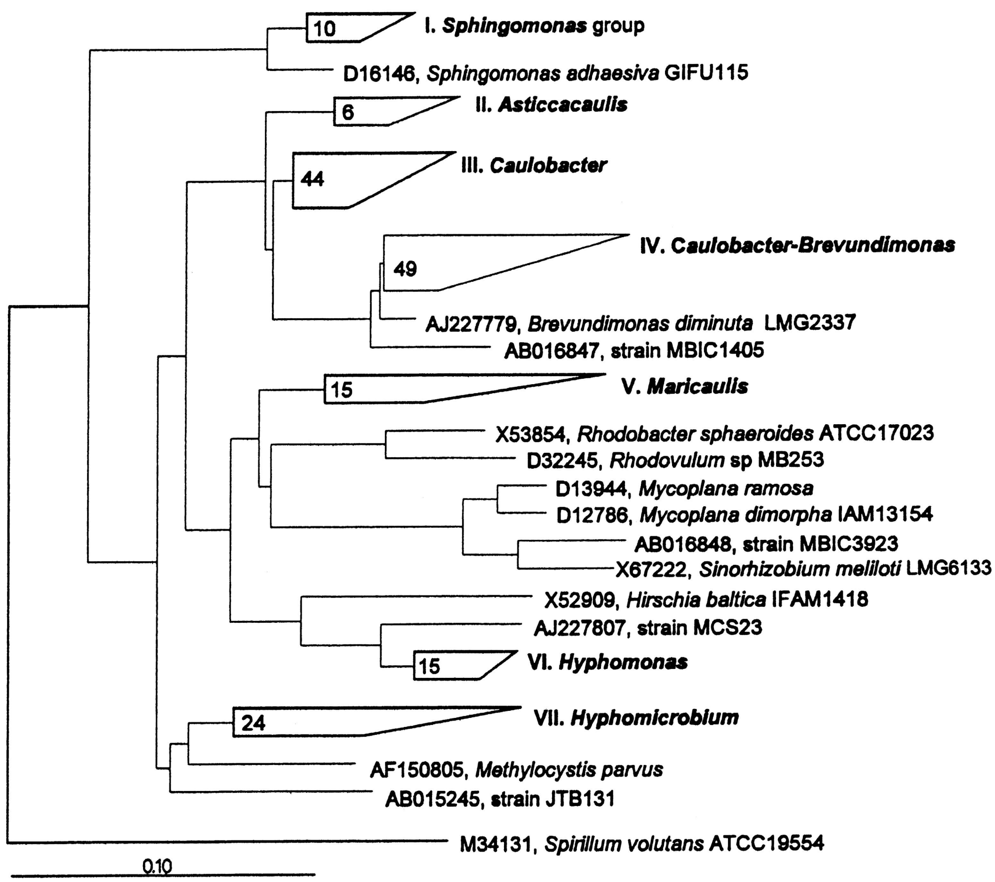

FIGURE BXII.α.111. Phylogenetic tree of 177 16S rDNA sequences built by neighbor-joining analysis, using all available sequences for caulobacters and nonphototrophic hyphal-budding bacteria available as of January 2001. The set includes many sequences that are redundant (determined for the same strain and identical within experimental error), as well as four whose labels are suspect (see text). Within the tree are 99 sequences for caulobacters, 40 for non-phototrophic hyphal-budding bacteria, 13 included by virtue of sequence similarity without phenotypic descriptions of the isolates, and 25 for isolates that are phenotypically distinguishable from prosthecate bacteria. The seven groups accommodate all but 14 of the sequences; excluded are one caulobacter (strain MCS23), one hyphal-budding bacterium (*Hirschia baltica* IFAM1418), three sequences for undescribed organisms, and nine for isolates known to be phenotypically distinguishable from caulobacters and hyphal-budding bacteria. Bar indicates evolutionary distance. Each enclosed numeral indicates the number of sequences grouped. The minimum similarities within each of the caulobacterial genus groups are: I. *Sphingomonas* group (*C. leidyi*), 95.7%; II. *Asticcacaulis*, 95.9%; III. *Caulobacter*, 94.9%; IV. Group IV caulobacters, 94.8%; and V. *Maricaulis*, 94.7%. See Fig. BXII.α.114 for a more stringent (maximum-likelihood) analysis of these sequences.

drinking water, natural bodies of fresh water, and sewage (principally from activated sludge during secondary treatment). Not encountered as clinical isolates and not known to be pathogenic for plants or animals.

The mol% G + C of the DNA is: 62–65.

Type species: **Caulobacter vibrioides** Henrici and Johnson 1935b, 84.

Further descriptive information

Morphology Morphological details of *Caulobacter* cells are illustrated in Fig. BXII.α.115, Fig. BXII.α.116, and Fig. BXII.α.117. Cell shape and life cycle are major characteristics in the description of caulobacters, and the redistribution of these bacteria among five genera (see "Taxonomic Comments") increases the usefulness of morphology in the description of each genus. Cells of *Caulobacter* isolates have distinctly tapered poles; only isolates of the species *C. fusiformis*, atypical in several ways, yet more reasonably accommodated here than elsewhere in the family, lack the distinct curvature of the others, all of which are vibrioid. Neither the sharp tapering nor the cell curvature varies with cultivation in liquid media under conditions that support exponential growth of morphologically uniform populations. Morphology of these, as of most bacteria, becomes aberrant when cells are subjected to conditions unfavorable for growth. In unfavorable conditions (e.g., being buried under millions of other cells in a colony on an agar surface, or in media rich in soluble organic nutrients, ammonium ions, or NaCl), cells may become irregular in many ways, which include branching of cells or of stalks, uneven bloating, failure of stalk elongation, development of supernumerary stalks, loss of motility, heavy shedding of the S-layer and other cell surface components, frequent lysis and, typically, a decrease in ability to form colonies, i.e., loss of viability. Such populations are not suitable for description of the morphology of an isolate.

Morphology is uniform, swarmers are motile, cells are adhesive, stalks elongate, and bands are added through successive

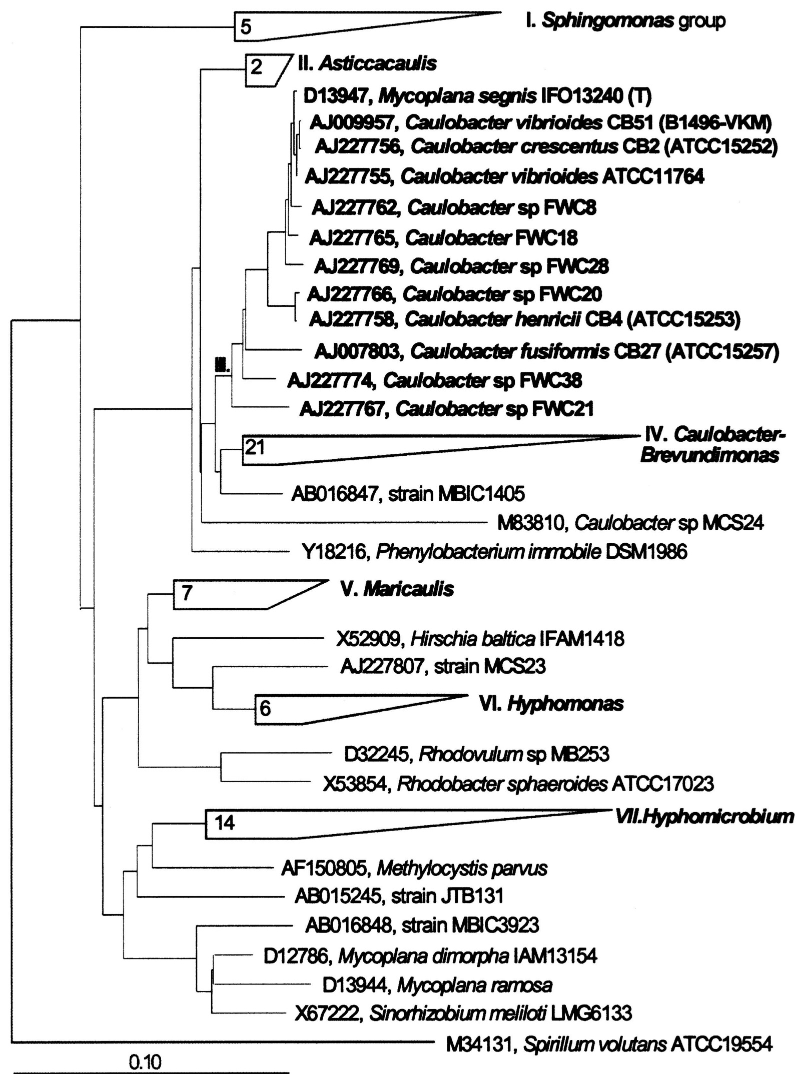

FIGURE BXII.α.112. Phylogenetic tree of 81 16S rDNA sequences, with group III. *Caulobacter* expanded to display GenBank accession numbers and strain identities. (See Fig. BXII.α.114.) Also represented are the positions of sequences AB023427 (by D13947); AB008531, AF125194, AJ227754, AJ227757, AJ227768, M83798, M83799, M83801, M83802, M83803, M83804, and X52281 (by AJ009957 and AJ227756); AJ227761, AJ227763, AJ227764, AJ227773, AJ227776, and AJ227777 (by AJ227755); AJ227770 (by AJ227762); AJ227772 and AJ227775 (by AJ227765); AJ227760 and AJ227771 (by AJ227769); AB008532 and AJ007805 (by AJ227758 and AJ227766); AB008533, AJ227759, and M83796 (misidentified as *Caulobacter bacteroides* strain CB7) (by AJ007803); and M83805 (by AJ227774). Bar indicates evolutionary distance. Each enclosed numeral indicates the number of sequences grouped.

cell cycles when *Caulobacter* isolates are cultivated aerobically in dilute media at neutral pH and at or below 30°C. Isolates identifiable as *Caulobacter* species by additional, non-morphological criteria fail to thrive and typically die in rich media, apparently due to inhibition of one or more steps in their morphogenetic sequence. "Rich" may apply to a single excess nutrient, as demonstrated for ammonium by Felzenberg et al. (1996). Generally, for any isolate, mean stalk length decreases with increasing concentration of nutrients in peptone–yeast extract media and with increasing phosphate concentration in both complex and defined media (Schmidt and Stanier, 1966; Haars and Schmidt, 1974; Poindexter, 1984; Felzenberg et al., 1996; Poindexter and Staley, 1996). Growth of the majority of isolates is adversely affected by phosphate concentrations in excess of 5 mM.

The flagella of most species contain three flagellins of slightly different mobilities (29, 27, and 25 kDa) in denaturing electrophoretic gels. The periodic synthesis and assembly of the flagellum of *C. crescentus* and of chemotaxis proteins are influenced by a hierarchy of expression of dozens of genes that is coordinated with the regulation of many other growth and morphogenetic genes (reviewed in, *inter alia*, Wu and Newton, 1997). The basal body has five rings, rather than the four typical of Gram-negative cells; it is possible that the fifth ring participates in some way in the regular shedding of the *Caulobacter* flagellum that precedes the onset of stalk development and general cellular growth.

Fine structure Stalk bands (see Figs. BXII.α.115D, BXII.α.116C, and BXII.α.117C) occur in all *Caulobacter* isolates. Each band is a set of concentric rings that are more electron-opaque and structurally more rigid than the remainder of the

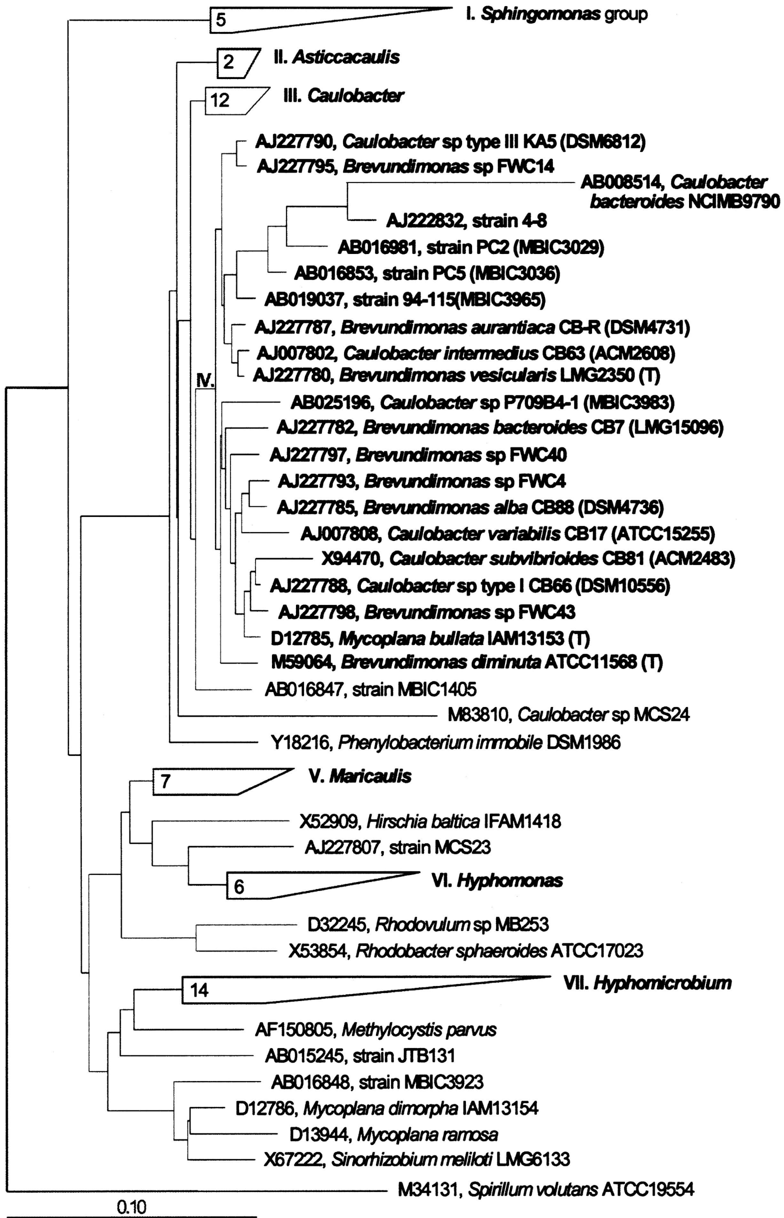

FIGURE BXII.α.113. Phylogenetic tree of 81 16S rDNA sequences, with group IV caulobacters expanded to display GenBank accession numbers and strain identities. (See Fig. BXII.α.114) Also represented are the positions of sequences M83800 (by AJ227795); AB016980 (by AB016981); AB016846, AB016849, AB016850, AB016851, AB016852, and AJ227796 (by AJ227787); AB023784 (by AJ007802); AB021414, AJ007801, and AJ227781 (by AJ227780); AJ227799 and M83808 (by AB025196) (neighbor-joining analysis groups M83810 with these sequences, although maximum-likelihood analysis places it in a unique position); AB008513 and AJ227792 (by AJ227782); AJ227794 (by AJ227793); AB008393 (by AJ227785); AB0083392 and AJ227784 (by X94470); AJ227789 and AJ227791 (by AJ227788). The position of the *Mycoplana bullata* sequence AB023428 is represented by D12785, same species. The positions of *Brevundimonas diminuta* sequences AB021415, AJ227778, and X87274 are represented by M59064, same species. Two additional sequences available for *B. diminuta* are not represented: D49422 falls within this group, but at a unique position, and AJ227779 falls outside the group (see Fig. BXII.α.111). Bar indicates evolutionary distance. Each enclosed numeral indicates the number of sequences grouped.

stalk (Jones and Schmidt, 1973). Earlier evidence that one band is added to the growing stalk during each cell cycle completed by the mature stalked cell of *C. crescentus* (Staley and Jordan, 1973) has been confirmed (Poindexter and Staley, 1996) and this trait exploited in the determination of the reproductive rate of diverse caulobacters *in situ* in a freshwater lake (Poindexter et al., 2000). The stalk band appears to be one more cellular feature to be added to the growing list of cell cycle-regulated events in the life of *C. crescentus*, and presumably of other species as well.

The cell and stalk of *C. crescentus* have long been known to be coated with an S-layer (Poindexter et al., 1967), a cellular feature of a wide variety of both Gram-negative and -positive bacteria (Sleytr et al., 1988). J. Smit and his coworkers have dem-

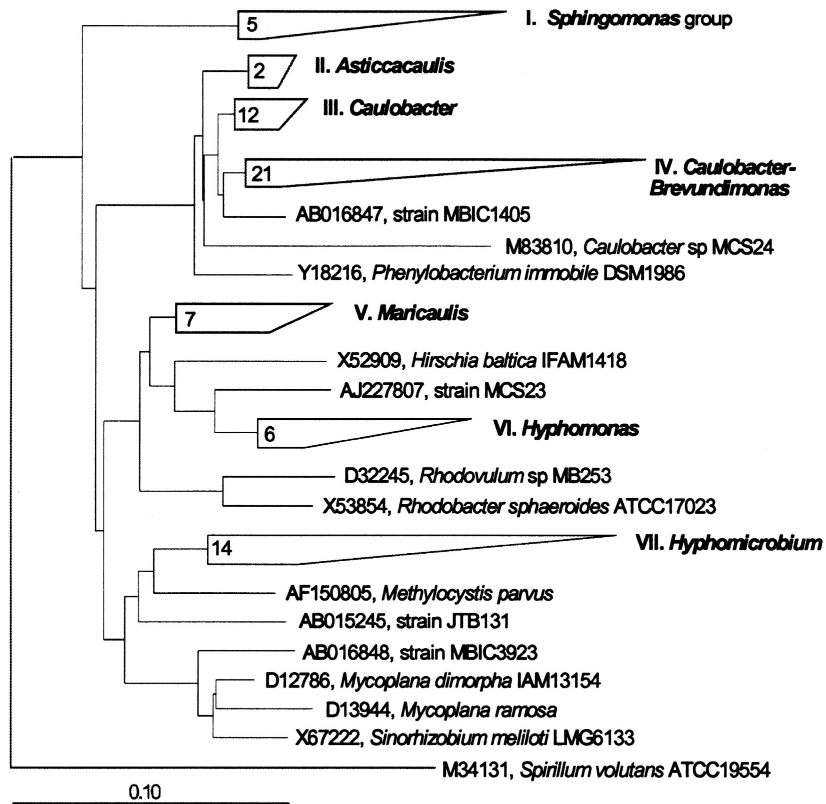

FIGURE BXII.α.114. Phylogenetic tree of 98 16S rDNA sequences built by maximum likelihood (DeSoete) analysis. After removal of redundant sequences (determined to be for the same strain and identical within experimental error), the four sequences whose labels are suspect, and one sequence that appeared to be only very distantly related (X97079, strain TM16; not described phenotypically), all positions of the complete tree are here represented by 81 sequences: 37 for caulobacters, 20 for hyphal-budding bacteria, 14 for bacteria phenotypically distinguishable as nonprosthecate bacteria, and 10 included by virtue of sequence similarity without phenotypic descriptions of the isolates. Relevant branches are expanded in Fig. BXII.α.112 and BXII.α.113 and in other chapters (*Asticcacaulis*, Fig. BXII.α.119 and *Maricaulis* Fig. BXII.α.76), where GenBank accession numbers and strain identities are shown, and sequences represented but not shown are listed in the legends. Bar indicates evolutionary distance. Each enclosed numeral indicates the number of sequences grouped.

onstrated that this structural feature is typical of *Caulobacter* isolates; exceptions occur only among isolates that are atypical in other respects as well. Attachment of the S-layer to the cell surface is mediated by calcium and requires an anchoring oligosaccharide. Both the S-layer protein and the oligosaccharide are antigenic, and serological cross-reaction occurs among the S-layers and their anchors (Walker et al., 1992). An S-layer gene probe prepared from *C. crescentus* detects similar genes in most *Caulobacter* isolates, but not in Group IV caulobacters or random nonprosthecate isolates from wastewater samples that yielded *Caulobacter* spp., suggesting one cultivation-independent means for enumeration of *Caulobacter* spp. in environmental samples (MacRae and Smit, 1991). Although an S-layer may provide some defense against *Bdellovibrio* predation (Koval and Hynes, 1991), the function of this layer is as uncertain in *Caulobacter* species as it is in other bacteria.

A third surface structure of all caulobacters is the holdfast. Again, it is J. Smit and his coworkers who have most thoroughly examined this structure, both in regard to its chemistry (Merker and Smit, 1988; MacRae and Smit, 1991; Abraham et al., 1999) and (in *C. crescentus*) its genetics (Mitchell and Smit, 1990). As noted by Merker and Smit (1988), the function of this organelle is uncomplicated in caulobacters; in nature, it serves to mediate adhesion of the cell to surfaces. It does not coat the entire cell surface, trap molecules, or join cells in biofilms. In dense laboratory cultures, cells stick to each other in rosettes; while that is helpful in recognition and differentiation of caulobacter isolates by microscopy, it is an artifact of cultivation (Poindexter, 1964). Some *Caulobacter* species also bear pili, which typically arise around the base of the flagellum and disappear as stalk development is initiated. Pili probably also participate in adhesion of cells to surfaces, and are demonstrably able to bind RNA bacteriophages (Schmidt, 1966).

Assays based on the binding of plant lectins by holdfasts, the susceptibility of adhesiveness to competition by monomers, dimers and trimers of *N*-acetylglucosamine, and the stability of adhesion in the presence of various hydrolytic enzymes have consistently implied that the holdfasts of most *Caulobacter*, Group IV caulobacters, and *Maricaulis* (but not *C. leidyi*) isolates consist of or contain some oligo-*N*-acetylglucosamine that participates in adhesion. In contrast to the marine caulobacters, all of which bind wheat-germ agglutinin (WGA) on their holdfasts, some isolates of each of the freshwater genera did not bind WGA; some of those also failed to bind any of six other lectins tested, indicating some diversity of holdfast composition in the freshwater genera (Merker and Smit, 1988).

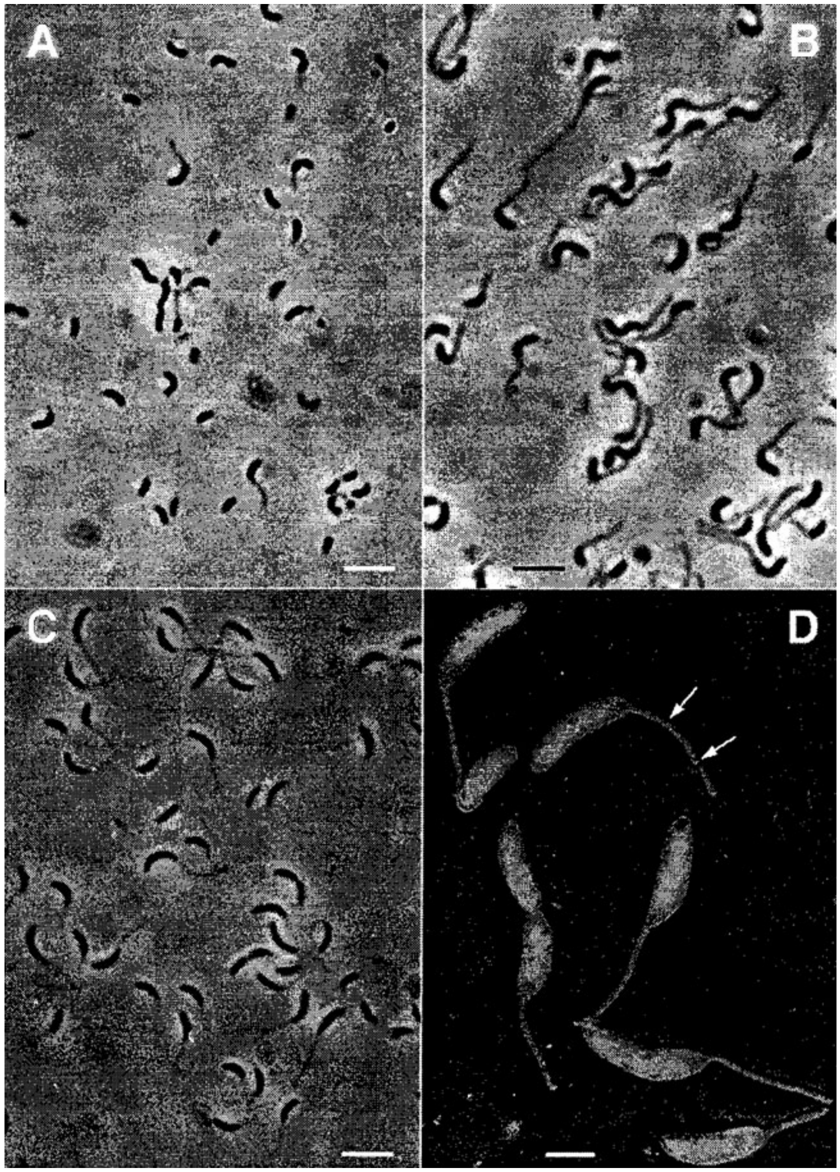

FIGURE BXII.α.115. *C. crescentus* grown in peptone–yeast extract medium (*A*) and in glucose–glutamate minimal medium (*B–D*). *A–B*, strain CB15 (ATCC19089), phase-contrast microscopy of dried smears to which Gray's flagella stain mordant and cover slips were added. *C–D*, strain CB2 (ATCC15252). *C*, phase-contrast microscopy, wet mount. *D*, electron microscopy, shadowed specimen, negative image; arrows indicate stalk bands. Bars = 5 μm (*A–C*) and 1 μm (*D*).

Cellular composition All isolates examined possess a thin peptidoglycan sacculus that extends continuously through the cell pole into the stalk. The peptidoglycan is composed of essentially the same directly cross-linked, diaminopimelic acid-containing polymer that is typical of Gram-negative bacteria. However, while whole-cell peptidoglycan exhibits a 50% excess of muramic acid over glucosamine (Poindexter and Hagenzieker, 1982), the relative proportions of the two sugars appear to be reversed in the stalk peptidoglycan, which has been assayed separately only for *C. crescentus*. This implies that stalk outgrowth involves a modification of the peptidoglycan or of its synthesis. The composition of the peptide side chains of the peptidoglycan may vary with medium composition; glycine is a component in some media (Markiewicz et al., 1983), but it is not invariably detected in the peptidoglycan. Major membrane proteins unique to the stalk have not been discerned.

The principal phospholipid in *Caulobacter* and group IV caulobacter cells is phosphatidylglycerol, and the most abundant fatty acid species are $C_{18:1}$ and $C_{16:0}$. All isolates tested also contain lower, but significant amounts of $C_{18:1\ \omega7c\ 11CH_3}$ and of species of $C_{17:1}$, $C_{16:1}$, $C_{17:0}$, $C_{15:0}$, $C_{14:0}$. *Caulobacter* isolates contain $C_{12:1\ 3OH}$ and an irresolvable mixture of C_{12} fatty acids designated ECL 11.798 by Abraham et al. (1999). A single type of phosphoglucolipid (PGL), 3-O-[6′-(*sn*-glycero-3′-phosphoryl)-α-D-glycopyranosyl]-*sn*-glycerol, is identifiable in this genus. This is lipid pattern C of Abraham et al. (1997), found in 34 of 37 *Caulobacter* isolates, but in only one of 19 Group IV caulobacter isolates tested. The three exceptional *Caulobacter* strains contained PGLs

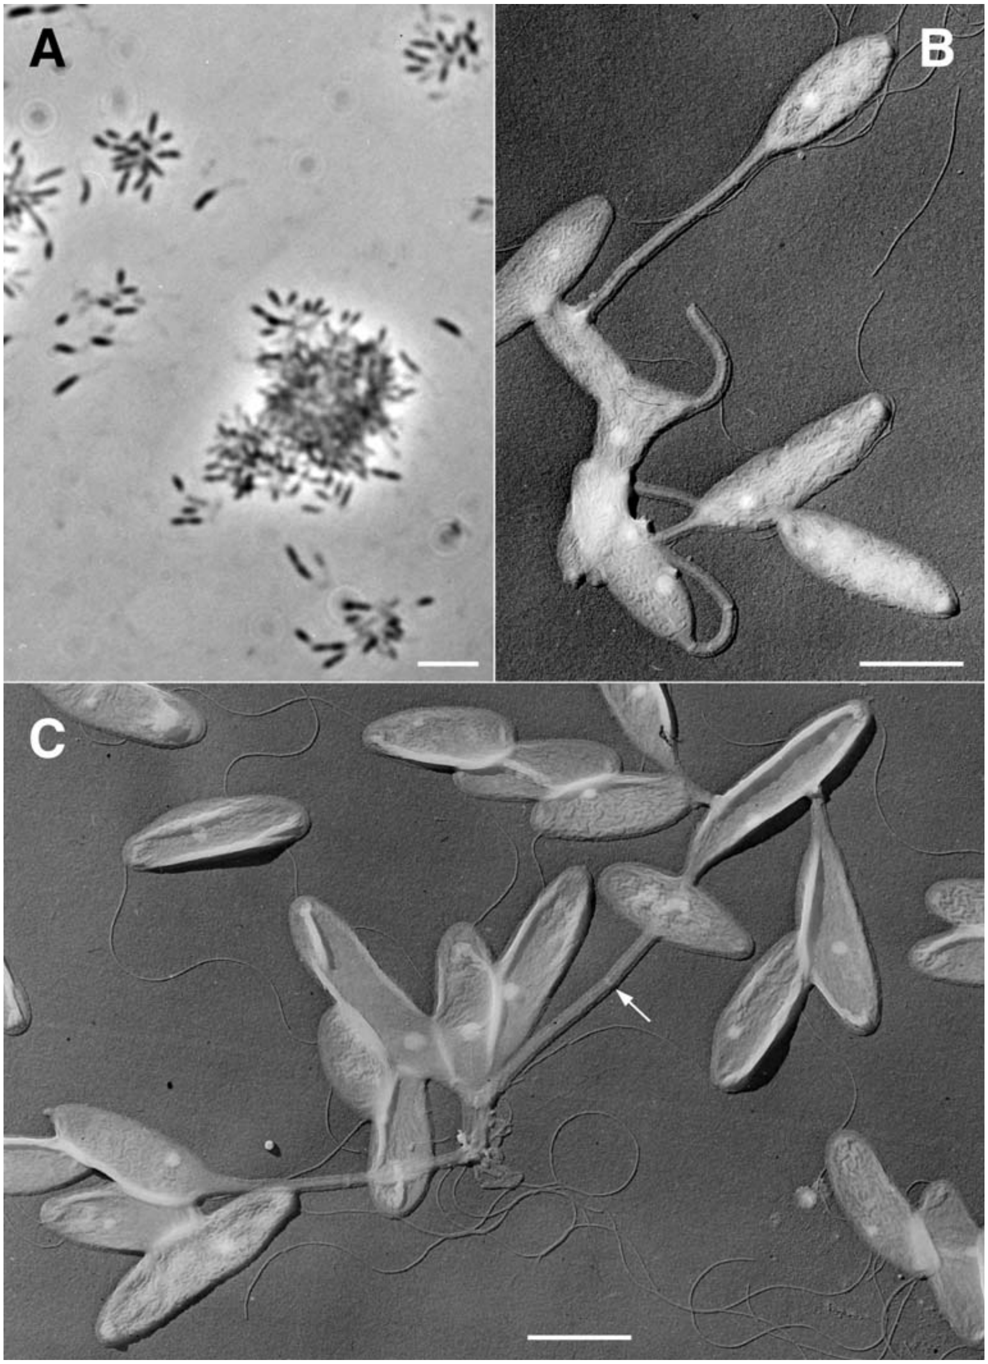

FIGURE BXII.α.116. *C. fusiformis* strain CB27 (ATCC15257) grown in peptone–yeast extract medium. *A*, phase-contrast microscopy, wet mount. Bar = 5 µm. *B–C*, electron microscopy, shadowed specimen, negative image. *Arrow* in (*C*) indicates a stalk band. Y-shaped cells, like the one visible here, are not common. Bars = 1 µm.

that also occur in some Group IV caulobacter isolates. Typically, Group IV caulobacters are distinguished from *Caulobacter* by the presence of $C_{12:0\ 3OH}$ and the absence of $C_{12:1\ 3OH}$ and ECL 11.798. Eight of 12 Group IV caulobacter isolates analyzed contain the PGL typical of *Caulobacter,* and all 12 also contain at least two other PGL types resolvable by the chromatographic methods used in these analyses. This is lipid pattern B of Abraham et al. (1997), found in 18 of 19 Group IV caulobacter isolates, but in only two of 37 *Caulobacter* isolates tested. Five of 12 Group IV caulobacter isolates also contain sulfoquinovosyl diacylglycerols, one of which was identified as 1-O(α-6′,6-deoxy-aldohexopyranosyl-6'-sulfonic acid)-3-O-diacylglycerol. Such compounds are uncommon in nonphototrophic bacteria, but are typical of *Maricaulis* isolates.

Enzymes As far as tested, *Caulobacter* and Group IV caulobacters employ the Entner–Doudoroff pathway for hexose catabolism. Enzymes for catabolism of some carbohydrates are induced by exposure to substrate, but induced levels are not much more than 10-fold higher than noninduced levels (Poindexter,

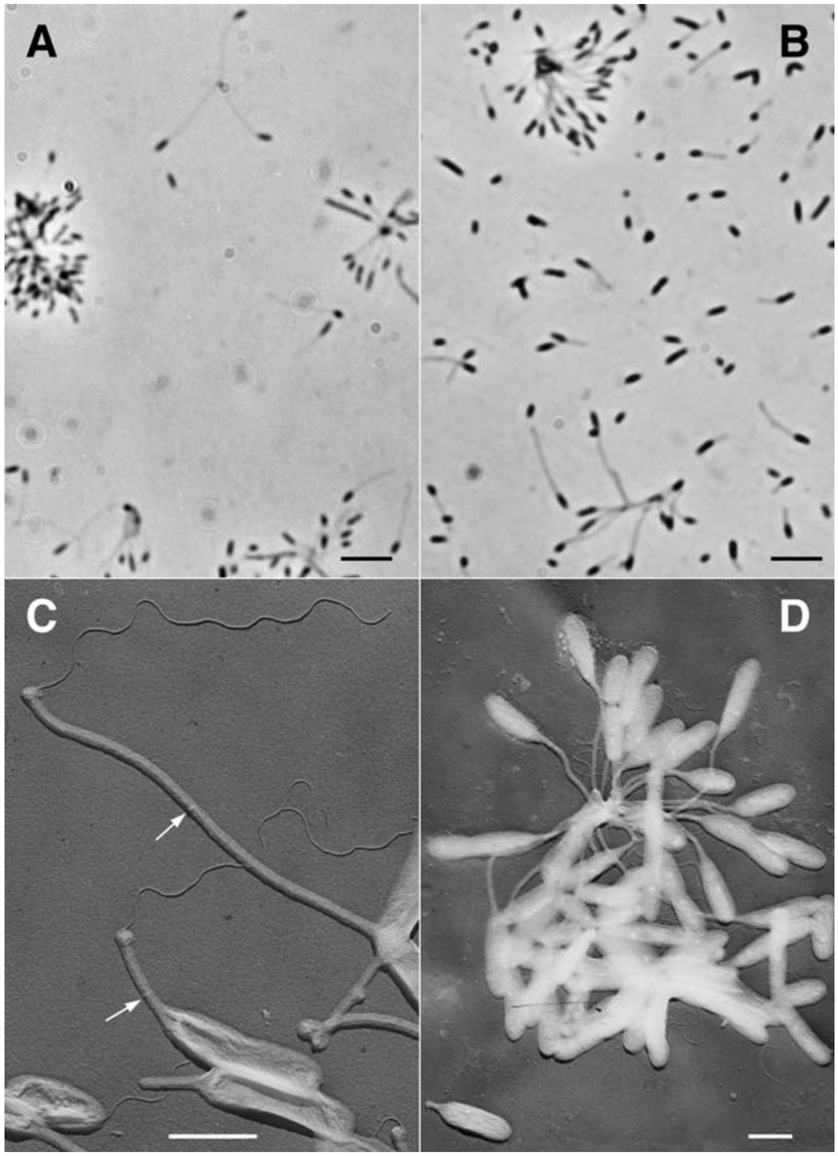

FIGURE BXII.α.117. Group IV caulobacter isolates of the bacteroides cell shape grown in peptone–yeast extract medium. *A–C*, strain 25 (VKM v-1183); *D*, strain CB11a (ATCC19090). *A*, phase-contrast microscopy, wet mount. *B*, phase-contrast microscopy of dried smear to which Gray's flagella stain mordant and cover slip were added. *C–D*, electron microscopy, shadowed specimens, negative image. *Arrows* in *C* indicate stalk bands. *A–B*, Bars = 5 μm; *C–D*, Bars = 1 μm.

1981). Ammonium assimilation has been examined only in *C. crescentus*, which lacks glutamic dehydrogenase and employs the glutamine synthetase–glutamate synthase system only (Ely et al., 1978). This may in part account for susceptibility of growth to excessive (relative to glutamate) availability of ammonium (Felzenberg et al., 1996). *C. crescentus* cells have more than one enzymatic defense against toxic oxygen species. Two superoxide dismutases (SOD) are made, a cytoplasmic Fe-SOD and a Cu-Zn-SOD that is localized in the periplasm (Steinman and Ely, 1990); the ability of the periplasmic enzyme to protect cells against extracellular superoxide has been demonstrated (Schnell and Steinmann, 1995). *C. crescentus* also produces a catalase/peroxidase whose activity increases significantly in the stationary phase of laboratory cultures (Schnell and Steinmann, 1995). The presence, location, and inducibility of these enzymes may contribute to two characteristics of caulobacter ecology: their tolerance of close association with O_2 generators such as algae, and their slow deterioration during periods of nutrient deprivation.

Genome structure The complete genome sequence of *Caulobacter crescentus* strain CB15 has been determined (Nierman et al., 2001) and is available through GenBank as accession number AE005673. *C. crescentus* was the first free-living alphaproteobacterium to be analyzed this thoroughly. In the report an interpretation of the genome structure and probable roles of the 3767 genes recognized is presented. The report by Nierman et al., (2001), in particular, gives considerable attention to the characteristics of this genome that are consistent with the oligotrophic, aquatic existence of the organism.

DNA–DNA hybridization has not been used extensively with caulobacters since the study by Moore et al. (1978), where only *C. vibrioides* and *C. crescentus* showed hybridization values greater than 58%, and some pairs of strains were more than 90% homologous. Analysis of restriction endonuclease digests of the 16S–23S rDNA interspacer regions (ISR) of *C. vibrioides* and *C. crescentus* strains and of other *Caulobacter* isolates revealed two patterns, but neither was indicative of either species (Abraham et al., 1999). More such analyses—both hybridization and ISR analysis—would be helpful in determining the extent of genomic overlap between isolates that grow vigorously, rapidly, and independently of riboflavin (*C. crescentus*) and those that grow at lower rates, with lower yields, and require both riboflavin and other unidentified organic micronutrients (*C. vibrioides*).

Plasmids, often quite large (>50 kb), have been detected in some *Caulobacter* and Group IV caulobacter isolates (Gregory and Staley, 1982; Schoenlein and Ely, 1983; MacRae and Smit, 1991). The identities of genes on the native plasmids have not yet been determined. However, expression of several foreign plasmid-borne genes has been demonstrated in *C. crescentus*. These include genes for mosquitocidal toxins from Gram-positive bacteria (Thanabalu et al., 1992), and a phosphate-regulated porin gene from *Pseudomonas aeruginosa* (Walker et al., 1991). Ribosomal rDNA sequences have been determined for a large number of caulobacter isolates. *Caulobacter* sequences constitute one of five coherent groups among caulobacterial sequences. The minimum similarity among sequences grouped within "III. *Caulobacter*" in Fig. BXII.α.111 is 94.9%. All known sequences for 16S rDNA are less similar except sequences for organisms identified as *Mycoplana segnis* (95.9–99.9%) and *Phenylobacterium immobile* (95.5–96.4%). See "Taxonomic Comments," below, for further discussion of 16S rDNA sequences and of bacteriophages.

Antibiotic susceptibilities *Caulobacter* and Group IV caulobacter isolates obtained from natural fresh water and from drinking water have usually exhibited susceptibility to both cell wall- and protein synthesis-inhibiting antibiotics (Poindexter, 1964; Nikitin et al., 1990; MacRae and Smit, 1991), but resistance has been encountered in the majority of isolates from wastewater treatment systems. Some of those isolates appear resistant to antibiotics of various chemical types, targets, and mechanisms of antibacterial action, implying that sewage treatment facilities—like hospitals—may provide environments that encourage the propagation, and possibly the transfer, of genes for antibiotic resistance (MacRae and Smit, 1991).

Enrichment and Isolation Procedures

Because of their unique morphology, caulobacter cells can be recognized in natural materials by phase-contrast and electron microscopy. Generally, they are most readily observed in water samples with low soluble organic nutrient content and among the bacteria attached to the surfaces of algal thalli. They are commonly found among the bacterial contaminants of unialgal cultures and may influence the course of development in the algae (Klaveness, 1982). They are also frequently detected in moist soils, either attached to diatoms or among members of rhizosphere communities, and in activated sludge. In samples from such environments, particularly aqueous ones, caulobacters may account for more than 40 of every 100 viable aerobic, oligotrophic, chemoheterotrophic bacteria. When they occur in such relative abundance, caulobacters can be isolated by direct plating, and their colonies identified and selected for purification as described below for colonies from enrichment cultures.

The lack of identification of any physiologic peculiarity within this group has prevented the development of a strongly selective enrichment procedure. Enrichment depends on a mechanical process: the accumulation of stalked cells in the air–water interface of a water sample or soil extract that has been protected during incubation and examination against turbulence, which would disturb the air–water interface. The most dependable, although tedious, procedure for enrichment and isolation of caulobacters has not changed since it was introduced by Houwink (1955). A sample of water or a water extract of soil is enriched with at most 0.01% (w/v) peptone and allowed to stand at room temperature. Within a few days, a sample of the surface film is taken with a bacteriological loop or a cover slip and is examined by phase-contrast microscopy for the presence of stalked cells. Some cells may possess a stalk at each pole and so be indistinguishable from *Prosthecobacter* (*q.v.*) until clones have been isolated and examined for the motility characteristic of caulobacters. When caulobacter cells account for 10–50% of the population, a sample (again, taken with a loop, not a pipette) is streaked on a dilute (0.05%, maximum 0.1%, w/v) peptone or peptone–yeast extract medium prepared with 1.0% or 1.5% agar. By the third or fourth day of incubation, small, hyaline or crystalline, non-iridescent colonies of caulobacters begin to appear. It is helpful to remove these colonies while they are very small, by using sterile toothpicks, to small sites ("patches") on secondary plates, for two reasons. First, samples of oligotrophic populations often include bacteria that swarm as a continuous film on the agar surface and invade other colonies. Second, preparation of a wet mount to screen the initial, small colony may consume the entire colony. It is preferable to begin microscopic screening only after the patches of growth on the secondary plate have developed.

Identification requires phase-contrast microscopy because of the small diameter of the stalk (<0.2 μm), which is below the resolution afforded by ordinary light microscopy. The addition of a stain to the wet mount or the use of a mordanted stain such as is designed for flagella may be helpful. The mordant alone applied to dried smears clearly reveals stalks by phase-contrast microscopy. However, examination of wet mounts of living cells is necessary because motility is characteristic of caulobacters, and its detection aids particularly in distinguishing caulobacter and Group IV caulobacters from *Prosthecobacter*. In the dense populations developed on an agar surface, caulobacter cells will adhere to each other's holdfasts, and the characteristic rosettes with cells peripheral to the stalks, which are united in a common holdfast, are often the most dependable way to detect the presence of stalks. In enrichment samples and in pure populations, stalked cells become trapped within air bubbles in wet mounts, and stalks not clearly discernible in the suspended population are more obvious in such regions.

Typical caulobacters multiply less rapidly than do bacteria such as *Pseudomonas* and *Flavobacterium* species that are often present in the same samples. It has been suggested that serial dilutions of the sample might allow the caulobacters to develop without becoming outnumbered by such other types. However, this procedure is suitable only when the caulobacters are initially predominant and are not attached to other cells, two conditions not commonly met. Particularly in dilute media, the bacteria that develop first exhaust the nutrients and preclude multiplication of slower organisms, even if those were more numerous in the initial sample (Belyaev, 1967; Poindexter, unpublished).

It is also possible to enrich a water sample *in situ* by "baiting" the caulobacters with cover slips, to which they will attach. The submerged cover slip can be removed, rinsed well with sterile water, then used as inoculum for a stationary culture as described above. Caulobacter attachment is tenacious; the cells cannot be efficiently scraped from the cover slip but should be allowed to release swarmers by cell division. Some success with thin plastic foil carefully laid on the surface of quiet water has also been reported.

In any of these procedures, the most helpful factor important to successful isolation is that the sample be low in soluble organic nutrient content. Caulobacters are not necessarily absent from richer samples, but their proportion is typically low, and their reproductive rate is not competitive in nutrient-rich cultures. Nevertheless, they can be isolated from soil (e.g., Poindexter, 1964; Belyaev, 1969) and from wastewater treatment facilities, particularly from secondary-stage activated sludge (MacRae and Smit, 1991).

Maintenance Procedures

Once isolated, *Caulobacter* species can be dependably maintained in at least four ways. First, vegetative stocks should be maintained on 1% agar slants of dilute (0.05–0.3% organic material) complex medium or defined medium (if possible, with a given isolate) that contains at least 100 mg organic carbon/mg phosphate-phosphorus and 1 mM each of $MgSO_4$ and $CaCl_2$. Such a medium promotes the storage of carbon reserves and prolongs the viability of the population during storage. Isolates should be transferred every 8 or 9 weeks, incubated 2 or 3 days at 20–25°C (higher incubation temperatures reduce stability during storage), then refrigerated. Second, cells grown in dilute complex medium can be stored in small volumes frozen at −70°C without cryoprotectant. Survival varies among isolates, ranging from 10 to 50%. Such frozen cultures can be thawed at room temperature and transferred to growth medium to resume vegetative cultivation. This is the most dependable method of maintenance of freshwater and soil caulobacters. Third, washed cells diluted to 10^3–10^4 cells/ml of sterile water and sealed in ampules can be stored at room temperature for 2–3 years. This procedure is more dependable than lyophilization but requires periodic recultivation. The fourth method, lyophilization, is the least dependable means of maintenance. If a protectant such as milk solids is used, the rehydrated specimen should be diluted immediately in order to avoid the inhibitory effect of the solids. Lyophilization on strips of sterile filter paper, without any additive, has proven to be the most dependable means of lyophilization.

Procedures for Testing Special Characters

All caulobacter species groups are distinguished by the morphology of the dividing cell—specifically, by the asymmetry of its appendages. Both appendages are best characterized by electron microscopy. Shadowed specimens provide the clearest image, but negatively stained specimens need not be washed and so preserve a higher proportion of attached flagella. The holdfast is best detected by its adhesive function, although it, too, is discernible by electron microscopy.

Differentiation of the genus *Caulobacter* from other genera

Three groups of bacteria other than caulobacters produce long cellular appendages of the envelope that are of constant diameter. These bacteria may occur in habitats with caulobacters, and a motile stage is produced by one type (Poindexter, 1992). Nevertheless, they are distinguishable from caulobacters, and from each other, by the morphology of their reproductive stages, as shown in Table BXII.α.101. Relationships to non-prosthecate bacteria implied by 16S rDNA analysis are illustrated and discussed under "Taxonomic Comments," below. The five species groups of caulobacters are distinguished as shown in Table BXII.α.102.

Taxonomic Comments

The genus *Caulobacter* was created by Henrici and Johnson (1935b) on the basis of their observations of bacterial populations attached to slides submerged in a freshwater lake. They did not obtain isolates or study pure cultures. Nevertheless, they correctly inferred the developmental sequence of the life cycle and recognized that this type of bacterium was unique. The laboratories of several investigators, notably Shapiro, Newton, Brün, Mullins, Gomes, Marczynski, Gober, and Ely, continue to explore that life cycle and the intricate regulatory genetic system that guides it (Gober and Marques, 1995; Marczynski and Shapiro, 1995; Wu and Newton, 1997). Those genetic and developmental studies have exploited the ability of the species *C. crescentus* to grow in unsupplemented, chemically defined media and thereby to present itself as the caulobacter most suitable for detectable expression of genetic change. *C. crescentus* has been found to be amenable to various means of genetic manipulation and analysis and is now one of the most thoroughly characterized bacterial genomic systems. Focus on that species has yielded a vast amount of information with considerable significance for prokaryotic developmental biology and molecular genetics. The major taxonomic import of those studies is the finding that the type of asymmetric cell division unique to the caulobacters reflects a complex of genes, not a single gene or operon or cassette, whose expression has been interwoven into the information that guides reproduction and on which viability depends. Whatever the non-prosthecate ancestry of this group, evolution of the caulobacter type of life cycle has clearly involved steps that led to a nearly irreversible commitment to it. The rarest morphogenetic mutant of *C. crescentus* is a stalkless but otherwise unaltered clone, although loss of motility or of adhesiveness can occur through mutations that do not affect other aspects of morphogenesis or viability. Nature may yet provide a recognizable stalkless caulobacter, but at first isolation, it is certain to be assigned to a non-prosthecate taxon. Meanwhile, nature does provide a diversity of bacterial types that exhibit the life cycle inferred by Henrici and Johnson. That diversity is the focus of this and two other chapters (*Asticcacaulis* and *Maricaulis*) in this *Manual*. These comments are related to all three chapters and to all four species groups. (*C. leidyi* is not included in this edition of the *Manual*.)

The initial system for classification of species of caulobacters (Poindexter, 1964; Poindexter and Lewis, 1966), continued in previous editions of this *Manual* (Poindexter, 1974, 1989), employed cell morphology as the principal subdividing criterion, in part because of the limited availability of other significant taxonomic criteria. More compelling, however, was the recognition that cell form under standard conditions is a complex and highly conserved feature of unicellular organisms; a feature such as cell pole contour is intimately associated with the reproductive mechanism, and mutations that affect cell shape can be lethal when expressed and often can be studied only in conditional mutants.

More than a decade of chemotaxonomic, ultrastructural, and genomic studies of the caulobacters has yielded taxonomically useful information that can now be added to morphological and

nutritional traits in the continuing effort to recognize relationships among caulobacters and propose a phylogenetic classification.

As of 1 January 2001, 153 16S rDNA sequences of at least 1200 nucleotides in length, representing 71 caulobacter isolates and 39 isolates of hyphal budding bacteria, had been deposited with data banks. All 153 sequences, plus 24 sequences for other bacteria, were used to build a series of trees to guide this reconsideration of caulobacter classification. Neighbor-joining, maximum likelihood, and parsimony analyses repeatedly generated four major groups, which were further divisible into seven subgroups—five of caulobacters and two of hyphal budding bacteria. The tree shown in Fig. BXII.α.118 exemplifies the core topology of those trees. The tree displays the identity and location of 58 sequences, as follows: 1) all 37 sequences available for type strains of species and subspecies of caulobacters and hyphal budding bacteria that have been named or proposed; 2) 20 for strains for which sufficient phenotypic characterization is available to regard them as dimorphic prosthecate bacteria and as representative of other unnamed isolates with similar descriptions and similar sequences; 3) a sequence for *Spirillum volutans*, a genus of *Alphaproteobacteria* that occurs in caulobacter-laden waters. A neighbor-joining tree built using all 177 sequences is shown as groups of sequences in Fig. BXII.α.111. A DeSoete maximum-likelihood tree built using 98 sequences (trimmed here to 81: 57 nonredundant sequences for caulobacters and hyphal-budding bacteria, the 13 most similar sequences that could be found among nonprosthecate bacteria, 10 similar sequences for organisms of unknown phenotype, and the *S. volutans* sequence) is shown as groups of sequences in Fig. BXII.α.114. The relevant branches of this tree are expanded to display strain identity and sequence accession numbers for *Caulobacter* (Fig. BXII.α.112), Group IV caulobacters (Fig. BXII.α.113), *Asticcacaulis* (Fig. BXII.α.119), and *Maricaulis* (Fig. BXII.α.76 in the *Maricaulis* chapter), along with the positions of other similar sequences.

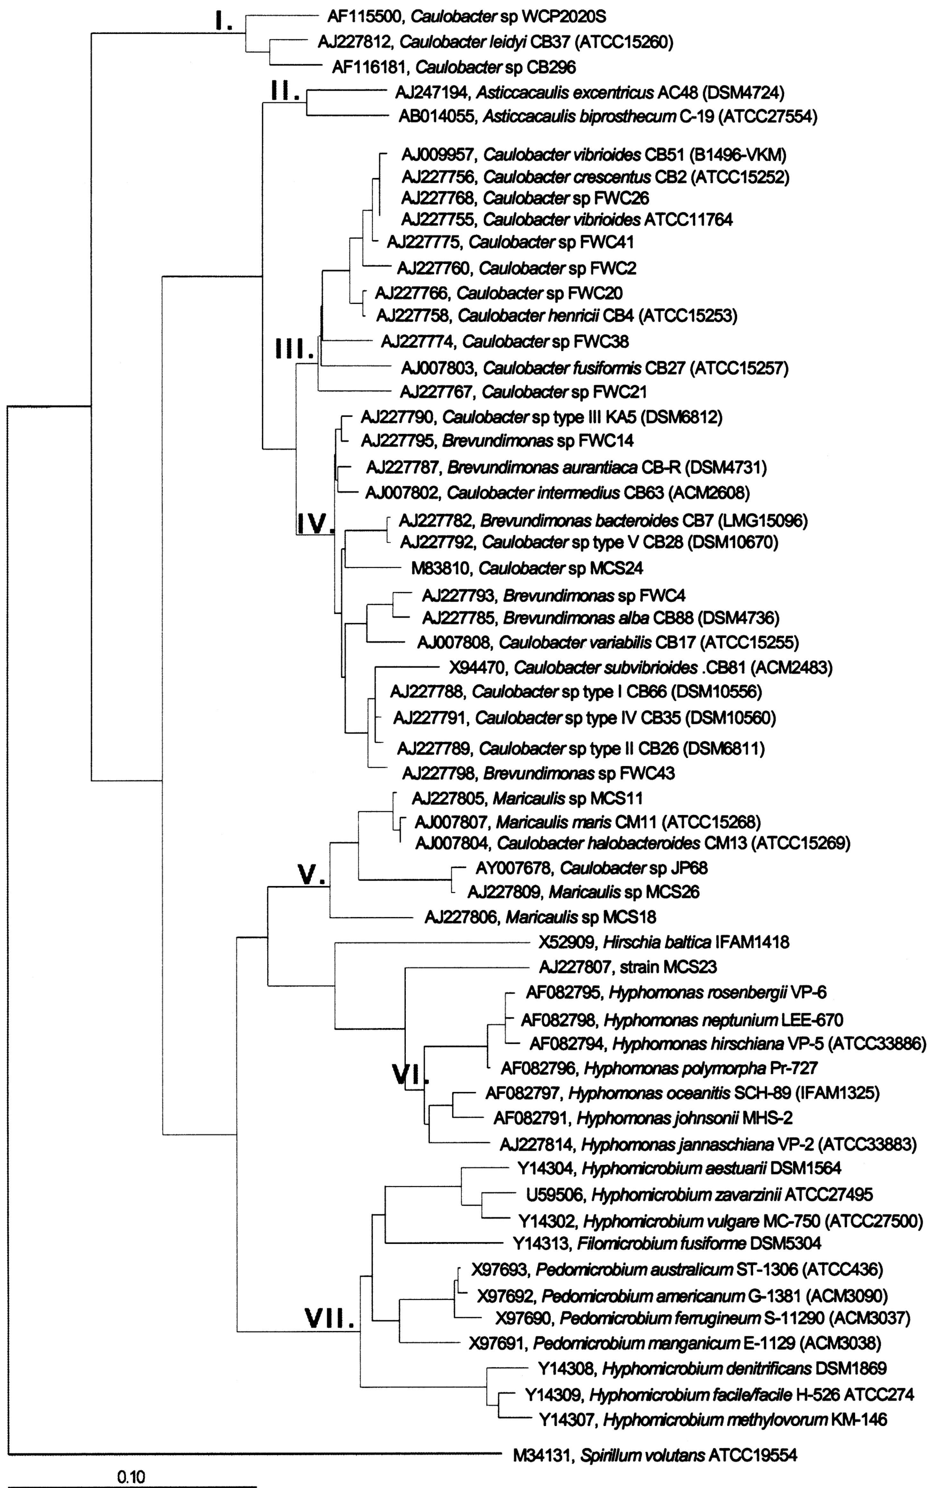

FIGURE BXII.α.118. Phylogenetic tree of 58 16S rDNA sequences of caulobacters (38), nonphototrophic hyphal-budding bacteria (19), and *Spirillum volutans* (1) built using maximum likelihood (PAUP 4.0) analysis. The correlations between 16S rDNA pattern and genus are as follows. I. *Sphingomonas* group (*C. leidyi*), II. *Asticcacaulis*, III. *Caulobacter*, IV. Group IV caulobacters, V. *Maricaulis*, VI. *Hyphomonas*, VII. *Hyphomicrobium*. Bar indicates evolutionary distance.

The four major groups of caulobacters and hyphal budding bacteria reflect the natural distribution of these organisms: a pair of genera (*Maricaulis* and *Hyphomonas*) characteristically isolated from marine habitats; three species groups (*Caulobacter*, *Asticcacaulis*, and the group IV caulobacters) encountered principally in freshwater environments; a diverse group (which includes *C. leidyi*) isolated from soil, arthropod guts, desert soils, mine tailings, and fresh water that exhibit exceptional tolerance toward

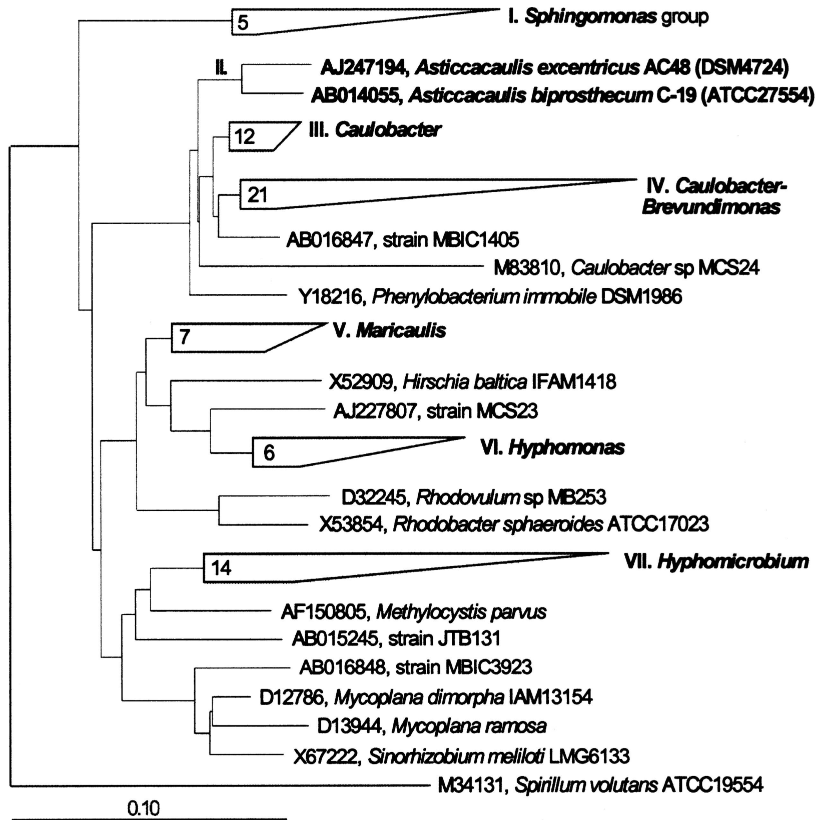

FIGURE BXII.α.119. Phylogenetic tree of 81 16S rDNA sequences, with group II. *Asticcacaulis* to display GenBank accession numbers and strain identities (see Fig. BXII.α.114 in the *Caulobacter* chapter). Also represented are the positions of sequences AB016610 and AF115499 (by AJ247194), and AF115501 and AJ247193 (by AB014055). Bar indicates evolutionary distance. Each enclosed numeral indicates the number of sequences grouped.

changes in environmental conditions; and oligocarbophilic, CO_2-dependent methylotrophs (*Hyphomicrobium*) that are widely distributed in soil, water, and sewage systems. Natural distribution and 16S rDNA sequence similarities correlate with differences in morphology, life cycle, certain nutritional and physiological properties, and details of ultrastructure and cell composition. Accordingly, they seem to constitute well-defined taxa, and the seven subgroups should be genera.

BLAST searches among GenBank sequences revealed different relationships outside the seven groups. Sequences like those of *C. leidyi* are more similar to sequences of *Sphingomonas* species than to those of any of the other caulobacters, whereas the sequences of the two species of *Asticcacaulis* appear to be meaningfully similar only to sequences of *Caulobacter* and Group IV caulobacters. The sequence of one species of Gram-negative branching bacteria, *Mycoplana segnis*, is similar to some *Caulobacter* sequences. At least one strain of *M. segnis* contains cellular lipids similar to those found in *Caulobacter* isolates, but this organism is readily distinguished from caulobacters by its morphology, its lack of adhesiveness, its reproduction by multiple fragmentation, its peritrichous flagella, and much of its physiology. The sequences of other *Mycoplana* spp. group near other prosthecate bacteria: *M. bullata* near Group IV caulobacters and *M. dimorpha* and *M. ramosa* near *Hyphomicrobium*. Whether these sequence similarities imply an evolutionary relationship between branching and prostheca development cannot be assessed at present.

Some Group IV caulobacter sequences are noticeably similar to sequences of the two nonprosthecate species of *Brevundimonas* (*B. diminuta* and *B. vesicularis*); *B. vesicularis*, in particular, also shares similarities of lipid composition with Group IV caulobacters. As suggested by Abraham et al. (1999), it is conceivable that the *Brevundimonas* species are of prosthecate ancestry, but are now "locked in the motile phase" (Abraham et al., 1999, p. 1070). However, general phenotypic similarity is low, and without the prosthecate species, *Brevundimonas* comfortably accommodates nonstalked, small rods that bear short-wavelength, polar flagella, divide symmetrically, and grow abundantly on rich media designed for the isolation and cultivation of clinically encountered microorganisms.

The greater similarity of sequences of the two marine genera to each other than to any of the nonmarine groups strongly suggests an independent evolutionary origin of the appendages in the marine organisms. The absence of bands from the stalks of marine caulobacters (Anast and Smit, 1988), as from all budding hyphae, supports the inference that the stalks of marine and freshwater caulobacters are less likely to be homologous structures than are the stalks and hyphae of *Maricaulis* and *Hyphomonas*, respectively. Unlike freshwater caulobacters, *Maricaulis* and *Hyphomonas* isolates share detectable 16S rDNA similarity with some purple photoheterotrophic bacteria (*Rhodopseudomonas*, *Rhodovulum*) and with members of the *Rhizobium* group. The sequences of nonmarine hyphal budding bacteria (the *Hyphomicrobium* group) are not significantly similar to any caulobacter sequences or to those of their marine morphological twins; they are more similar to sequences of nonhyphal methylotrophic bacteria (*Methylosinus* and *Methylocystis*). The 16S rDNA sequence

similarities between the two types of hyphal budding bacteria are of the same degree as similarities between each group and rhizobial sequences.

The 16S rDNA sequences imply that isolates previously assigned to *Caulobacter* represent three independent origins of the dimorphic life cycle characterized by asymmetric binary fission that produces a stalked cell and a monoflagellate swarmer cell—informally, "caulobacters." To accommodate this implication, it is appropriate to redistribute former *Caulobacter* species and isolates among three groups. (1) *Maricaulis* (Abraham et al. 1999) has been proposed to accommodate the marine caulobacters. (2) A new genus will be proposed to accommodate *C. leidyi* and other nonmarine caulobacters that appear to be more closely related to *Sphingomonas* than to any of the other caulobacters (Kurtz and Poindexter, unpublished). (3) The remaining caulobacter species and unassigned isolates appear to comprise a phylogenetically coherent group that also includes *Asticcacaulis*. On the bases of relative similarities of 16S rDNA sequences and of phenotypic characteristics as shown in Table BXII.α.102, these non-marine caulobacters can be appropriately accommodated in three species groups: *Caulobacter* (rDNA group III) for classical vibrioid, colorless or lightly pigmented caulobacters as described (without isolates) by Henrici and Johnson (1935b), as well as one fusiform type; *Asticcacaulis* (rDNA group II), which continues to accommodate colorless, rod-shaped caulobacters with stalks that are banded (as in the other two species groups), but do not bear the cell's holdfast; and a new genus that will be proposed (Kurtz and Poindexter, unpublished) to accommodate caulobacters of varied but rarely classically vibrioid cell shape that are often deeply pigmented and seem adapted to various levels of environmental salinity (rDNA Group IV).

This redistribution of caulobacters has been guided by investigations of 16S rDNA sequences and chemotaxonomic properties reported since the previous edition of this *Manual*, principally by the laboratories of W.R. Abraham, D.I. Nikitin, L.I. Sly, J. Smit, E. Stackebrandt, and D. Stahl (Anast and Smit, 1988; Merker and Smit, 1988; Stackebrandt et al., 1988a; Nikitin et al., 1990; MacRae and Smit, 1991; Stahl et al., 1992; Walker et al., 1992; Abraham et al., 1997, 1999; Sly et al., 1997, 1999). It is offered as a means of reducing heterogeneity within the genera used for the classification of these prosthecate bacteria and of resolving to some extent the question of the significance of cell morphology and life cycle as taxonomically useful traits. The accumulated work of several laboratories now implies a polyphyletic history of both caulobacter stalks and budding bacterial hyphae. Nevertheless, it is reasonable to propose that the detection of both nonmotile prosthecate and motile (mono-flagellated cells) in a pure population should be regarded as taxonomically helpful in assigning such an isolate to a taxon of phenotypically and genomically similar organisms.

Bacterial classification has become heavily dependent on genomic sequences, particularly of 16S rDNA, as one standard of taxonomic acceptability. Although genes descend and function within a genomic and cytoplasmic context, and one gene does not a genus make, sequences of 16S rRNA genes change very slowly and alert the systematist to spurious similarities of other characteristics that may well be instances of convergent evolution. They also aid in the recognition of phenotypic characteristics that are probably of phylogenetic import, and so help in interpreting the selective pressures that have influenced the course of evolution of a kind of organism. Without doubt, 16S rDNA sequences are sound and valuable guides to probable natural relationships, but they are neither all-powerful (Stackebrandt and Goebel, 1994) nor—in practice—totally dependable. As this author delved into the sequences available for motile, prosthecate bacteria, several problems were discovered that have already led to confusion and occasional misinterpretation in caulobacter taxonomy. First, it was not at all uncommon to encounter sequences that had been determined for the same isolate (strain), but are currently listed and labeled in sequence banks as though that strain's sequence represents more than one species, even more than one genus! A second impediment to exploitation of this promising approach to microbial taxonomy was the difficulty of distinguishing between high similarity of phylogenetic significance and high similarity of techniques employed with the same strain obtained from different culture collections, labeled according to its shelf position in each collection rather than by the original label, which should accompany and identify the strain wherever it is used for any purpose. The current presence of unrecognizable strain redundancy encourages the discovery of "groups" created by unacknowledged label changes, not by natural selection.

The worst problem was the persistence in data banks of sequences that are mislabeled, probably because the cultures from which the DNA was extracted were either mislabeled or contaminated (see, e.g., comments in Sly et al. (1997), and in Abraham et al. (2001)). When such a sequence is detected, it would benefit every systematist who employs sequences if the label were corrected or the sequence withdrawn.

In preparation for this review of caulobacter classification, an effort was made to identify redundant sequences (those determined for the same strain and essentially identical) and sequences from probably mislabeled cultures. Of the 153 sequences deposited, 43 were regarded as recognizably redundant, and four were suspected to be mislabeled (M83797, recognized by Sly et al., 1997; M83796, recognized by Abraham et al., 1999; AJ007799 and AJ007800, recognized by Abraham et al. (2001)). While the overall approach and ultimate validity of 16S rDNA sequence analyses are undeniably valuable in systematics, there are pitfalls for the unwary attempting to use the expanding collection of data. It would be a great service to bacteriological (and probably all biological) systematics if someone regularly reviewed, and—with depositors' assent—removed or corrected the labels of sequences from misidentified cultures, cross-referenced sequences that purportedly display the same genomic region from the same strain, and otherwise edited, corrected, and updated taxonomic assignations with which sequences are labeled.

Lipid composition has become a taxonomically useful criterion in many bacterial groups, and the caulobacters are not an exception. Among these bacteria, there is a strong correlation between lipid composition and 16S rDNA sequence, providing two strong legs under the table on which to place three new (since the previous edition of this *Manual*) genera to accommodate isolates formerly or tentatively assigned to *Caulobacter*. Studies of caulobacterial lipids prior to the application of automated methods for lipid analysis (Chow and Schmidt, 1974; Carter and Schmidt, 1976; DeSiervo and Homola, 1980; DeSiervo, 1985) found evidence of two features of taxonomic importance: 1) fatty acids were not clearly distinctive among (then) *Caulobacter* species, and 2) marine caulobacters possessed significantly lower levels of phospholipids than did freshwater isolates. Differences in lipid composition were also detected between growing and stationary-phase cells.

More recently, technological developments have provided more detailed analysis of bacterial lipids, and the greatest detail regarding caulobacterial lipids has been reported by the labo-

ratory of W.R. Abraham (Abraham et al. 1997, 1999, 2001). Those studies reported fatty acid and polar lipid composition for isolates of four groups of caulobacters (*Caulobacter*, Group IV caulobacters, *Asticcacaulis*, and *Maricaulis*) and one of budding hyphal bacteria (*Hyphomonas*) in comparative studies that also included isolates of two nonprosthecate genera (*Brevundimonas* and *Mycoplana*). *C. leidyi* was included, but seemed to be characterized mainly by the absence of identifiable polar lipids and the presence of $C_{14:0\ 2OH}$, an uncommon bacterial fatty acid that is, however, common among *Sphingomonas* spp. The two nonprosthecate types share some similarities with caulobacters in both lipid composition and 16S rDNA sequence. The major distinguishing features of the lipids detected are presented in both procedural and chemical detail in the reports from Abraham's group, which should be consulted. A similar composition was reported for one freshwater isolate by Batrakov et al. (1997). A brief summary of these reports is presented here.

Three patterns of lipid composition, designated "C", "B", and "M" by Abraham et al. (1997), appear to distinguish the three groups *Caulobacter*, Group IV caulobacters, and *Maricaulis*, respectively (see Table BXII.α.102), and a fourth pattern, designated "H", is found in *Hyphomonas*. The lipids of *Asticcacaulis* isolates appear to be somewhat more like those of *Caulobacter* than of the other genera. All groups, even *C. leidyi*, share five fatty acids. The greatest differences, as anticipated by DeSiervo's studies, were detected between freshwater and marine caulobacters. The marine groups possess significant amounts of six fatty acids that are absent (five) or very low (the sixth) in freshwater organisms; the reverse was observed for three fatty acids—significant in freshwater, absent or scant in marine isolates.

Glucolipid patterns were also found to be distinctive. One type of phosphoglucolipid (PGL), 3-O-[6′-(*sn*-glycero-3′-phosphoryl)-α-D-glycopyranosyl]-*sn*-glycerols was the only such lipid found in the two *Asticcacaulis* and in 34 of 37 *Caulobacter* isolates tested. The exceptional *Caulobacter* isolates possess that PGL plus at least two others, as do 9 of the 13 Group IV caulobacter isolates and 1 of the 4 *Brevundimonas* strains. PGLs, at least one of which is present in every freshwater isolate, are scant or undetectable in marine isolates. Sulfonolipids were detected in many strains. All seven *Maricaulis* strains, 10 of 19 Group IV caulobacter strains, and two *Caulobacter* strains possess sulfoquinovosyl diacyglycerols (SQ), as do two of the four *Brevundimonas* strains and two marine isolates tentatively assigned to *Brevundimonas*. Sulfur-containing lipids were not found in *Asticcacaulis* isolates (Abraham et al., 2001). The *Hyphomonas* isolates lack SQ, but contain taurineamide diacylglycerides, found also in four *Maricaulis*, one *Caulobacter*, and one *Brevundimonas* strain. SQ are uncommon among nonphototrophic organisms, and it is remarkable and probably taxonomically useful that they occur in both freshwater and marine caulobacters.

Seven kinds of bacteriophages have been isolated for caulobacters, two of which are not commonly encountered among noncaulobacters (Schmidt and Stanier, 1965; reviewed in Poindexter, 1981). The first of these is the most frequently reported type of caulophage; it is produced by strains of *Caulobacter*, Group IV caulobacters, and *Asticcacaulis*. The virions have large (50–65 × 170–260 nm), prolate, cylindrical heads and long (200–320 nm), flexible, noncontractile tails, and genomes of 2S DNA; they appear most like *Siphoviridae* among formal phage families. These phages exhibit wide host ranges among caulobacters; an individual phage may infect not only more than one species, but also more than one of the three freshwater species groups. The second, uncommon type consists of small icosahedral RNA phages (family *Leviridae*) produced by both *Caulobacter* and Group IV caulobacter isolates. Unlike the DNA-containing caulophages, each of the RNA phages is host species-specific, for *C. crescentus*, *C. fusiformis*, or *Brevundimonas bacteroides* (a Group IV caulobacter). Phages have not been reported to be produced by *Maricaulis* or *C. leidyi*. None of the caulophages tested is lytic for non-caulobacters, and phages lytic for other genera are not lytic for caulobacters. Like most events in the life of caulobacters, the ability to adsorb and allow infection by some of the phages are traits expressed only intermittently during the cell cycle (Schmidt, 1966; Bendis and Shapiro, 1970; Lagenaur et al., 1977; Bender et al., 1989), usually during the swarmer stage. This is a further indication that asymmetric fission, with its intricate regulatory background and multiplicity of cell surface participants, continues to be the distinctive trait of caulobacters.

Four species of *Caulobacter* are recognized: *C. vibrioides*, *C. crescentus*, *C. henricii*, and *C. fusiformis*. Distinguishing and other traits are shown in Tables BXII.α.103 and BXII.α.104, respectively. The other nine species included in the previous edition of this *Manual* have been removed to other assignments: *C. bacteroides*, *C. henricii* subsp. *aurantiacus*, *C. intermedius*, *C. subvibrioides*, *C subvibrioides* subsp. *albus*, and *C. variabilis* to *Brevundimonas* as six species; *C. halobacteroides* and *C. maris* to *Maricaulis*; and *C. glutinosus*, *C. kusnezovii*, and *C. leidyi* to limbo.

ACKNOWLEDGMENTS

The author is deeply grateful to Dr. Thomas M. Schmidt of the Department of Microbiology and Molecular Genetics and Center for Microbial Ecology, Michigan State University, for his guidance in the analysis of 16S rDNA sequences and preparation of phylogenetic trees. His patience and generosity as a tutor are inexhaustible. The taxonomic conclusions, of course, are the responsibility of the author alone. The analysis and writing were supported in part by a Barnard College Faculty Grant during the author's sabbatical leave at Michigan State University in 2001.

List of species of the genus Caulobacter

1. **Caulobacter vibrioides** Henrici and Johnson 1935b, 84[AL]
vib.ri.oi′ des. M.L. n. *Vibrio* name of a genus; Gr. n. *eidus* form, shape; M.L. adj. *vibrioides* resembling a vibrio.

Vibrioid cells slender or nearly ovoid. Colonies colorless or pale yellow. Vitamin B_2 essential for growth, but additional unidentified growth factors available in peptone–yeast extract also required by most strains.

Strain CB51 was isolated from a freshwater pond in Berkeley, CA.

The mol% G + C of the DNA is: 64–65 (Bd, determined for two isolates).

Type strain: CB51, DSM 9893, VKM B-1496.

GenBank accession number (16S rRNA): AJ009957, AJ227754.

Additional Remarks: It is not clear whether any of the copies of strain CB51 currently available from culture collections is identical with the original isolate (Poindexter, 1964), which was not deposited with the ATCC. CB51 appears to have been or to have very early become overgrown by a strain of *C. crescentus*, resulting in identity of the 16S rDNA sequences that have been determined for CB51 and *C. crescentus* strain CB2, and DNA–DNA hybridization >90% (Moore et al., 1978). Response to riboflavin, the most easily tested distinction between the two species, has not been

[a]Symbols: +, 90% or more of strains are positive; −, 90% or more of strains are negative; d, 11–89% of strains are positive; and nd, not determined.

[b]Carbon-source utilizations were determined with D-isomers of sugars, with L-isomers of amino acids, or (when single isomers were not available) with racemic mixtures.

[c]2sDNA phage types: I, head prolate cylinder 50–65 × 170–260 nm, tail noncontractile 200–320 nm long; II, head elongated polyhedron 65–70 × 100–105 nm, tail noncontractile 260–300 nm long; III, head icosahedron 50–80 nm diameter, tail noncontractile 150–200 nm long. ssRNA phages: icosahedron 20–29 nm diameter, no tail.

reported for current copies of "CB51." As suggested by Sly et al. (1997), a search for original CB51 DNA should be made, or a substitute neotype strain matching the phenotype of *C. vibrioides* designated. Krasil'nikov and Belyaev (1973) reported 20 isolates of *C. vibrioides*. Babinchak and Gerencser (1976) reported 28 vibrioid isolates; however, characteristics other than morphology and phage sensitivities have not been described for their isolates. MacRae and Smit (1991) reported the isolation of 25 colorless vibrioid caulobacters from wastewater facilities; although they noted that many of the isolates were distinctly stimulated by supplementation of complex media with riboflavin, they did not indicate which of their isolates responded. Those isolates would be accommodated by *C. vibrioides*, whereas the riboflavin-indifferent isolates should be assigned to *C. crescentus*. Further colorless, vibrioid freshwater isolates were obtained from other sources and used by Merker and Smit (1988) and by Abraham et al. (1997, 1999), but these were not significantly different from each other or the wastewater isolates in lipid composition. Different strains in the collection did, however, bind different plant lectins, a trait that might eventually prove to be an additional aid in distinguishing between the two colorless vibrioid species, *C. vibrioides* and *C. crescentus*.

2. **Caulobacter crescentus** Poindexter 1964, 288^{AL}
cres' cen.tus. L. adj. *crescentus* of the moon in its first quarter, crescent.

Vibrioid cells slender (see Fig. BXII.α.115). Colonies colorless, with centers becoming tan or dark pink upon aging. Lack of growth factor requirements is unique among *Caulobacter* species, as is the ability to utilize primary alcohols as sole sources of carbon and energy in defined media; other species may utilize butanol, but not methanol, ethanol, propanol or pentanol, as do *C. crescentus* isolates. Some of the wastewater caulobacters isolated by MacRae and Smit (1991) may be *C. crescentus*, but this species cannot be distinguished from *C. vibrioides* by the traits (lipid composition, 16S rDNA sequences, lectin binding) so far reported for these isolates.

Strain CB2 was isolated from tap water in Berkeley, CA.

The mol% G + C of the DNA is: 62–67 (Bd, determined for one isolate; T_m, determined for three isolates; paper electrophoresis of hydrolysate, determined for one isolate; complete sequence for one isolate).

Type strain: CB2, ATCC 15252.

GenBank accession number (16S rRNA): AJ227756.

3. **Caulobacter fusiformis** Poindexter 1964, 289^{AL}
fus.i.form' is. L. n. *fusus* spindle; L. n. *forma* shape, form; M.L. adj. *fusiformis* spindle-shaped.

Fusiform cells slender (see Fig. BXII.α.116). Colonies bright yellow. Sugars not utilized as carbon sources. Organic growth factor requirements not satisfied by mixtures of B vitamins, amino acids, and purine and pyrimidine bases.

Strain CB27 was isolated from a freshwater pond in Berkeley, CA.

The mol% G + C of the DNA is: not determined.

Type strain: CB27, ACM 5108, ATCC 15257, DSM 4728.

GenBank accession number (16S rRNA): AJ227759, AJ007803, AB008533.

Additional Remarks: Krasil'nikov and Belyaev's (1973) strain 25 (VKM v-1183) was assigned by them to this species. However, based on its morphology, pigmentation, and ability to utilize a variety of sugars, it is assignable to Group IV caulobacters. Another fusiform isolate, strain 1 (VKM v-1189), designated *"Caulobacter rossii"* sp. nov. by Krasil' nikov and Belyaev (1973), is not assignable to *C. fusiformis*; because only one such isolate is known and its physiological characteristics are predominantly inabilities and appear variable, *"C. rossii"* is not included in this list. Babinchak and Gerencser (1976) reported five fusiform isolates; however, characteristics other than morphology and phage sensitivities have not been described for their isolates. Yellow fusiform isolates were not obtained from wastewater by MacRae and Smit (1991).

4. **Caulobacter henricii** Poindexter 1964, 288^{AL}
hen.ric' i.i. M.L. gen. n. *henricii* of Henrici; named for A.T. Henrici, who observed stalked bacteria on slides that had been submerged in freshwater.

Vibrioid cells slender. Colonies bright yellow and may be somewhat translucent. Vitamin B_{12} typically required as growth factor in peptone–yeast extract media.

Strain CB4 was isolated from a freshwater pond in Berkeley, CA.

The mol% G + C of the DNA is: 62–65 (Bd, determined for two isolates).

Type strain: CB4, ATCC 15253, DSM4730, ACM5105.

GenBank accession number (16S rRNA): AJ227758, AJ007805, AB008532.

Additional Remarks: Krasil' nikov and Belyaev' s (1973) strain 44 (VKM v-1190), designated *"Caulobacter rutilus"* sp. nov. is not distinguishable from *C. henricii*. As described here, *C. henricii* accommodates all known *Caulobacter* isolates of yellow-pigmented, riboflavin-indifferent vibrioid types. Only two wastewater isolates (FWC20 and FWC23) reported by MacRae and Smit (1991) were yellow and vibrioid; the 16S rDNA sequence of one (FWC20) has been determined and found to be more similar (99.8%) to the type strain of *C. henricii* than to any other caulobacter sequence.

Genus II. **Asticcacaulis** *Poindexter 1964, 282*^{AL}

JEANNE S. POINDEXTER

A' stic.ca.cau' lis. Gr. *alpha* privative without; Anglo-Saxon n. *sticca* stick; L. n. *caulis* stalk; L. masc. n. *Asticcacaulis* stalk that does not stick.

Cells single, unbranched, **rod-shaped**, poles blunt or gently rounded; 0.5–0.7 × 1–3 µm during growth in most media. Some cells in any growing population have one subpolar or one or two lateral **prosthecae**. Each prostheca includes outer membrane, peptidoglycan, cell membrane, and a core sometimes observed to be occupied in part by membranes, but other cytoplasmic components cannot be discerned through most of its length. Beyond the cell–prostheca juncture, prostheca diameter is constant, 0.10–0.15 µm; each prostheca possesses at least one **stalk band** as a substructure after the cell has matured and completed at least one cell cycle. Other cells in the same population bear a **single, subpolar flagellum**. Each type of cell bears a small mass

of adhesive material, the **holdfast**, at one pole; the holdfast site is not coincident with the site of the flagellum or of the prostheca(e). Binary fission occurs by **septation**, typically resulting in the production of a longer, prosthecate cell and a shorter, flagellated cell. Fission may occur in cells lacking prosthecae. In both instances, **cell division** is **unequal**.

Gram negative. Strictly **respiratory** and **aerobic** but may be somewhat O_2 sensitive; O_2 serves as the only terminal electron acceptor for growth, although nitrate may be reduced to nitrite. Colonies circular, convex, glistening, with smooth margins, butyrous in texture, and colorless. In standing liquid cultures, cells accumulate as a **surface film** or heavier pellicle and develop as a ring of growth on the vessel wall at or just below the air–liquid interface. Growth in agitated liquid cultures is evenly dispersed.

Chemoorganotrophic and **oligotrophic**; grow readily in media such as peptone–yeast extract containing 0.05–0.3% (w/v) organic solutes, but not in standard nutrient broth with 0.8% (w/v) organic solutes. During growth, may produce acid from sugars but do not produce gas. Optimal temperature for growth: 25–30°C; tolerated range for growth: 15–35°C. Optimal pH near neutrality; pH 6–9 tolerated. Typically do not grow in media containing 2% (w/v) NaCl. Maximum specific rates of exponential growth: 0.23–0.57 h^{-1}. All isolates require biotin as the only organic micronutrient. Glucose, fructose, maltose, or lactose may be utilized as the sole carbon source.

Sequences of 16S rDNA are consistent with placement of *Asticcacaulis* among the *Alphaproteobacteria*. The positions of the six sequences grouped as *Asticcacaulis* in Fig. BXII.α.111 in the chapter describing the genus *Caulobacter* are represented in Fig. BXII.α.119 (in the *Caulobacter* chapter) by the two nonredundant sequences grouped in Fig. BXII.α.114 in *Caulobacter*; their strain identities and GenBank accession numbers are displayed. These sequences were determined for the type strain of each species. (See "Taxonomic Comments" in the chapter describing the genus *Caulobacter* for a description of this tree.)

Sources: isolated from tap water and natural bodies of fresh water. Not encountered as clinical isolates, and not known to be pathogenic for plants or animals. Rarely encountered; only four isolates of *Asticcacaulis excentricus* are known, and only one of *Asticcacaulis biprosthecum* has been described.

The mol% G + C of the DNA is: 55–61.

Type species: **Asticcacaulis excentricus** Poindexter 1964, 292.

Further descriptive information

Morphology and fine structure The prosthecae of all isolates are banded (see Figs. BXII.α.120B and BXII.α.121C). Each band is a set of concentric rings that are more electron-opaque and structurally more rigid than is the remainder of the prostheca (Schmidt and Swafford, 1975). Earlier evidence that one band is added to each growing prostheca during each cell cycle of *Caulobacter crescentus* (Staley and Jordan, 1973) has been confirmed for both that species and for *Asticcacaulis biprosthecum* (Poindexter and Staley, 1996). However, the function of the bands is unknown. They occur in the prosthecae of only three species groups: *Caulobacter*, *Asticcacaulis*, and "other caulobacters."

The pattern of prostheca development in *Asticcacaulis* species as it relates to the cell cycle appears to vary among isolates and, in a given isolate, with composition of the growth medium (Pate et al., 1973; Larson and Pate, 1975). In some cultures, development occurs only toward the end of exponential growth; in others, practically all dividing cells are prosthecate in all growth phases of the culture. As far as is known, only one progeny cell of each reproductive event is flagellated, whether or not the other progeny cell bears a prostheca. Prosthecae that arise laterally are usually inherited by the nonmotile progeny cell, but may also be inherited by the motile cell. However, the capacity for development is not lost by a clone arising from a nonmotile, nonprosthecate cell; clones without prosthecae have not been encountered as spontaneous variants. As with other caulobacters, prostheca length is greatly increased in dilute media; prostheca length is also promoted in defined media, especially when phosphate concentration is growth limiting (Schmidt and Stanier, 1966), but also when the available carbon source is only slowly utilized (Larson and Pate, 1975).

Cellular composition The thin peptidoglycan layer of the *Asticcacaulis* cell body continues without interruption into the prostheca. Peptidoglycan of both known species is similar with respect to the glycan component, in which muramic acid is present in a 50% excess over glucosamine (Poindexter and Hagenzieker, 1982). The species, however, differ in peptide composition. *A. biprosthecum* contains a significantly higher proportion of glutamic acid than is found in *A. excentricus* and other Gram-negative bacteria. Prostheca peptidoglycan has not been separately assayed in either species.

The principal respiratory quinone in *Asticcacaulis* cells is ubiquinone-10, and the principal phospholipid is phosphatidylglycerol. The most abundant fatty acid species are $C_{18:1}$ and $C_{16:0}$. Both isolates tested (one of each species) also contain lower, but significant amounts of $C_{18:1\ \omega7c\ 11CH_3}$ and of species of $C_{17:1}$ and $C_{15:0}$. As in *Caulobacter*, the principal hydroxy fatty acid detected by Abraham et al. (2001) was $C_{12:1\ 3OH}$, although a study of the lipid composition of an isolate described as "*A. biprosthecum*-like" (Sittig and Schlesner, 1993) reported detection of $C_{12:0\ 3OH}$, as well. Neither isolate studied by Abraham et al. (2001) contained the PGLs found in *Caulobacter* and "other caulobacters."

Enzymes Intermediary metabolism has been examined in only a preliminary fashion. The Entner–Doudoroff pathway for carbohydrate dissimilation is present. Enzymes for catabolism of some carbohydrates are induced by exposure to substrate, but induced levels are only 1.5–10-fold higher than uninduced levels.

Genome structure DNA–DNA hybridization values were reported by Moore et al. (1978) to be in the range of 33–88% among isolates of *A. excentricus*, but to be undetectable between the type strains of the two species in this genus. Ribosomal rDNA sequences have been determined for both species of *Asticcacaulis*, which appear to comprise one of five coherent groups among caulobacterial sequences. The minimum similarity between the sequences that represent the two isolates grouped within "II. *Asticcacaulis*" in Fig. BXII.α.111 in the *Caulobacter* chapter is 95.9%. All known sequences for 16S rDNA are less similar; the highest similarities outside the genus are with sequences for organisms identified as *Caulobacter henricii* (93.7%) or *Brevundimonas aurantiaca* (formerly *C. henricii* subsp. *aurantiacus* (94.7%).

Three morphological types of bacteriophages that are lytic for *Asticcacaulis* species have been isolated from fresh water and sewage (Pate et al., 1979; reviewed in Poindexter, 1981). All are two-stranded DNA phages with long, flexible, noncontractile tails. Heads may be icosahedral, prolate cylindrical, or elongated polyhedral. Of more than 40 phage isolates known from *Asticcacaulis*, only two (of the prolate cylindrical type) are lytic for a few *Caulobacter* and "other caulobacter" isolates; all others are lytic only

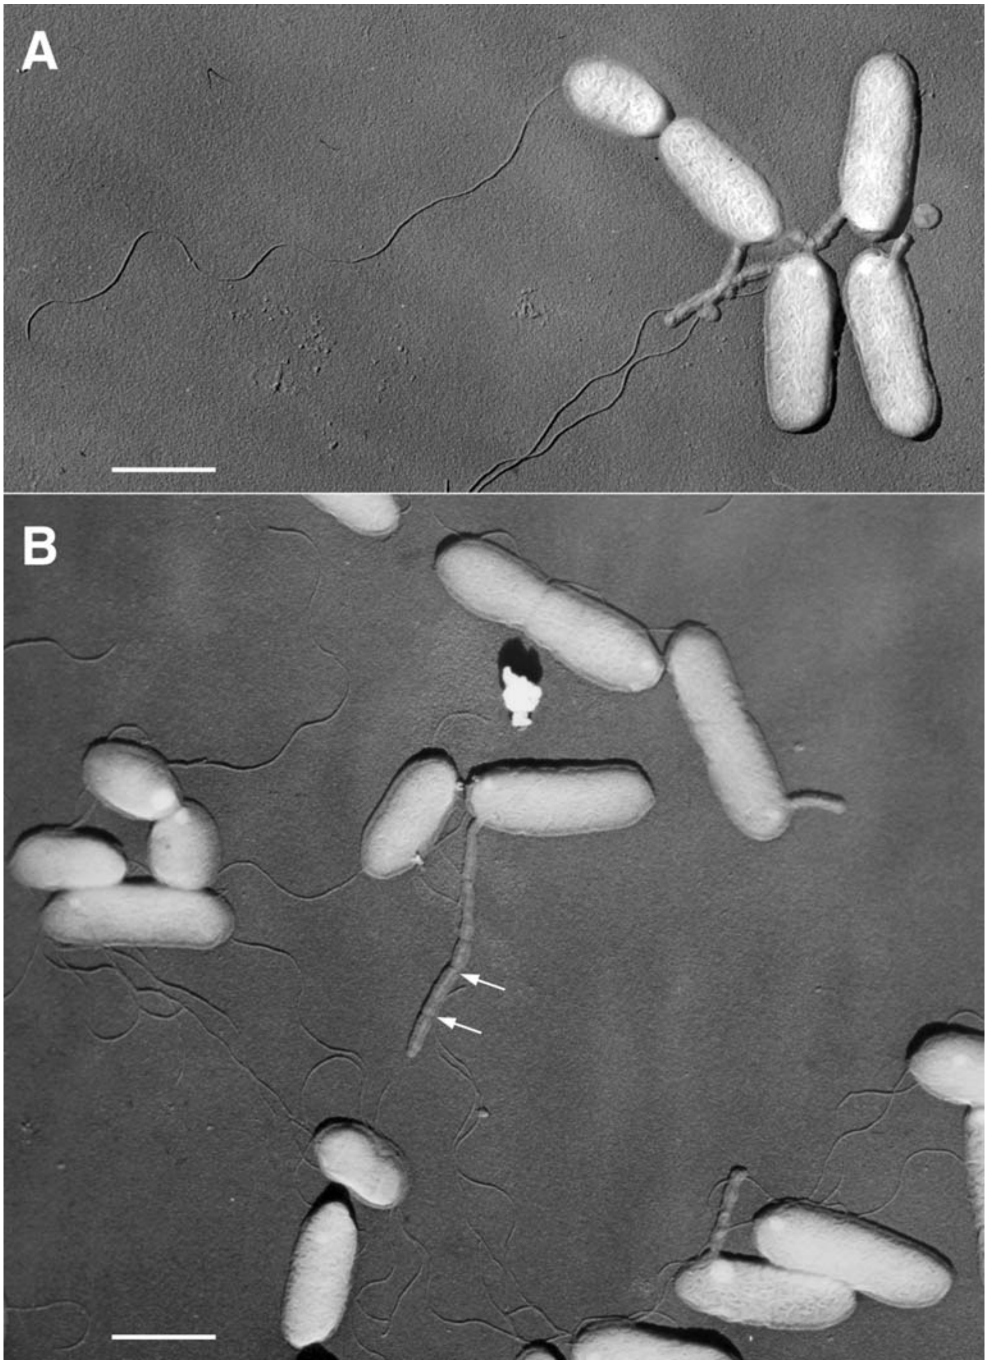

FIGURE BXII.α.120. *A. excentricus* strain S-3 grown in peptone–yeast extract medium. Electron microscopy, shadowed specimen, negative image. *Arrows* in (*B*) indicate stalk bands. Bars = 1 μm.

for *Asticcacaulis* isolates. No phages that are lytic for any other genus (including other caulobacters) are also lytic for *Asticcacaulis* isolates. Generally, this genus appears to be isolated from other genera with respect to phage propagation. Genetic studies have not been done for this genus, but *A. excentricus* has been found to be capable of accepting and expressing plasmid-borne genes, including genes for insect larvicide production (Liu et al., 1996).

See "Taxonomic Comments" below and in the chapter describing the genus *Caulobacter* for further discussion of 16S rDNA sequences and other bacteriophages.

Enrichment and Isolation Procedures

Asticcacaulis is not frequently observed in natural samples and is rarely isolated. Isolation has been achieved by the same procedure as described for *Caulobacter* (*q.v.*). A sample of clean water is enriched with at most 0.01% (w/v) peptone and allowed to stand at room temperature. Within a few days, a sample of the surface film, taken with a bacteriological loop or a cover slip, is examined by phase-contrast microscopy for the presence of prosthecate cells or rosettes of rod-shaped cells. When such cells account for 10–50% of the population, a sample (again, taken with a loop, not a pipette) is streaked on a dilute (0.05%; max-

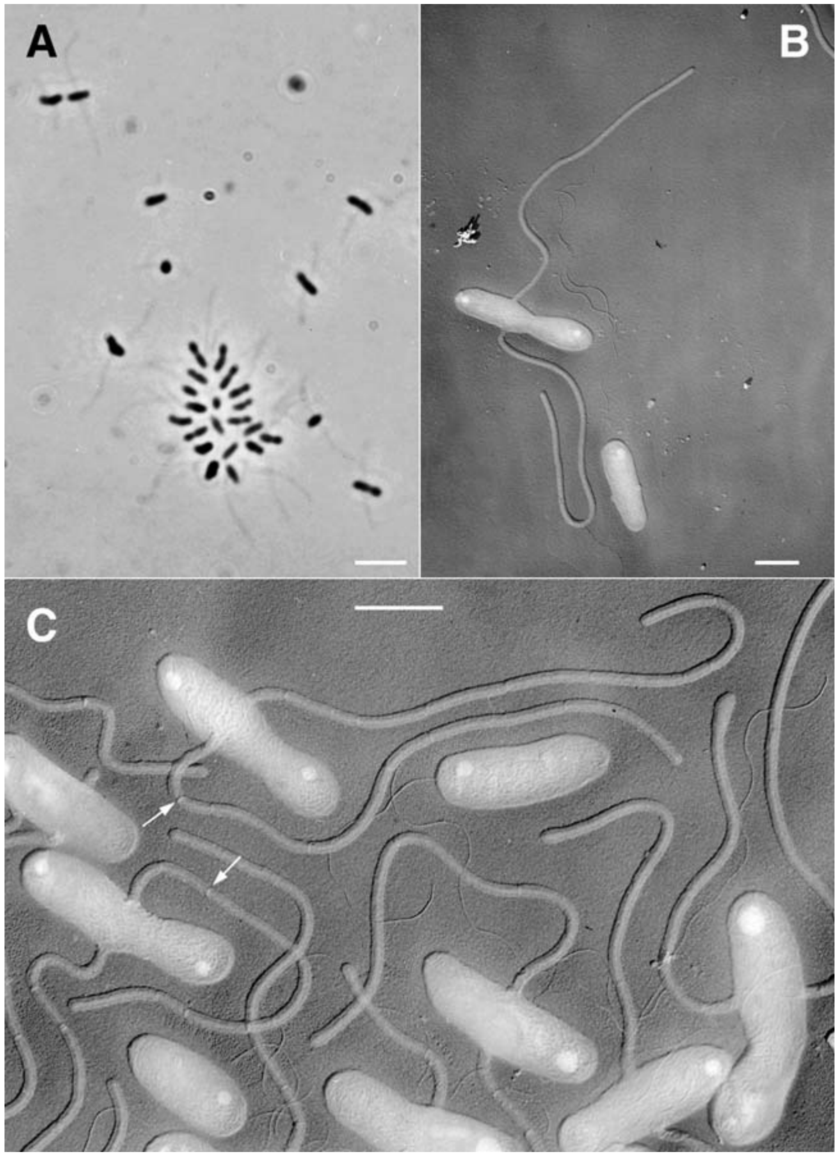

FIGURE BXII.α.121. *A. biprosthecum* strain C-19 grown in peptone–yeast extract medium. *A*, phase-contrast microscopy, wet mount. *B–C*, electron microscopy, shadowed specimen, negative image. *Arrows* in (*C*) indicate stalk bands. Bars = 5 μm (*A*) and 1 μm (*B–C*).

imum 0.1%, w/v) peptone or peptone–yeast extract medium prepared with 1.0 or 1.5% agar. By the third or fourth day of incubation of the plates, small, hyaline or crystalline, noniridescent colonies of prosthecate bacteria begin to appear. These colonies, or patches of growth inoculated from them, are then screened by phase-contrast microscopy. Clones of *Asticcacaulis* are often difficult to recognize during the microscopic screening. However, any clone that includes frequent rosettes should be purified, cultivated in dilute (e.g., 0.1% peptone, 0.05% yeast extract) broth, and examined by electron microscopy for the presence of prosthecate and flagellated cells in whole-cell mounts, such as shadowed or negatively stained specimens.

A. biprosthecum has been isolated only once, by a modification of this procedure in which a loopful of the enrichment culture was streaked on a dilute medium containing 0.02% beef extract, 0.05% tryptone, 0.05% yeast extract, and 0.02% sodium acetate, prepared with 1.5% agar. After several days of incubation at 30°C, very small colonies were transferred as deep cultures to the same medium prepared with 0.4% agar. *A. biprosthecum* was detected by microscopic examination of the submerged colonies (Pate et al., 1973).

Maintenance Procedures

Once isolated, *Asticcacaulis* species can be maintained as vegetative, frozen, or lyophilized populations. Vegetative stocks should be maintained on 1% agar slants of dilute (0.05–0.3% organic material) complex medium, transferred every 8 or 9 weeks, incubated 2 or 3 days at 20–25°C, and then refrigerated. Cells grown in dilute complex medium can be stored in small volumes frozen at −70°C without cryoprotectant. Such frozen cultures can be thawed at room temperature and transferred to growth medium to resume vegetative growth. Lyophilization is a dependable means for maintenance, either in milk solids or on strips of filter paper.

Procedures for Testing Special Characters

This genus is distinguished by the number, positions, and substructures of its appendages, particularly the prosthecae. The appendages are best examined by electron microscopy. Shadowed specimens provide the clearest image, but negatively stained specimens need not be washed and so preserve a higher proportion of attached flagella. The holdfast is best detected by its adhesive function, although it, too, is discernible by electron microscopy.

Differentiation of the genus *Asticcacaulis* from other genera

Four groups of bacteria other than caulobacters produce long cellular appendages of the envelope that are of constant diameter; these bacteria also tend to occur in the same habitats as caulobacters. They are distinguishable from caulobacters and from each other by the morphology of their reproductive stages. The five groups are distinguished in Table BXII.α.101 in the *Caulobacter* chapter, and the five genera of caulobacters are distinguished in Table BXII.α.102 in the *Caulobacter* chapter. Relationships to nonprosthecate bacteria implied by 16S rDNA analysis are illustrated and discussed further in "Taxonomic Comments" in the chapter describing the genus *Caulobacter*.

Taxonomic Comments

The genus *Asticcacaulis* was created (Poindexter, 1964) to accommodate isolates originally regarded as *Caulobacter* species, but whose prosthecae were not adhesive and consequently not equivalent to *Caulobacter* stalks as adhesive organelles. Subsequent investigations of a greater variety of prosthecate bacteria have revealed that only caulobacterial appendages lack cytoplasm along most or all of their length and that stalk bands occur only in freshwater caulobacters. The unique structure of the freshwater caulobacter appendages suggests that they are homologous. Although the mol% G + C of *Asticcacaulis* DNA is lower than that known for other freshwater caulobacters, and only two of more than 100 caulophage isolates are lytic for both *Asticcacaulis* and other freshwater caulobacters, 16S rDNA sequence analysis places *Asticcacaulis* well within the caulobacter group (*Caulobacter*, *Asticcacaulis*, and "other caulobacters"). Its closest nonprosthecate relative is *Brevundimonas*, whose sequences are more similar to "other caulobacter" sequences than to those of *Asticcacaulis*.

Two species are recognized and are distinguished by the number and position of the prosthecae (Table BXII.α.105); other characteristics are listed in Table BXII.α.106. Individual strains of the icosahedral-head DNA phages are lytic for both species, but cellular genomic DNA–DNA similarity has not been detected (Moore et al., 1978).

[c]2sDNA phage types: I, head prolate cylinder 50–65 × 170–260 nm, tail noncontractile 200–320 nm long; II, head elongated polyhedron 65–70 × 100–105 nm, tail noncontractile 260–300 nm long; III, head icosahedron 50–80 nm diameter, tail noncontractile 150–200 nm long. ssRNA phages: icosahedron 20–29 nm diameter, no tail.

List of species of the genus Asticcacaulis

1. **Asticcacaulis excentricus** Poindexter 1964, 292[AL]

ex.cen' tri.cus. L. pref. *ex* out, beyond; Gr. n. *centron* center of circle; M.L. adj. *excentricus* out from the center.

Rod-shaped cells thick (see Fig. BXII.α.120). A single prostheca arises from a subpolar site previously occupied by a single flagellum. Colonies colorless. Biotin is the only growth factor required in glucose–ammonium salts medium. Sugars are the preferred carbon sources; all isolates can also use ethanol, but use of other primary alcohols is variable among isolates.

Strain AC48 was isolated from a freshwater pond in Berkeley, CA.

The mol% G + C of the DNA is: 55–60 (Bd, T_m).

Type strain: AC48, ACM 1263, ATCC 15261, DSM 4724.

GenBank accession number (16S rRNA): AJ247194.

2. **Asticcacaulis biprosthecum** Pate, Porter and Jordan 1973, 582[AL]

bi.pros.thec′ um. L. pref. *bi, bis* twice; Gr. fem. n. *prosthece* appendage; M.L. adj. *biprosthecum* twice-appendage(d).

Rod-shaped cells thick (see Fig. BXII.α.121). One or, more often, two prosthecae arise near the equator of the cell at roughly diametrically opposite positions from each other; neither site is coincidental with the site occupied by the single, subpolar flagellum. Colonies colorless. Biotin is the only growth factor required in glucose–ammonium salts medium, but growth is markedly stimulated by mixtures of amino acids; supplementation with single amino acids can be inhibitory. Somewhat sensitive to dissolved O_2, growing faster and more efficiently (as measured by yield) when allowed to reduce medium prior to aeration. Pili as well as holdfast material participate in adhesion.

Strain C-19 was isolated from a freshwater pond in Madison, WI.

The mol% G + C of the DNA is: 61 (T_m).

Type strain: C-19, ACM 2498, ATCC 27554, DSM 4723, MBIC 3411.

GenBank accession number (16S rRNA): AJ247193.

Additional Remarks: There is a single known isolate of this species; strain C-19 was the original strain designation, but this isolate also appears in the literature as AC-2. One "*A. biprosthecum*-like" isolate has been reported (Sittig and Schlesner, 1993). (Note: The species epithet was misspelled "biprosthecium" in the 1989 Approved List; the spelling originally proposed by Pate et al., 1973, should be used.)

Genus III. **Brevundimonas** *Segers, Vancanneyt, Pot, Torck, Hoste, Dewettinck, Falsen, Kersters and De Vos 1994, 507[VP] emend. Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1070*

Marc Vancanneyt, Paul Segers, Wolf-Rainer Abraham and Paul De Vos

Brev.un.di′ mo.nas. L. adj. *brevis* short; L. fem. n. *unda* wave; Gr. *monas* a unit, monad; M.L. fem. n. *Brevundimonas* bacteria with short wavelength flagella.

Gram-negative, rod-shaped, subvibrioid or vibrioid cells, 0.4– 0.5 × 1–2 μm. **Cells of some species can form prosthecae (stalks).** These species are characterized by an asymmetric cell division whereby fission results in a prosthecate (nonmotile) and a flagellated (motile) cell. Motility by means of single polar flagella. Nonsporeforming. A yellow or orange carotenoid pigment may be formed.

Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Catalase positive. Nitrate is rarely reduced.

Chemoorganotrophic and oligotrophic. Good growth occurs on most common media at a pH range of 6.0–8.0 and at 25–30°C. **Growth factors are required by all strains.** Growth occurs without NaCl, but is optimal at 0.5–2% NaCl (w/v). All species can utilize pyruvate, and most isolates are also positive for growth on the organic acids acetate, butyrate, fumarate, and succinate and on the amino acids glutamate and proline. Glucose, galactose, maltose, and starch can be utilized by all species except the type species, which has a restricted nutritional spectrum. Growth on primary alcohols is usually negative. No or weak acid production from sugars.

Dominant fatty acids are $C_{12:0\ 3OH}$, $C_{14:0}$, $C_{15:0}$, $C_{16:0}$, $C_{16:1}$, $C_{17:0}$, $C_{17:1\ \omega6c}$, $C_{17:1\ \omega8c}$, and $C_{18:1}$. Polar lipids are α-D-glucopyranosyl diacylglycerol, α-D-glucopyranuronosyl diacylglycerol, 1,2-di-*O*-acyl-3-*O*-[D-glucopyranosyl-(1→4)-α-D-glucopyranuronosyl] glycerol, 6-phosphatidyl-α-D-glucopyranosyl diacylglycerol (main mass numbers 1413 and 1439 Da), and phosphatidylglycerol. Most strains contain sulfoquinovosyl diacylglycerol. Ubiquinone Q-10 and the polyamines spermidine and homospermidine are present in the species examined. Cells accumulate poly-β-hydroxybutyrate as a reserve material but are, so far as known, not able to hydrolyze this polymer. The genus belongs to the class *Alphaproteobacteria.* Strains are isolated from water, soil, and clinical specimens.

The mol% G + C of the DNA is: 62–68.

Type species: **Brevundimonas diminuta** (Leifson and Hugh 1954b) Segers, Vancanneyt, Pot, Torck, Hoste, Dewettinck, Falsen, Kersters and De Vos 1994, 507 (*Pseudomonas diminuta* Leifson and Hugh 1954b, 68.)

Further descriptive information

Phylogenetic treatment Within the class *Alphaproteobacteria*, *Brevundimonas* belongs to the family *Caulobacteraceae*, which also includes the genera *Asticcacaulis*, *Caulobacter*, and *Phenylobacterium*. *Brevundimonas* is most closely linked to *Caulobacter*, with 16S rDNA sequence similarities of 95–96% (Fig. BXII.α.122; Abraham et al., 1999). Lower similarities of 93–94% and 92–93% are obtained with *Asticcacaulis* and *Phenylobacterium*, respectively. Within *Brevundimonas*, the interspecies 16S rDNA sequence similarities are higher than 96%. Remarkably, the misclassified species, *"Mycoplana bullata"*, groups among the *Brevundimonas* species, with similarities above 97% (see below). No phylogenetic subgroups are recognized that reflect the distinct morphological characteristics of the species (see below; Fig. BXII.α.122; Abraham et al., 1999).

Cell morphology Cell morphology may be a primary criterion for distinguishing between the dimorphic prosthecate and nonprosthecate *Brevundimonas* species. Reproduction of six prosthecate species, *Brevundimonas alba*, *Brevundimonas aurantiaca*, *Brevundimonas bacteroides*, *Brevundimonas intermedia*, *Brevundimonas subvibrioides*, and *Brevundimonas variabilis*, results in the separation of two cells that are morphologically and behaviorally different from each other. Cells divide by binary transverse fission (which is constrictive without formation of a septum), in which the younger pole bears a single flagellum, and the older pole bears a prostheca derived from the cell envelope. The stalk includes membranes and peptidoglycan, but not cytoplasmic components. The stalk-bearing progeny cell grows and eventually repeats the asymmetric cell division. The flagellum-bearing progeny cell, after a period of motility, releases the flagellum and develops its stalk at the previously flagellated site as it grows and proceeds to its asymmetric cell division (Poindexter, 1989). At the base of the flagellum and at the outer tip of the stalk is a

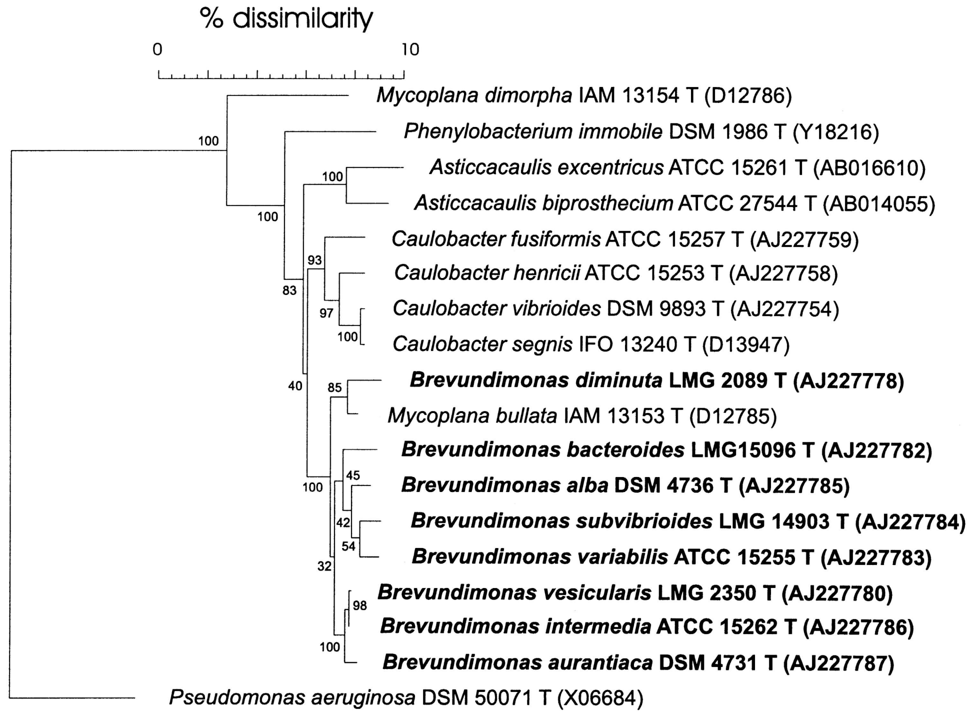

FIGURE BXII.α.122. Phylogenetic tree based on a comparison of 16S rDNA sequences of strains belonging to the genera *Brevundimonas* and related taxa (accession numbers are given in brackets). *T*, indicates type strain.

small mass of adhesive material, the holdfast, which confers adhesiveness on each of the progeny (Poindexter, 1989). Stalk position is species-specific or, for one species, may vary among strains, but the stalk length varies greatly among isolates (0.11–0.18 μm; Poindexter, 1989). The cell is rod-shaped, vibrioid, or subvibrioid, depending on the species, but cell shape may be influenced by medium composition (e.g., phosphate concentration) or culture age (Poindexter, 1989).

Strains of the nonprosthecate species, *Brevundimonas diminuta* and *Brevundimonas vesicularis*, are short rods with an unusual short-wavelength flagellar morphology (average wavelength, 0.62 μm). The flagellum originates for most cells from the periphery of the pole rather than from the center of the pole (Leifson and Hugh, 1954b; Clark et al., 1984).

Cultural characteristics Colonies are usually circular, convex, and glistening with smooth margins. Colony diameter varies with strain and medium, but usually reaches 3–5 mm after several days of incubation. Colonies are colorless or may have a pink, yellow, orange, or dark-red carotenoid pigment (Table BXII.α.107; Poindexter, 1964, 1989; Ballard et al., 1968).

The prosthecate *Brevundimonas* species grow well in peptone–yeast extract media supplemented with salts (Poindexter, 1981, 1989). Although in the literature it is indicated that they generally require a low concentration of organic material for growth, they are able to grow on common, nutrient-rich culture media, like tryptic soy agar or nutrient agar (M. Vancanneyt, personal communication). In standing broth cultures, they may form a pellicle that develops at the surface of the medium and adheres firmly to the wall of the culture vessel (Poindexter, 1989).

The nonprosthecate species, *B. diminuta* and *B. vesicularis*, grow on blood agar, infusion agar, tryptic soy and nutrient agar, Mueller–Hinton medium, and King A medium. After 3 d, a brownish-black, diffusible pigment is produced by most *B. diminuta* strains. Contrary to Richard and Kiredjian (1995), Gilardi (1978b) has indicated that *B. vesicularis* might occasionally produce a brown discoloration of the agar medium surrounding the colony. *B. diminuta* produces a water-soluble brown pigment. On heart infusion agar with tyrosine, more than 60% of the *B. vesicularis* strains produce a tan-brown, water-soluble pigment, and about 15% of the strains produce a yellow pigment (Gilardi, 1978b; Clark et al., 1984). Most *B. diminuta* strains and only about 25% of the *B. vesicularis* strains grow on MacConkey medium. No growth occurs on *Salmonella–Shigella* agar or on mineral base medium with acetate (Gilardi, 1978b; Gilligan, 1995). Hemolysis is not observed, and the egg-yolk reaction for lecithinase is negative (Gilardi, 1978b).

The optimal growth temperature is 28–30°C. Maximum growth for most species occurs at around 37°C, although nonprosthecate species grow well at this temperature, and about 50% of *B. diminuta* strains are able to grow at 42°C. Suboptimal growth is observed at 25°C, and no growth is observed at 4°C (Ballard et al., 1968; Gilardi, 1978b; Poindexter 1981).

Optimal pH is around neutrality. For the species examined, growth is observed in a range of pH 6–8 (Poindexter, 1964), although strains have been isolated from water and soil with a pH of about 5–9 (Poindexter, 1981).

Although *Brevundimonas* strains can grow without sodium chloride, optimal growth is obtained in a range of 0.5–2% NaCl for all species. Depending on the species, reduced growth may occur with salt concentrations of 2–6% and no growth is obtained at concentrations of 6–8% NaCl (Abraham et al., 1999).

Nutrition All species require growth factors in chemically defined media (Poindexter 1964; Ballard et al., 1968). For the prosthecate species, growth factors (available in peptone or yeast extract) remain undetermined, except for *B. intermedia*, for which growth is supported by biotin (Poindexter, 1981). Both non-

prosthecate species require pantothenate, biotin, and cyanocobalamin to support growth. *B. diminuta* requires the amino acid cystine, for which methionine may be substituted, resulting in less effective growth (Ballard et al., 1968).

The nutritional spectrum of the genus *Brevundimonas* is very variable and can be used for species differentiation (Table BXII.α.108). Only a few carbon sources are assimilated by the majority of the isolates: the organic acids acetate, butyrate, fumarate, pyruvate, and succinate; the amino acids glutamate and proline; and the carbohydrates glucose, galactose, maltose, and starch. The latter carbohydrates are not utilized by *B. diminuta*, which is regarded as an alkali-producing species (Gilardi, 1978b)

[b]Data from Poindexter (1964, 1981, 1989), Palleroni (1984), Urakami et al. (1990d), Segers et al. (1994), and Abraham et al. (1999).

[c]Reactions of the type strain are given between brackets for *B. diminuta* and *B. vesicularis.*

[d]Additional nutritional features for *B. diminuta* and *B. vesicularis* as determined by API 50CH, 50AO, and 50AA galleries. Substrates used by fewer than 10% of the strains are: adonitol, amygdalin, D-arabitol, L-arabitol, arbutin, dulcitol, erythritol, D-fucose, L-fucose, β-gentiobiose, gluconate, 2-ketogluconate, 5-ketogluconate, *N*-acetyl-glucosamine, methyl-α-D-glucose, glycerol, glycogen, inositol, inulin, D-lyxose, mannitol, methyl-α-D-mannoside, D-melezitose, D-melibiose, D-raffinose, salicin, sorbitol, L-sorbose, D-tagatose, trehalose, D-turanose, xylitol, methyl-β-xyloside, adipate, azelate, benzoate, *m*-hydroxybenzoate, *o*-hydroxybenzoate, *p*-hydroxybenzoate, caprate, *n*-caproate, caprylate, citraconate, citrate, isobutyrate, glutarate, DL-glycerate, glycolate, heptanoate, itaconate, levulinate, maleate, D-malate, malonate, D-mandelate, L-mandelate, mesaconate, oxalate, phenylacetate, phthalate, isophthalate, terephthalate, pelargonate, propionate, sebacate, suberate, D-tartrate, L-tartrate, *meso*-tartrate, acetamide, amylamine, 2-aminobenzoate, 3-aminobenzoate, 4-aminobenzoate, benzylamine, betaine, diaminobutane, butylamine, DL-2-aminobutyrate, DL-3-aminobutyrate, DL-4-aminobutyrate, L-citrulline, creatine, L-cysteine, ethanolamine, ethylamine, glucosamine, glycine, histamine, DL-kynurenine, L-norleucine, L-lysine, L-methionine, L-ornithine, L-phenylalanine, sarcosine, spermine, trigonelline, tryptamine, D-tryptophan, L-tryptophan, urea, and DL-5-aminovalerate. DL-β-hydroxybutyrate is used by all strains of both species. Also, the following substrates are not used by either species (according to conventional test results; Segers et al., 1994): anthranilate, benzoylformate, 2,3-butyleneglycol, *n*-dodecane, eicosanedioate, ethyleneglycol, geraniol, *n*-hexadecane, hippurate, isobutanol, isopropanol, kynurenate, methylamine, mucate, naphthalene, nicotinate, phenol, phenylethanediol, propyleneglycol, quinate, saccharate, testosterone and DL-α-aminovalerate. A negative reaction is also obtained by conventional tests (Segers et al., 1994) for gelatin liquefication, indole formation, urease, lysine and ornithine decarboxylases, arginine dihydrolase, phenylalanine deaminase, lecithinase (egg yolk), and lipase (Tween 80).

[e]Activity of the following enzymes as determined for *B. diminuta* and *B. vesicularis* by API ZYM. Always absent: lipase (C_{14}), cystine arylamidase, α-fucosidase, α-galactosidase, β-galactosidase, β-glucosidase, *N*-acetyl β-glucosidase, and α-mannosidase; present: alkaline and acid phosphates, ester lipase (C_8), leucine arylamidase, phosphoamidase, trypsin, and indophenol oxidase.

[f]Isomer not specified for *B. alba, B. aurantiaca, B. bacteroides, B. intermedia, B. subvibrioides,* and *B. variabilis.*

because of its inability to utilize most carbohydrates. Characteristic for both nonprosthecate species is also the utilization of DL-β-hydroxybutyrate, a feature that has not been tested for the prosthecate species. It is clear from Table BXII.α.108 that several phenotypic characteristics are available solely for either the prosthecate or the nonprosthecate species, which is a result from their—until recently—different generic classification. No comprehensive phenotypic studies are available in which all species of the genus are compared in a consistent and reproducible way.

The nonprosthecate species are oxidase positive and urease and gelatinase negative, and they do not produce indole. The prosthecate species have, as far as is known, not been examined for these features. Metabolic studies using *B. bacteroides* have indicated the presence of 2-keto-3-deoxy-6-phosphogluconate aldolase which suggests that glucose is catabolized via the Entner–Doudoroff pathway (Poindexter, 1981). *Brevundimonas* strains also have the ability to degrade or detoxify aromatic compounds and organophosphates (Poindexter, 1981; Weissenfels et al., 1990; Caldwell et al., 1991; Labuzek et al., 1994; Hoskin et al., 1995; Hong and Raushel, 1996; Davis et al., 1997), a characteristic that has recently been used to develop an amperometric enzyme biosensor for the direct measurement of parathion (Sacks et al., 2000). *B. diminuta* strains are also characterized by a specific control mechanism for DAHP synthetase (3-deoxy-D-arabino-heptulosonate 7-phosphate synthetase), an activity that is not always recovered for *B. vesicularis* (Whitaker et al., 1981). Byng et al. (1980) have demonstrated the presence of an NADP-dependent prephenate dehydrogenase (tyrosine biosynthesis) in nonprosthecate *Brevundimonas* species, and West (1992) has studied their ribonucleoside catabolic enzyme activities. Polyvinyl alcohol oxidase activity has been demonstrated for a particular *B. vesicularis* strain (Kawagoshi and Fujita, 1997; Kawagoshi et al., 1997). EDTA resistance is demonstrated for *B. diminuta* (Wilkinson, 1968). Finally, the unusual metabolic capacities of some *Brevundimonas* members have recently been investigated for bioconversion of intermediate components of cephalosporin production (e.g., Kim et al., 2000b).

Lipid composition The polar lipids are α-D-glucopyranosyl diacylglycerol, α-D-glucopyranuronosyl diacylglycerol, 6-phosphatidyl-α-D-glucopyranosyl diacylglycerol, phosphatidylglycerol, 1,2-di-*O*-acyl-3-*O*-[D-glucopyranosyl- (1→4) -α-D-glucopyranuronosyl] glycerol, and sulfoquinovosyl diacylglycerol (Abraham et al., 1997).

Data on the lipopolysaccharides are available only for the two nonprosthecate species and have some unusual features (Wilkinson and Taylor, 1978). The lipid A contains 2,3-diamino-2,3-dideoxy-D-glucose instead of 2-amino-2-deoxy-D-glucose (the backbone of lipid A in lipopolysaccharides of most Gram-negative bacteria). The component 9-hydroxy-delta-tetradecalactone has been detected in lipid A of both species (Arata et al., 1989). Acetylated mannan and D-threo-pent-2-ulose have been isolated from the lipopolysaccharides of one *B. diminuta* strain NCTC 8545 (Wilkinson 1981b, a). Purified lipid A preparations of *B. vesicularis* may activate macrophages to resist infection by an opportunistic bacterium in mice (Arata et al., 1994).

Brevundimonas strains are characterized by the following dominant fatty acids $C_{12:0\ 3OH}$ (1–3%), $C_{14:0}$ (tr–5%), $C_{15:0}$ (tr–8%), $C_{16:0}$ (10–24%), $C_{16:1}$ (1–11%), $C_{17:0}$ (tr–8%), $C_{17:1\ \omega6c}$ (tr–6%), $C_{17:1\ \omega8c}$ (1–11%), and $C_{18:1}$ (39–69%) (Abraham et al., 1999). Species may be differentiated on the basis of quantitative differences in these fatty acids. *B. diminuta* and *B. alba* are further differentiated from the other *Brevundimonas* species by the presence of a significant amount of $C_{19:0\ cyclo\ \omega8c}$ (methyleneoctadecanoic acid; Yamada et al., 1982; Segers et al., 1994; Abraham et al., 1997, 1999).

Polyamines Prosthecate species have not been examined for the presence of polyamines. *B. diminuta* strains produce homospermidine as the major polyamine component (1.7–3.4 μmol/g protein) as well as trace amounts of spermidine. *B. vesicularis* strains (except one strain) produce spermidine as the major component (1.6–2.5 μmol/g protein), homospermidine as a minor component (0.1–0.5 μmol/g protein), and, in some cases, trace amounts of norspermidine, putrescine, and spermine. Two currently unnamed *Brevundimonas* strains yield a similar polyamine pattern to the *B. vesicularis* strains, and another strain produces only spermidine in high amounts (Segers et al., 1994).

Genetic features Rather small genomes (3–3.5 Mb) are observed for the nonprosthecate species (Grothues and Tümmler, 1991). No information on genome size is available for the prosthecate species. Plasmids have so far been detected only for *B. bacteroides* (Poindexter, 1989). DNA–DNA hybridization studies among all currently described species of *Brevundimonas* (M. Vancanneyt, personal communication) have shown relatedness values below 70%, thus confirming their status as separate species. Intermediate levels of DNA–DNA relatedness of 50% and 41% are observed between the nonprosthecate species *B. vesicularis* and the prosthecate species *B. aurantiaca* and *B. intermedia*, respectively. The latter two species show 65% DNA–DNA relatedness, indicating their close relationship.

Antimicrobial agents All species are sensitive to penicillin G and streptomycin. Significantly more data on antibiotic resistance are available for the two nonprosthecate species, which may be explained by their occurrence in clinical sources. *B. diminuta* is sensitive to aminoglycosides and β-lactam antibiotics and is highly sensitive to tetracyclines and rifampicin. Susceptibility to carbenicillin, sulfonamides, and chloramphenicol differs among strains of the species. All strains are resistant to nalidixic acid (a diagnostic feature), furans, trimethoprim, colistin, ampicillin, cephalothin, polymyxin, and gentamicin. *B. vesicularis* is usually more sensitive to antibiotics than is *B. diminuta*, especially to cephalothin (Gilardi, 1976; Richard and Kiredjian, 1995); however, treatment with tobramycin and ceftazidime of a case of *B. vesicularis* bacteremia in a patient was not successful (Planes et al., 1992).

B. subvibrioides and *B. bacteroides* have been found to be sensitive to some *Caulobacter* phages (Poindexter, 1989).

Source or habitat The organisms are typical aquatic bacteria. At least some species have been isolated from mineral water (Jayasekara et al., 1999). Prosthecate species may be isolated from soil (e.g., *B. alba*). Nonprosthecate species have also been identified in clinical specimens, such as blood cultures, infected biological fluids, urine, wounds, vagina, eye, and tissue cultures (Aspinall and Graham, 1989; Morais and da Costa, 1990; Gilardi, 1991; Planes et al., 1992; Abraham et al., 1997; Giardini et al., 1997). In particular, *B. vesicularis* has been reported as an important nosocomial agent (Gilad et al., 2000).

Enrichment and Isolation Procedures

There is no strong selective enrichment procedure described for the isolation of *Brevundimonas* strains. Nevertheless, the tolerance

of prolonged nutrient scarcity by prosthecate members of the genus provides a dependable physiological basis for their enrichment. Successful enrichments from water and from soil suspended in water are obtained when the sample is allowed to stand undisturbed for one to several weeks (Poindexter, 1992). Enrichment/isolation procedures are also described based on the accumulation of the stalked cells at the air–water interface or on a cover slip of a liquid culture with low nutrient content that is carefully protected against turbulence (Houwink, 1955; Poindexter, 1989). Methods and media for enrichment and further differentiation from other organisms are described in more detail in this chapter and in the literature (Leifson and Hugh, 1954b; Poindexter, 1964, 1981, 1989, 1992; Ballard et al., 1968; Gilardi, 1978b; Clark et al., 1984; Palleroni, 1984; Segers et al., 1994; Gilligan, 1995; Grimont et al., 1996).

Maintenance Procedures

Strains can be easily cultured aerobically on most common agar media containing peptone or yeast extract at 30°C. These media support growth without growth-factor supplements, which are necessary in defined media and enhance growth in complex media (Table BXII.α.107). Nonprosthecate cultures can be maintained for at least 1 week at room temperature or in a refrigerator before being transferred. Prosthecate isolates streaked on dilute complex media (and incubated for 2 or 3 d at 20–30°C) should be transferred every 8–9 weeks when refrigerated (Poindexter, 1989).

Cultures may be stored for many years by lyophilization, by freezing at −80°C, or in liquid nitrogen. In general, cryoprotective agents such as 10% glycerol or dimethyl sulfoxide are added to cultures before freezing, although prosthecate species can be frozen at −70°C without cryoprotectant (Poindexter, 1989).

Differentiation of the genus *Brevundimonas* from other genera

Characteristics that differentiate *Brevundimonas* from phylogenetically and phenotypically related genera and species are listed in Table BXII.α.107. *Caulobacter* is the closest phylogenetic neighbor with 16S rDNA sequence similarities of 95–96%. Based on morphological features, both nonprosthecate species of *Brevundimonas* are easily distinguished from *Caulobacter* species of which all, except *Caulobacter segnis*, are stalk-forming organisms. Within the latter genus, *C. segnis* has a unique morphology with irregular, peritrichously flagellated rods and branching filaments. Morphology does not allow differentiation among prosthecate species of both taxa. There are also no straightforward nutritional properties that unequivocally distinguish both genera, although particular tests can be used to characterize individual species (Table BXII.α.108; Poindexter, 1989). Some useful cultural and chemotaxonomic differentiating features between the genera *Brevundimonas* and *Caulobacter* are their salt tolerances and polar lipid and fatty acid contents (Table BXII.α.107; Stahl et al., 1992; Abraham et al., 1999). Strains of the genus *Caulobacter* show optimal growth at 0.5% NaCl and reduced or no growth at salt concentrations of 1–2% (depending on the species). *Brevundimonas* strains have a broader optimal salt concentration of 0.5–2% NaCl. The polar lipids 1,2-di-*O*-acyl-3-*O*-[D-glucopyranosyl-(1→4)-α-D-glucopyranuronosyl]glycerol, and sulfoquinovosyl diacylglycerol are present in most *Brevundimonas* strains (>80%) and absent in *Caulobacter*. *Brevundimonas* is furthermore differentiated from *Caulobacter* by the absence of significant amounts of $C_{12:1\ 3OH}$ and of an unknown fatty acid with ECL 11.789, and by the presence of at least traces of an unknown fatty acid with ECL 17.897 and higher amounts of $C_{12:0\ 3OH}$ and $C_{18:1}$ (Abraham et al., 1999).

Differentiation among *Brevundimonas* and *Caulobacter* strains is also obtained based on the reactivity of antisera. A 43-kDa protein exhibits genus-specific epitopes (Abraham et al., 1999). These authors have also demonstrated that desorption chemical ionization (DCI) mass spectrometry of glycolipids and subsequent multivariate analysis of the relative intensities of the $[M+NH_4]^+$ ions between m/z 740–840 has allowed differentiation between the genera *Brevundimonas* and *Caulobacter*.

Asticcacaulis is, at the generic level, the closest phylogenetic neighbor of *Brevundimonas* and *Caulobacter*, but clearly represents a separate branch within the family *Caulobacteraceae* (16S rDNA sequence similarity of 93–94%; Abraham et al., 2001). The genus *Asticcacaulis* was created by Poindexter (1964) to accommodate prosthecate isolates originally regarded as *Caulobacter* species. They are morphologically distinguished from prosthecate *Brevundimonas* and *Caulobacter* species by the site of adhesion of sessile cells to substrata; *Brevundimonas* and *Caulobacter* cells adhere by the distal tip of the prostheca, while *Asticcacaulis* cells adhere by the cell pole, and the prostheca is not adhesive (Poindexter, 1989, 1992). With a mol% G + C content between 55 and 61, *Asticcacaulis* can be differentiated from *Brevundimonas* and *Caulobacter* by its mol% G + C content of 62–68. The phylogenetic branches are further differentiated by the lack of 1,2-diacyl-3-*O*-[6′-phosphatidyl-α-D-glucopyranosyl]glycerol (PGL) in *Asticcacaulis*. Strains of this genus also do not contain 1,2-di-*O*-acyl-3-*O*[D-glucopyranosyl-(1→4)-α-D-glucopyranuronosyl]glycerol (DGL) found in most *Brevundimonas* strains but not in strains of the genus *Caulobacter* (Abraham et al., 2001). These authors have demonstrated, furthermore, that *Asticcacaulis* species are characterized by the presence of $C_{12:1\ 3OH}$ in their fatty acid profile, a component that has also been observed to be characteristic for *Caulobacter* species, but not for *Brevundimonas* taxa.

A deeper branching in the *Caulobacteraceae* is found for *Phenylobacterium*, a taxon characterized by nonmotile rods or cocci that do not produce prosthecae. Although there are some common features with the other members of the family, such as their growth factor requirements and carbohydrates for growth, the genus is easily distinguished by its high nutritional specialization. Good growth occurs on chloradizon, antipyrin, and L-phenylalanine (Lingens et al., 1985).

The two nonprosthecate species of *Brevundimonas* were previously classified in *Pseudomonas* (Palleroni, 1984). Both species can easily be differentiated from members of the present genus *Pseudomonas* (in general terms restricted to rRNA group 1; Palleroni, 1984) not only by their separate phylogenetic position, but also by one or more of the following characteristics: cell morphology, short wavelength of the flagella, polyamines and quinone content, a restricted nutritional spectrum, and their salt tolerance (Table BXII.α.107; Ballard et al., 1968; Gilardi, 1978b; Palleroni, 1984; Segers et al., 1994; Abraham et al., 1997, 1999). Both species are further distinguished by the absence of phosphatidylethanolamine and by the presence of phosphatidylglycerol, phosphatidylglucosyldiacylglycerol, and some major glycosyldiacylglycerols in their polar lipids (Wilkinson and Bell, 1971; Wilkinson and Taylor, 1978; Wilkinson and Galbraith, 1979;

Barnes et al., 1989). The presence or absence of specific 2-OH and 3-OH fatty acids can be used as diagnostic features to differentiate *Brevundimonas* taxa from other members of the former genus *Pseudomonas* (Table BXII.α.107; Oyaizu and Komagata, 1983; Palleroni, 1984; Segers et al., 1994). Also, genomic differences are found, like the small genomes of *Brevundimonas* spp. (3–3.5 Mb) and the absence of host factor for coliphage Qβ RNA replication (DuBow and Ryan, 1977; Grothues and Tümmler, 1991).

Taxonomic Comments

The genus *Brevundimonas* currently contains eight species and belongs to the class *Alphaproteobacteria* as a member of the family *Caulobacteraceae*. Originally, *Brevundimonas* contained only *B. diminuta* and *B. vesicularis*, which were reclassified members of the genus *Pseudomonas sensu lato* (Segers et al., 1994). Techniques based on rRNA similarities (Palleroni et al., 1973; De Vos and De Ley, 1983) demonstrated the phylogenetic heterogeneity of the latter genus and showed that the rRNA Group IV members, *Pseudomonas diminuta* and *Pseudomonas vesicularis*—often called the "diminuta group" (Ballard et al., 1968; Gilardi, 1978b)—were found to occupy a unique position within the *Alphaproteobacteria*. It was also shown by Segers et al. (1994) that some strains that were preliminarily classified into EF group 21, a heterogenous group containing organisms that show phenotypic similarities to *Sphingomonas paucimobilis* (formerly *Pseudomonas paucimobilis*), are members of *Brevundimonas*.

In 1999, 16S rRNA gene sequencing studies indicated that *B. vesicularis* and *B. diminuta* are phylogenetically interrelated with *Caulobacter intermedius* and *Caulobacter variabilis* (Abraham et al., 1999; Sly et al., 1999) and with *Caulobacter subvibrioides* and *Caulobacter bacteroides*, as well as with the misclassified *Mycoplana bullata* (Abraham et al., 1999). Other validly described species of the genus *Caulobacter*, including the type species *Caulobacter vibrioides* and *Caulobacter segnis*, constitute a separate phylogenetic branch within the family *Caulobacteraceae* (Abraham et al., 1999; Fig. BXII.α.122).

A formal reclassification has been made based on phylogenetic data and the genus extended with six new species, *B. bacteroides*, *B. intermedia*, *B. subvibrioides*, *B. variabilis*, *B. alba*, and *B. aurantiaca*. The latter two were originally described as *C. subvibrioides* subsp. *alba* and *C. henricii* subsp. *aurantiaca*, respectively. Based on their distinct phylogenetic position in the genus, they have been elevated to the species rank (Abraham et al., 1999).

Abraham et al. (1999) have also emended the genus description of *Caulobacter*, which currently contains, in addition to the type species *Caulobacter vibrioides*, the species *Caulobacter fusiformis*, *Caulobacter henricii*, *Caulobacter leidyi*, and *Caulobacter segnis*. *Caulobacter segnis* was originally named *Mycoplana segnis*, a misclassified member of *Mycoplana* that belongs to a different lineage in the *Alphaproteobacteria* within the family *Rhizobiaceae*. Furthermore, Abraham et al. (1999) have proposed that *Caulobacter crescentus* is a subjective synonym of *C. vibrioides*.

As shown in Fig. BXII.α.122, not only *Caulobacter segnis* (*Mycoplana segnis*) was misclassified, but also *Mycoplana bullata*, which clearly belongs on phylogenetic arguments to *Brevundimonas*. Additionally, 39% DNA relatedness has been found to the type strain of *B. diminuta* by DNA–DNA hybridizations (M. Vancanneyt, personal communication). Up to now, however, no formal reclassification has been proposed for the misclassified *Mycoplana bullata*. Except for the very distinct morphologic characteristics, i.e., peritrichously flagellated, rod-shaped cells forming filaments before fragmentation, most genomic, chemotaxonomic and nutritional features of *Mycoplana bullata* are analogous to those of related species of *Brevundimonas* (Table BXII.α.107; Yanagi and Yamasato, 1993; Abraham et al., 1999). If a formal reclassification is proposed to include *M. bullata* as a member of *Brevundimonas*, the emended genus description of the latter will have to encompass the features of *Mycoplana bullata*, as indicated below.

Differentiation of the species of the genus *Brevundimonas*

Features for differentiating *Brevundimonas* species are the cell morphology and cell division, stalk formation, pigmentation, requirement for growth factors, nutritional spectrum, and other characteristics as shown in Table BXII.α.108.

List of species of the genus Brevundimonas

1. **Brevundimonas diminuta** (Leifson and Hugh 1954b) Segers, Vancanneyt, Pot, Torck, Hoste, Dewettinck, Falsen, Kersters and De Vos 1994, 507[VP] (*Pseudomonas diminuta* Leifson and Hugh 1954b, 68.)
di.mi.nu′ta. L. adj. *minutus* small; M.L. fem. adj. *diminuta* defective, minute.

Short rods. Motile by means of one polar flagellum that has a short wavelength (0.6–1 μm). No prosthecae or special cell division. No pigmentation. The description of *B. diminuta* is the same as for the genus, with the additional characters given in Table BXII.α.107 and BXII.α.108.

Isolated from water, aqueous solutions and diverse clinical specimens in man and animals.

The mol% G + C of the DNA is: 66–68 (T_m).

Type strain: ATCC 11568, DSM 7234, IMET 10409, LMG 2089.

GenBank accession number (16S rRNA): AJ227778.

2. **Brevundimonas alba** (ex Poindexter 1964) Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1070[VP]
al′ ba. L. fem. adj. *alba* white.

Cell morphology varies within a clone; some poles distinctly tapered, others rounded; long axis gently curved. Colonies colorless. The description of *B. alba* is the same as that for the genus, with the additional characters given in Table BXII.α.107 and BXII.α.108.

Strains are characterized by the presence of detectable amounts of $C_{19:0\ cyclo\ \omega 8c}$.

The type strain was isolated from soil.

The mol% G + C of the DNA is: 67 (Bd); 68 (HPLC).

Type strain: CB88, DSM 4736, LMG 18360.

GenBank accession number (16S rRNA): AJ227785.

3. **Brevundimonas aurantiaca** (ex Poindexter 1964) Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1071[VP]
au.ran.ti.a′ ca. M.L. fem. adj. *aurantiaca* orange.

Vibrioid, unusually small cells. Dark golden colonies. The description of *B. aurantiaca* is the same as that for the genus, with the additional characters given in Table BXII.α.107 and BXII.α.108.

The type strain was isolated from a contaminated *Chlorella* culture.

The mol% G + C of the DNA is: 67 (HPLC).

Type strain: CB-R, DSM 4731, LMG 18359.

GenBank accession number (16S rRNA): AJ227787.

4. **Brevundimonas bacteroides** (Poindexter 1964) Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1071[VP] (*Caulobacter bacteroides* Poindexter 1964, 272.)
bac.ter.oi′ des. M.L. *bacter* masc. form of Gr. neut. n. *bactrum* rod; Gr. n. *eidus* form, shape; M.L. adj. *bacteroides* rod shaped.

Slender, rod-shaped cells. Stalk typically has a bulbous distal tip. Colonies colorless or brightly pigmented yellow or orange. The description of *B. bacteroides* is the same as that for the genus, with the additional characters given in Table BXII.α.107 and BXII.α.108.

Isolated from water and soil.

The mol% G + C of the DNA is: 66 (Bd); 68 (HPLC).

Type strain: CB7, ATCC 15254 , DSM 4726, LMG 15096.

GenBank accession number (16S rRNA): AJ227782.

5. **Brevundimonas intermedia** (Poindexter 1964) Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1071[VP] (*Caulobacter intermedius* Poindexter 1964, 272.)
in.ter.med′ i.a. L. adj. *intermedia* in the middle degree, between extremes.

Short, vibrioid cells. Colorless colonies. The description of *B. intermedia* is the same as that for the genus, with the additional characters given in Table BXII.α.107 and BXII.α.108.

Isolates reported from pond water.

The mol% G + C of the DNA is: 66 (HPLC).

Type strain: CB63, ATCC 15262, DSM 4732, LMG 18361.

GenBank accession number (16S rRNA): AJ227786.

6. **Brevundimonas subvibrioides** (Poindexter 1964) Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1071[VP] (*Caulobacter subvibrioides* Poindexter 1964, 272.)
sub.vib.ri.oi′ des. L. pref. *sub* almost, somewhat, near; M.L. n. *vibrio* name of a genus; Gr, n. *eidus* resembling; M.L. adj. *subvibrioides* somewhat like a vibrio.

Cell morphology variable within a clone: some poles distinctly tapered, others rounded; long axis gently curved or not curved. Colonies orange, golden, or colorless. The description of *B. subvibrioides* is the same as that for the genus, with the additional characters given in Table BXII.α.107 and BXII.α.108.

Isolated from water and soil.

The mol% G + C of the DNA is: 67 (Bd); 68 (HPLC).

Type strain: CB81, ATCC 15264, LMG 14903.

GenBank accession number (16S rRNA): AJ227784.

7. **Brevundimonas variabilis** (Poindexter 1989) Abraham, Strömpl, Meyer, Lindholst, Moore, Christ, Vancanneyt, Tindall, Bennasar, Smit and Tesar 1999, 1071[VP] (*Caulobacter variabilis* Poindexter 1989, 495.)
var.i.a′ bil.is. M.L. adj. *variabilis* variable.

Short, thick, rod-shaped cells; position of stalk variable, arising from the center of the cell pole or from a subpolar (eccentric) site. Colonies red-orange or colorless. The description of *B. variabilis* is the same as that for the genus, with the additional characters given in Table BXII.α.107 and BXII.α.108.

Isolated from water and soil.

The mol% G + C of the DNA is: 65 (HPLC).

Type strain: CB17, ATCC 15255, DSM 4737, LMG 18362.

GenBank accession number (16S rRNA): AJ227783.

8. **Brevundimonas vesicularis** (Büsing, Döll and Freytag 1953) Segers, Vancanneyt, Pot, Torck, Hoste, Dewettinck, Falsen, Kersters and De Vos 1994, 508[VP] (*Pseudomonas vesicularis* (Büsing, Döll and Freytag 1953) Galarneault and Leifson 1964, 167; *"Corynebacterium vesiculare"* Büsing, Döll and Freytag 1953, 76.)
ve.si.cu.la′ ris. M.L. adj. *vesicularis* pertaining to a vesicle.

Short rods. Motile by means of one polar flagellum that has a short wavelength (0.6–1 μm). No prosthecae or special cell division. An intracellular carotenoid pigment (pink, yellow, or orange) is usually produced. The description of *B. vesicularis* is the same as that for the genus with the additional characters given in Table BXII.α.107 and BXII.α.108.

Isolated from water, aqueous solutions, and diverse clinical specimens from humans and animals.

The mol% G + C of the DNA is: 65–66 (T_m).

Type strain: ATCC 11426, CCUG 2032, DSM 7226, LMG 2350.

GenBank accession number (16S rRNA): AJ227780.

Other Organisms

1. *Mycoplana bullata* Gray and Thornton 1928, 83[AL]
bul.la′ ta. L. adj. *bullata* with a knob.

As shown above and reported in the literature (Fig. BXII.α.122; Abraham et al., 1999), *M. bullata* can also be phylogenetically considered a member of the genus *Brevundimonas.*

Cells are rod-shaped with round ends, occurring singly or rarely in pairs, motile by means of peritrichous flagella. They form branching filaments prior to fragmentation. No stalk formation. Calcium pantothenate and an unidentified compound are required for growth. Nitrate reduction and catalase activity are weak or negative. The Voges–Proskauer test is positive. Acid is produced oxidatively from D-glucose but is not produced from D-arabinose, D-xylose, D-mannose, D-fructose, D-galactose, maltose, sucrose, lactose, trehalose, D-sorbitol, D-mannitol, inositol, glycerol, or soluble starch. Other features are given in Table BXII.α.107 and in Urakami et al. (1990d).

Isolated from soil.

The mol% G + C of the DNA is: 66–68 (T_m).

Deposited strain: ATCC 4278, DSM 7126, IFO 13290, LMG 17157.

GenBank accession number (16S rRNA): D12785.

Genus IV. **Phenylobacterium** *Lingens, Blecher, Blecher, Blobel, Eberspächer, Fröhner, Görisch, Görisch and Layh 1985, 38*[VP]

JÜRGEN EBERSPÄCHER

Phe.ny.lo.bac.te′ ri.um. Gr. n. *phen* benzene; Gr. n. *bacterion* a small rod; M.L. neut. n. *Phenylobacterium* benzene bacterium, so named because of its unique preference for phenyl moieties from heterocyclic compounds as carbon sources.

Rods, coccobacilli, or cocci; 0.7–1.0 × 1.0–2.0 μm occurring singly, in pairs, or in short chains. Some strains tend to clump. In old cultures, pleomorphic forms, such as long rods (1.0 × 2.0–4.0 μm), long chains (10–50 μm) connected by filaments, and elliptical forms, may occur. Capsule stain negative; flexible capsule present. **Nonmotile.** Nonsporeforming. Non-acid-fast. Sheaths and prosthecae not produced. Nonpigmented. **Gram negative.** Growth on chloridazon–mineral salts agar is slow and colonies are small (1–2 mm) after 2–3 weeks. Colonies may be either smooth, convex, moist with shiny surfaces and entire edges, and easily emulsified in saline, or rough, dry, and not emulsifiable in saline. In liquid media, there is slight production of a greenish-yellow nonfluorescent pigment; in media containing L-phenylalanine a yellowish-green fluorescent pigment is produced. **Strictly aerobic. Catalase positive, weakly oxidase positive. Chemoorganotrophic, having a strictly respiratory type of metabolism.** Optimal temperature, 28–30°C. No growth at 4°C or 37°C; at 37°C cultures die within several days. Optimal pH 6.8–7.0; growth occurs between pH 6.5 and 8; no growth at pH 4 or 9. **Osmotically sensitive. Vitamin B_{12} is a growth factor. High nutritional specialization; grows well on chloridazon, antipyrin, and L-phenylalanine (most strains only after long lag phase).** Slow growth on L-glutamate, pyruvate, fumarate, succinate, and malate as well as on diluted complex media (0.5–2 g/l peptone). **Most sugars, alcohols, amino acids, carboxylic acids, and ordinary complex media are not utilized.** Does not denitrify; does not produce nitrite from nitrate. NH_4^+ and NO_3^- are used as sole sources of nitrogen; no growth with N_2. Gelatin, casein, starch, and esculin not hydrolyzed. Urease negative. Litmus milk negative. Weak H_2S production from thiosulfate or cysteine. Methyl red and Voges–Proskauer negative. Indole negative. No acid or gas produced from sugars or alcohols. Not pathogenic for rats or rabbits. **Isolated from soil after enrichment in mineral salts media containing chloridazon, antipyrin, or pyramidon** (synthetic heterocyclic compounds).

The mol% G + C of the DNA is: 65–68.5.

Type species: **Phenylobacterium immobile** Lingens, Blecher, Blecher, Blobel, Eberspächer, Fröhner, Görisch, Görisch and Layh 1985, 38.

FURTHER DESCRIPTIVE INFORMATION

Two strains of *Phenylobacterium immobile*, namely strains E and A13 (see Fig. BXII.α.123, parts a and b) form exclusively coccal rods, which tend to clump, and growth in liquid cultures is sometimes flocculent. All other strains have short rod-shaped cells, which occur singly, in pairs, or in short chains. These strains never clump in liquid cultures. Chains are found mainly in cultures of strains that form smooth colonies on agar plates (e.g., strain K_2, see Fig. BXII.α.123c). In old cultures, especially when the bacteria are cultivated in a dilute complex medium that allows only poor growth, pleomorphic forms, such as long rods, long chains of cells connected by small filaments, or club-shaped and elliptical forms, sometimes occur.

Capsule staining and Gram staining are negative. Electron microscopy of thin sections reveal the typical Gram-negative cell wall pattern. Ultrathin sections of ruthenium red-treated cells of strain K_2, which forms smooth colonies, show a microcapsule surrounded by a slime layer of acidic polysaccharides (Fig. BXII.α.124a). No slime layer is detected in ruthenium-red-stained cells of strain E, which forms rough colonies on agar (Fig. BXII.α.124b). According to Costerton et al. (1981), *Phenylobacterium* cells possess flexible capsules, which can be made visible only by electron microscopy, but not rigid capsules, which represent the typical India ink-excluding capsule type.

The murein main component from the type strain is identical to the C_6 muropeptide of *E. coli.* The carbohydrate moiety from the lipopolysaccharide of the type strain consists of heptose, 3-deoxyoctulosonic acid, and D-glucose in a molar ratio of 1:2:2.3 (Weisshaar and Lingens, 1983). Lipid A is composed of 1 mol 2,3-diamino-2,3-dideoxy-D-glucose, 2 mol amide-bound fatty acids, and 2.6 mol ester-bound fatty acids per mol lipid A. 2,3-diamino-2,3-dideoxy-D-glucose is typical of *Alphaproteobacteria* but absent in other Gram-negative bacteria, which contain glucosamine as the main lipid A component. Amide-bound fatty acids are 3-hydroxydodecanoic acid and 3-hydroxyhexadecanoic acid; ester-linked fatty acids are dodecanoic acid and 3-hydroxy-5-*cis*-dodecenoic acid. The detection of the latter, unusual fatty acid, not found in nature before, can be used to demonstrate the presence of *Phenylobacterium immobile* in soil samples (Bellmann and Lingens, 1985).

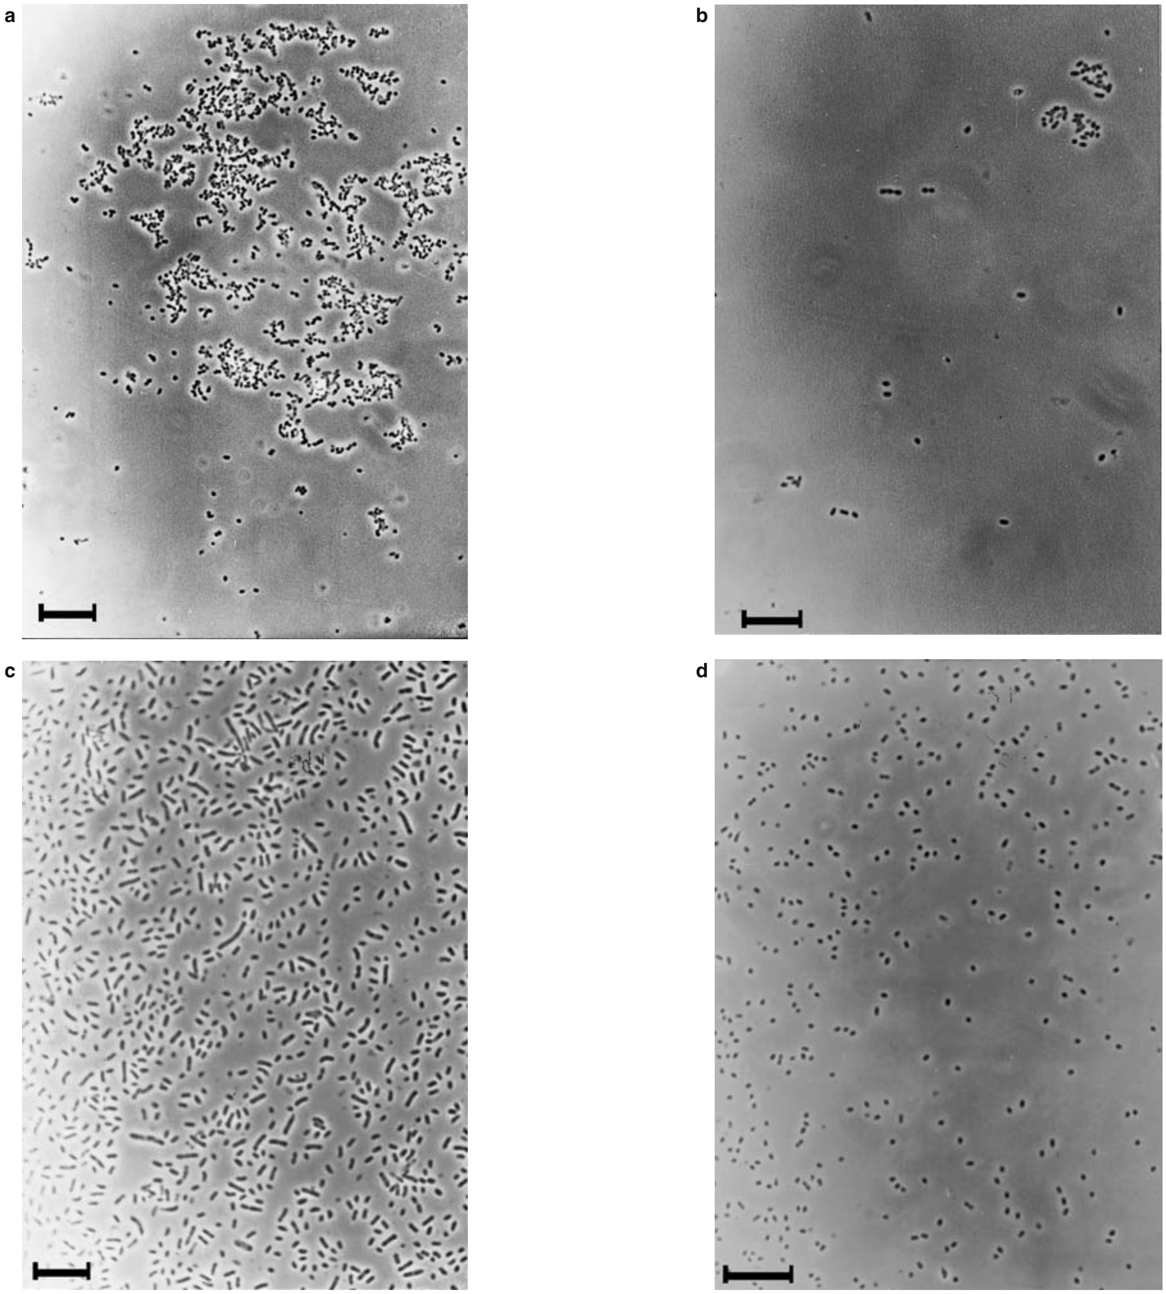

FIGURE BXII.α.123. Phase contrast photomicrographs of cells of *Phenylobacterium immobile.* *a*) Strain A_{13}; *b*) strain E, the type strain; *c*) strain K_2; and *d*) strain N. Bars = 10 μm.

In liquid cultures, during growth on mineral salts medium with phenylalanine, especially at higher concentrations (3–5 g/l), a yellowish-green fluorescent pigment is produced. On chloridazon or antipyrin mineral salts media, a greenish-yellow nonfluorescent pigment is formed.

Optimal growth on agar plates occurs on mineral salts medium containing chloridazon, antipyrin, or L-phenylalanine as the carbon source. Single colonies are not visible before 4–7 days, and after 2–3 weeks the colonies are 1–2 mm in diameter, circular with entire edges, slightly raised, and not adherent to the agar. Nearly half of the strains form smooth and shiny colonies that can be readily emulsified in water. The other strains have rough and dry colonies that clump when suspended in water.

Each different strain of *Phenylobacterium immobile* does not utilize all three xenobiotic substrates (formula, Fig. BXII.α.125). Whereas chloridazon and antipyrin are well utilized by most strains, only 7 of the 22 isolates use pyramidon as a growth substrate (Table BXII.α.109). When pyramidon is added to media containing chloridazon or antipyrin, the growth of all isolates is inhibited.

The pathway for the degradation of the three xenobiotics follows the well-known route for the oxidative dissimilation of aromatic compounds. From these xenobiotic compounds, only the phenyl moiety is used as a carbon source; the heterocyclic moiety remains unchanged. In the first step, O_2 is incorporated in the benzene nucleus by the action of a dioxygenase. The

chloridazon antipyrin pyramidon

FIGURE BXII.α.125. The herbicide chloridazon and the structurally related analgesics antipyrin and pyramidon were used for the enrichment of *Phenylobacterium immobile* from soil. These xenobiotics are also the best growth substrates for the bacteria.

resulting *cis*-dihydro-dihydroxy compound is oxidized by a dehydrogenase, yielding a catechol derivative, which leads to a dephenylated heterocycle and 2-hydroxymuconate by *meta*-cleavage and the subsequent action of an amidase. Meta-cleaving enzymes from *P. immobile* form a distinct group among nonheme-iron dioxygenases (Schmitt et al., 1984) 2-Hydroxymuconate is further converted via 2-oxo-4-hydroxyvalerate to pyruvate and acetaldehyde, two compounds of intermediary metabolism that are potential carbon sources for the bacterium.

Citric acid cycle enzymes and enzymes catalyzing anaplerotic routes are present in *P. immobile* strain E. Tyrosine is synthesized exclusively via the arogenate pathway, not via prephenate (Keller et al., 1982).

More than 20 different heterocyclic or aromatic compounds that are structurally related to chloridazon or antipyrin have been tested as possible carbon sources. Most chloridazon analogs with an altered heterocyclic moiety are good growth substrates. A substitution at the aromatic nucleus, as for *o*-, *m*-, or *p*-methylchloridazon, makes the compound nondegradable. Of the aniline derivatives tested, *N*-methylacetanilide and *N*-methylformanilide are poor growth substrates. The following compounds fail to support growth: benzene, toluene, phenol, catechol, benzaldehyde, benzoate, and a number of mono- and dihydroxylated benzoates. One strain (strain N) grows well on L-phenylalanine with a normal lag phase of 1 day; all other strains have lag phases of 2–3 weeks but then grow well on phenylalanine. The long lag phases are observed only for the first transfer of the strains from chloridazon or antipyrin to phenylalanine; thereafter the bacteria grow immediately. Phenylalanine-induced cells also grow well on phenylpropionate, phenylpyruvate, and phenyllactate.

All strains tested are susceptible to tetracycline, bacitracin, chloramphenicol, kanamycin, and streptomycin. The majority (18 of 22) are susceptible to penicillin G and 15 of 22 strains are susceptible to novobiocin. All are resistant to cephaloridine, cloxacillin, fusidic acid, lincomycin, methicillin, and sulfafurazol.

P. immobile strains were found to be harmless when tested in rats and rabbits (Kaiser et al., 1981). No adverse reactions were observed when cells of strains E and N, respectively, were orally administered to rats over a period of 7 d. Exposure via air in inhalation experiments did not lead to specific pulmonary changes. Intracutaneous injection did not cause adverse skin reactions, and intraperitoneal injections did not kill the rats, although bacteria entered the blood. Intravenous injections of living and formalin-inactivated bacteria into rabbits during immunization did not lead to toxic effects.

As shown in Table BXII.α.109, depending on the strain, between one and six different plasmids have been found, which vary in size from 8–300 mDa (Kreis et al., 1981).

Agglutination and immunofluorescence tests with antisera against 4 strains of *Phenylobacterium immobile* have revealed the serological uniformity of the different strains (Layh et al., 1983). Slight differences in immune reactions allow a classification of the strains into 5 serological subgroups. No relationship was found between *Phenylobacterium immobile* and 40 representative Gram-negative bacteria, including *Acinetobacter calcoaceticus*, *Azospirillum brasilense*, *Caulobacter* spp., *Paracoccus denitrificans*, some *Pseudomonas* spp., *Rhizobium* spp., *Rhodomicrobium vannielii*, and *Rhodopseudomonas capsulata*. A slight but significant immunofluorescence reaction has been observed with *Brevundimonas vesicularis*, *Gluconobacter oxydans*, *Aquaspirillum itersonii*, and *Rhodospirillum rubrum* (Dorfer et al., 1985). Crossed immunoelectrophoresis reveals a serological relationship between *Phenylobacterium immobile* and *Brevundimonas diminuta*.

The detection of *Phenylobacterium immobile* as a new genus was the unintentional result of studies on the breakdown of the herbicide chloridazon. Chloridazon is the active ingredient of the herbicide Pyramin®. This compound has been used since about 1960 for the control of weeds in sugar beet and beet root cultures. The decomposition of chloridazon (formerly named pyrazon) was demonstrated to be a microbial process (Drescher and Otto, 1969; Frank and Switzer, 1969). The isolation of bacteria with the ability to grow on chloridazon as the sole carbon source was described by Engvild and Jensen (1969) and by Fröhner et al. (1970). Since 1969, more than 20 different strains that grow with the herbicide chloridazon or the structurally related analgesics antipyrin and pyramidon have been isolated from soils from various places over the world (Table BXII.α.109).

All attempts to identify the different isolates of chloridazon-degrading bacteria on the basis of routine characters have led to unsatisfactory results. The high nutritional specialization of these bacteria, which grow optimally on man-made compounds and utilize poorly only a few normal carbon sources, is their most distinguishing feature, along with the fact that nearly all biochemical tests give negative results.

P. immobile seems to be a typical inhabitant of the upper aerobic part of the soil. Different strains have been isolated from soil samples from various locations all over the world. All efforts to isolate chloridazon-degrading bacteria which grow at 37°C have failed. For this purpose, soil and water samples from hot springs, from near-volcanic regions, and from regions with tropical climates were subjected to chloridazon enrichment. Attempts to demonstrate the breakdown of chloridazon in soil or in mud samples under anaerobic conditions failed. In one case, a slow degradation of chloridazon in river water was observed, but efforts to isolate chloridazon-degrading bacteria from this specific water sample failed. However, one cannot rule out the possibility that phenylobacteria may occur in aquatic habitats.

The technique for the enrichment of chloridazon-degrading bacteria leads to the isolation of organisms that are able to utilize synthetic molecules not normally encountered in nature. Obviously, the chemical character of the selective agent (heterocyclic plus a phenyl moiety) is a special challenge for microbial cells, for which only a special sort of organism (*Phenylobacterium immobile*) seems to have the adequate response. This view is supported by the fact that in many different soil samples, the same sort of bacteria are always isolated. Furthermore, efforts to isolate the same bacteria with L-phenylalanine as the selective agent are unsuccessful. Enrichment techniques and nutritional characteristics raise the question of which substrates are used by these bacteria in their natural environments. Using an immunofluorescence membrane filter technique, evidence has been obtained that *Phenylobacterium immobile*, or serologically closely related organisms, also occur in soils which have never been treated with the herbicide. This suggests that these bacteria are able to survive in nature without their optimal growth substrate by utilizing other substrates—perhaps L-phenylalanine or mixtures of organic compounds such as pyruvate, succinate, malate, fumarate, and L-glutamate, which allow moderate growth.

Enrichment and Isolation Procedures

The following procedure leads to the isolation of bacteria that are able to utilize as a sole carbon source man-made compounds not normally encountered in nature. As a synthetic substrate for selective enrichment, either the herbicide chloridazon, or the analgesics antipyrin or pyramidon (Fig. BXII.α.125) can be applied. Chloridazon, the active ingredient of the herbicide Pyramin®, can be obtained from Riedel de Haen, D-30918 Seelze, Germany; antipyrin and pyramidon (4-dimethylaminoantipyrin) are available from Sigma-Aldrich Chemie, D-89555 Steinheim, Germany. About 300 g soil or compost is mixed with 0.5 g chloridazon, antipyrin, or pyramidon, and the preparation is incubated at 30°C or room temperature in a flower pot and regularly moistened with water. Degradation of the xenobiotic compound can be observed chromatographically (TLC or HPLC) by testing the excess water that drains from the flower pot for the presence of the xenobiotic. Decomposition is complete when the xenobiotic is no longer detectable, and a new compound corresponding to the dephenylated heterocyclic moiety of the xenobiotic appears, usually after one to several weeks, depending on the soil. A 5 g sample of the active soil is then placed into an Erlenmeyer flask containing 50 ml of mineral salts medium[1] supplemented with the xenobiotic as the carbon source at a concentration of 0.04– 0.1%.

This culture is incubated on a rotary shaker at 30°C, and degradation is monitored chromatographically. When the decomposition of the xenobiotic is complete, 1 ml of the culture fluid is transferred into a new Erlenmeyer flask. After 5–10 transfers, a sample of the liquid culture is streaked onto agar plates containing the same medium. Single colonies, which normally appear after 1–3 weeks, are picked and again streaked onto agar. After 5–10 transfers, pure cultures can usually be obtained. Growth on chloridazon mineral salts agar allows the removal of chloridazon to be perceived as a clearance zone around the bacterial colonies (see Fig. BXII.α.126). Since none of the *P. immobile* strains grows on ordinary complex media, the inoculation of a complex agar medium can be used for testing purity. This medium contains per liter deionized water: peptone, 5 g; meat extract, 3 g; yeast extract, 5 g, NaCl, 5 g. Growth on this medium indicates contamination of the culture.

Maintenance Procedures

For short-term preservation, the bacteria are transferred onto agar at intervals of 2–3 weeks. For long-term preservation, a bacterial suspension in skim milk is dropped onto silica gel grains and stored at 4°C. Good results are obtained with this method when transfer is repeated every 2–3 years; some of the strains have been viable even after a period of 10 years. Storage at −80°C of a concentrated bacterial suspension in fresh chloridazon-mineral salts medium supplemented with 15% glycerol has resulted in good viability after a storage of more than 8 years.

Procedures for Testing Special Characters

Nutritional specialization is a main feature of *Phenylobacterium immobile*. Therefore, tests for growth on chloridazon or antipyrin are of special importance. Optimal growth and maximum cell yield are achieved at 30°C in mineral salts medium with chloridazon or antipyrin at 0.4–1 g/l. Under these conditions, a dou-

1. The mineral salts medium has the following composition per liter deionized water: $Na_2HPO_4 \cdot 12H_2O$, 0.7 g; KH_2PO_4, 0.3 g; $(NH_4)_2HPO_4$, 0.7 g; $(NH_4)H_2PO_4$, 0.3 g; $(NH_4)_2SO_4$, 0.1 g; trace element solution (see text) 1 ml; vitamin B_{12} solution (0.03 mg/ml), 1 ml; $MgSO_4 \cdot 7H_2O$, 0.25 g; $CaCl_2 \cdot 6H_2O$, 0.05 g. To avoid precipitates, the magnesium and calcium salts are each dissolved separately. Trace element solution per liter deionized water: $MnSO_4 \cdot 4H_2O$, 400 mg; $ZnSO_4 \cdot 7H_2O$, 400 mg; $FeCl_3 \cdot 6H_2O$, 200 mg; $CuSO_4 \cdot 5H_2O$, 40 mg; H_3BO_3, 500 mg; $(NH_4)_2MoO_4 \cdot 4H_2O$, 200 mg; KI, 100 mg; biotin, 100 mg. Either chloridazon, antipyrin, or pyramidon is added as the carbon source at a concentration of 0.4–1 g/l. The pH of the medium is 7.0.

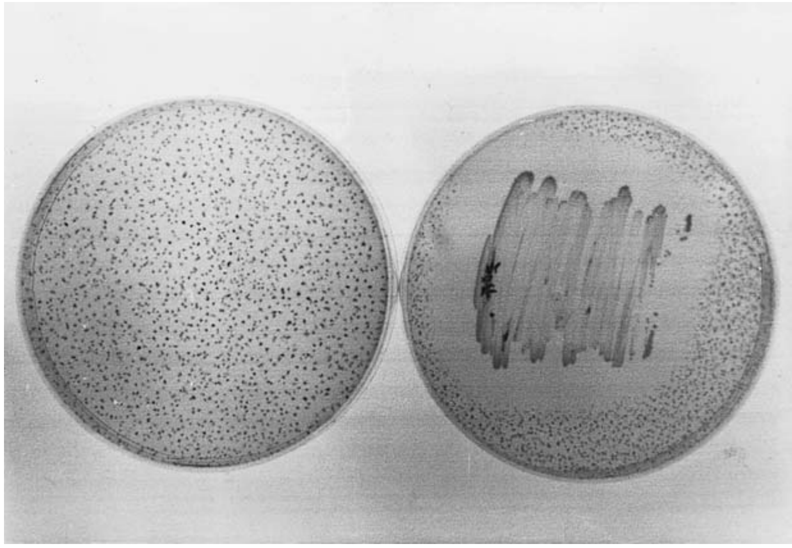

FIGURE BXII.α.126. Agar plates containing mineral salts medium with 2 g/l chloridazon. Fine crystals of chloridazon have precipitated in the agar. On the right-hand plate, a clearance zone around the bacterial smear of *Phenylobacterium immobile* has formed by chloridazon degradation. At the left margin of the bacterial smear, a large crystal is visible, which corresponds to the dephenylated heterocyclic moiety of chloridazon, the main metabolite of chloridazon degradation.

bling time of 7–8 h is observed, and, depending on the strain, a yield of about 0.4–1.0 g/l bacteria (wet weight) of culture fluid is obtained. Mineral salts medium with either 0.2% chloridazon or 0.1% antipyrin as the carbon source, supplemented with 15 g/l agar, allows good growth of *Phenylobacterium immobile*. Growth on agar may be made visible as follows: Agar plates containing mineral salts medium with 2 g/l chloridazon show a fine precipitate of chloridazon crystals in the agar. During growth on this agar, *Phenylobacterium immobile* removes the crystals by degradation, and a clearance zone around the bacterial smear develops (Fig. BXII.α.126). In agar cultures 4 or more weeks old, a new, and in most cases, relatively large sort of crystals forms within the bacterial smear. These crystals have been identified as the dephenylated heterocyclic moiety of chloridazon, which is a dead-end metabolite of chloridazon degradation.

The osmotic sensitivity and nutritional specialization of *Phenylobacterium immobile* do not allow the use of routine media for biochemical characterization. Therefore, tests have to be performed in modified media on which the bacteria are able to multiply. Mineral salts medium with 0.5 g chloridazon or 1 g antipyrin as the carbon source can be applied for testing catalase, oxidase, antibiotic susceptibility, and arginine-, lysine- and ornithine-decarboxylase. Mineral salts medium containing 1 g peptone, 1 g yeast extract, and 0.5 g antipyrin or chloridazon can be used for testing urease, indole reaction, Voges–Proskauer, methyl red, H_2S production, production of nitrite from nitrate, gelatin, starch, cellulose, and esculin hydrolysis.

Differentiation of the genus *Phenylobacterium* from other genera

Small subunit rRNA sequence analysis has shown sequence similarities between *P. immobile* and several *Caulobacter* and *Mycoplana* species, as well as one *Afipia* genospecies. A phylogenetic tree reflecting the relationships of *P. immobile* and selected members of the *Caulobacteraceae* group is shown in Fig. BXII.α.127. The sequence similarity values suggest a close phylogenetic relation between these members of the *Alphaproteobacteria*, despite great differences in their phenotypes and ways of life. *P. immobile* is not prosthecate like *Caulobacter*; however, it shares several properties, such as an oligotrophic nature with ready growth on dilute, complex medium (below 0.1% organic material), a strictly respiratory and aerobic metabolism, and a similar mol% G + C content of the DNA with *Caulobacter*. *Phenylobacterium* is Gram-negative like *Mycoplana* but, unlike *Mycoplana*, it does not exhibit branching filaments that fragment into motile, irregular rods—a trait that has led several workers to place *Mycoplana* in the order *Actinomycetales*. From DNA–RNA hybridization studies *M. dimorpha* and *M. bullata* seem to be remote relatives of the family *Rhizobiaceae*, a family whose members were also found to show some sequence similarity with *Phenylobacterium*; however, *Phenylobacterium* is neither a nitrogen fixer nor associated with plants. *Afipia* is the causal organism of cat scratch disease, whereas *Phenylobacterium* seems to be nonpathogenic. Comparative sequence analysis of the small subunit rRNA has demonstrated that the root-nodulating *Bradyrhizobium japonicum* and the budding bacteria *Blastobacter denitrificans* form a tight phylogenetic group with the human pathogens *Afipia felis* and *Afipia clevelandensis* (Willems and Collins, 1992).

Taxonomic Comments

Analysis of the 16S rDNA sequence[2] (1466 nucleotides) of the type strain (strain E), obtained by direct sequencing of the PCR

2. The 16S rDNA of the type strain was amplified by polymerase chain reaction using primers 27f and 1522rN from the 5′- and 3′-ends of the gene. Direct sequencing of the amplified product was performed using primers to conserved regions of the rRNA. The complete sequence of the 16S rDNA of the type strain, comprising 1466 nucleotides, was deposited at the EMBL Nucleotide Sequence Database under the accession number Y18216. Potential diagnostic targets for *Phenylobacterium*-specific probes were identified by analyzing the complete small subunit rRNA sequence data set (ARB data base; approximately 13,000 sequences) using the probe design and probe match tools of the ARB program package. The most promising diagnostic probes are: 5′-CCUGAUCGCCGGAGAGAU-3′ (*E. coli* pos. 1000–1017) and 5′-AAUGGUACUGCCGAGGUU-3′ (*E. coli* pos. 1151–1168).

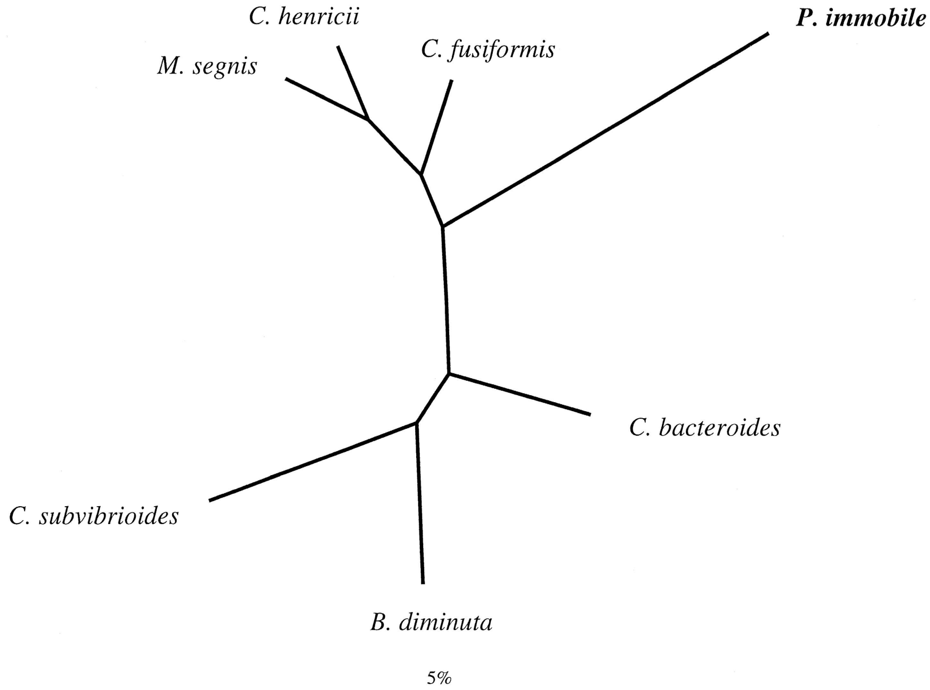

FIGURE BXII.α.127. Phylogenetic tree reflecting the relationships of *Phenylobacterium immobile* and selected members of the *Caulobacteraceae* group (*Caulobacter* spp., *Mycoplana* spp., and *Brevundimonas diminuta*). Only type strains for which 16S rRNA sequences are available are shown. The bar indicates 5% estimated sequence divergence. The tree was constructed on the basis of the complete small subunit rRNA sequence data (ARB data base, approximately 13,000 sequences. Compare: Ludwig, W. and Strunk, O. 1996 ARB: a software environment for sequence data.). The tree topology was evaluated by performing maximum parsimony and distance matrix analyses of the complete small subunit rRNA data set or a subset comprising all almost complete proteobacterial sequences together with reference data from selected representatives of the other bacterial lines of descent, respectively. Multiple data sets which varied with respect to the selection of alignment positions included were analyzed applying the alternative treeing methods. Alignment positions were included or excluded according to their degree of conservation. The majority of results support the depicted tree topology, which is based upon a data set comprising alignment positions that share identical residues in at least 50% of all sequences from members of the *Caulobacteraceae* group.

amplified gene product, reveals that *Phenylobacterium immobile* is a member of the *Caulobacteraceae.* Sequence similarities of 91.6–94.5% have been found for various *Caulobacter* species (*C. henricii, C. fusiformis, C. vibrioides, C. crescentus, C. bacteroides,* and *C. subvibrioides*). In addition, 95.9% similarity is obtained with *Afipia* genosp. 14, 94.3% with *Caulobacter segnis* (*Mycoplana segnis*), 93.2% with *M. bullata*, and 93.1% with *Brevundimonas diminuta.* Significantly, lower similarities of 90% and below are obtained with species of *Rhizobium, Paracoccus, Agrobacterium,* and other members of the *Alphaproteobacteria.* These results are in accordance with partial sequence analysis of 16S rRNA data of the type strain (Ludwig et al., 1984). Based on the formerly applied nucleotide cataloging method, *Phenylobacterium immobile* is a member of the *Alphaproteobacteria* with highest similarity (S_{AB} values of 0.51) to *Brevundimonas diminuta* (formerly *Pseudomonas diminuta*) and *Rhizobium leguminosarum.*

Several other features support the phylogenetic position of *Phenylobacterium* that has been established by small subunit rRNA sequence analysis. The presence of 2,3-diamino-2,3-dideoxy-D-glucose as a lipid A constituent of *Phenylobacterium immobile* indicates its relationship to the *Alphaproteobacteria.* This unusual sugar has also been detected in *Rhodopseudomonas viridis, R. palustris, R. sulfoviridis, Brevundimonas diminuta, B. vesicularis,* and *Nitrobacter winogradskyi* (Weckesser and Mayer, 1987). Busse and Auling (1988) have shown that polyamines may serve as a useful chemotaxonomic marker within the *Proteobacteria.* Like other species of the *Alphaproteobacteria, P. immobile* contains *syn*-homospermidine exclusively, as well as ubiquinone Q-10, composed of 10 isoprenoid units (R.M. Kroppenstedt, J. Eberspächer, and F. Lingens, unpublished). Weak serological reactions of *Phenylobacterium immobile* occur only with members of the *Alphaproteobacteria* (Dorfer et al., 1985) and not with any other Gram-negative bacteria.

DNA hybridization tests reveal 100% similarity of DNA preparations among four different strains with DNA of strain R. No similarity has been found using DNA from *Agrobacterium tumefaciens, Bacillus subtilis, Escherichia coli, Pseudomonas fluorescens,* or calf thymus. Morphological, physiological, biochemical, and nutritional studies, and serological and enzymological data have also demonstrated the high degree of similarity among the more than 20 different isolates. Therefore, the isolates have been grouped together in one single species. On the other hand, minor, but significant, differences exist in cell and colony morphology, in plasmid pattern, in the utilization of the xenobiotics chloridazon, antipyrin and pyramidon, and in serological properties that allow a classification into 5 serological subgroups (Table BXII.α.109).

The construction of *Phenylobacterium*-specific probes using 16S rDNA sequence analysis data should allow the detection of *Phenylobacterium immobile* and closely related bacteria in environmental samples without prior enrichment with xenobiotics. This technique using diagnostic target probes seems to be more specific than the previously applied serological method. Based on the probe examination of environmental samples, it would seem to be feasible to isolate *P. immobile* or *P. immobile*-like organisms without using the selective enrichment technique for growth on the xenobiotics chloridazon, antipyrin, or pyramidon.

Acknowledgments

The author is greatly indebted to Dr. Wolfgang Ludwig, Institute of Microbiology, Technical University of Munich, for processing 16S rDNA data and constructing a phylogenetic tree, and to Prof. Dr. Michael Schlömann and his coworkers from the Institute of Microbiology, University of Stuttgart, for his introduction into the 16S-rDNA sequencing method.

List of species of the genus Phenylobacterium

1. **Phenylobacterium immobile** Lingens, Blecher, Blecher, Blobel, Eberspächer, Fröhner, Görisch, Görisch and Layh 1985, 38[VP]
im.mo' bi.le. L. adj. *immobile* nonmotile.

The characteristics are as described for the genus and in Tables BXII.α.109 and BXII.α.110. *P. immobile* uses relatively few simple carbon sources. Growth occurs on L-glutamate, pyruvate, fumarate, succinate, and malate, but more poorly than on chloridazon or L-phenylalanine. A mixture of these compounds, e.g., pyruvate plus L-glutamate, yields better growth than do single compounds, although the growth rate and cell yield are still lower than with chloridazon. No growth occurs on more than 40 compounds tested as possible carbon sources, including various sugars, alcohols, carboxylic acids, and amino acids. A similar spectrum of compounds is negative for acid or gas production. Complex media with 10–20 g/l peptone or meat extract plus yeast extract does not support growth, whereas with 0.5–2 g/l peptone plus yeast extract, growth occurs, but more slowly than on chloridazon. *Phenylobacterium immobile* is osmotically sensitive; the addition of 5–7 g NaCl per liter chloridazon mineral salts medium result in considerable growth inhibition, 10 g NaCl leads to total growth inhibition.

The mol% G + C of the DNA is: 65–66.5 (Bd); strain C_2 has a somewhat higher value of 68.5 (Bd).

Type strain: E, ATTC 35973, DSMZ 1986.

GenBank accession number (16S rRNA): Y18216.

TABLE BXII.α.110. General characteristics of *Phenylobacterium immobile*[a]

Characteristic	*Phenylobacterium immobile*
Cell diameter, μm	0.7–1.0
Cell length, μm	1.0–2.0
Cells single, in pairs or short chains	+
Motility	−
Spores, sheaths, prosthecae	−
Pigmented	−
Long rods or chains or elliptical cells in old cultures	d
Gram-stain, Ziehl–Neelsen-stain, capsule-stain	−
Colonies smooth	d
Colonies rough	d
Strictly aerobic	+
Catalase	+
Oxidase	w
Growth at 4°C and 37°C	−
Optimal growth temperature, °C	28–30
Growth at pH 4 and 9	−
Optimal pH	6.8–7.0
Growth inhibition by 0.5–0.7% NaCl	+
Growth factor vitamin B_{12}	+
Optimal growth on chloridazon, antipyrin, and phenylalanine (after long lag phase)	+
Fluorescent pigment on phenylalanine medium	+
Non-fluorescent pigment on chloridazon medium	+
Moderate growth on glutamate, succinate, pyruvate, fumarate, malate	+
Growth on sugars, alcohols, amino acids (40 compounds tested)	−
Growth on aromatic compounds (18 compounds tested)	−
Acid or gas from sugars and alcohols (34 compounds tested)	−
Growth on complex media	−
Growth on dilute complex media (0.5–2 g/l organic material)	+
NH_4^+ and NO_3^- used as N-sources	+
Denitrification	−
N_2-fixation	−
Gelatine, casein, starch, esculin hydrolyzed	−
Litmus milk	−
H_2S from cysteine or thiosulfate	w
Methyl red, Voges–Proskauer, indole	−
Mol% G + C of DNA (Bd)	65–68.5

Order VI. **Rhizobiales** *ord. nov.*

L. DAVID KUYKENDALL

Rhi.zo.bi.a′ les. M.L. n. *Rhizobium* type genus of the family *Rhizobiaceae*; *-ales* ending to denote an order; M.L. fem. n. *Rhizobiales* the *Rhizobium* order.

The order *Rhizobiales* is a phenotypically heterogeneous assemblage of Gram-negative bacteria and is based solely on 16S rRNA gene sequence analysis.

Type genus: **Rhizobium** Frank 1889, 338.

Families of the Order Rhizobiales

I. Family *Rhizobiaceae*
II. Family *Bartonellaceae*
III. Family *Brucellaceae*
IV. Family *Phyllobacteriaceae*
V. Family *Methylocystaceae*
VI. Family *Beijerinckiaceae*
VII. Family *Bradyrhizobiaceae*
VIII. Family *Hyphomicrobiaceae*
IX. Family *Methylobacteriaceae*
X. Family *Rhodobiaceae*

Family I. **Rhizobiaceae** Conn 1938, 321[AL]

L. DAVID KUYKENDALL

Rhi.zo.bi.a′ ce.ae. M.L. n. *Rhizobium* type genus of the family; *-aceae* ending to denote a family; M.L. fem. n. *Rhizobiaceae* the *Rhizobium* family.

The family *Rhizobiaceae* is a phenotypically heterogeneous assemblage of aerobic, Gram-negative rod-shaped bacteria and is based solely on 16S rRNA gene sequence analysis. (Table BXII.α.111)

Type genus: **Rhizobium** Frank 1889, 338.

Genera of the Family Rhizobiaceae

I. Genus *Rhizobium*
II. Genus *Agrobacterium*
III. Genus *Carbophilus*
IV. Genus *Chelatobacter*
V. Genus *Ensifer*
VI. Genus *Sinorhizobium*

TABLE BXII.α.111. Some determinative phenotypic features of the genera of the family *Rhizobiaceae*[a]

Characteristic	*Rhizobium, Sinorhizobium, Allorhizobium*	*Agrobacterium*	*Carbophilus*	*Chelatobacter*	*Ensifer*
Reproduce by budding at one pole of the cell	−	−	nd	d	+
Attach endwise to various host bacteria and may cause lysis of the host cells	−	nd	−	−	+
Some strains induce hypertrophisms in plants as root nodules with or without symbiotic nitrogen fixation	+[b]	−[b]	nd	nd	nd
Some strains induce tumorous galls in plants	−[b]	+[b]	nd	nd	nd
Aminopolycarboxylic acid, nitrilotriacetic acid can be utilized as a sole source of carbon/energy and nitrogen	−	−	nd	+	nd
Can grow chemolithoautotrophically with carbon monoxide (CO) as a sole carbon and energy source	−	−	+	nd	nd

[a]For symbols see standard definitions; nd, not determined.

[b]Traditionally, *Agrobacterium* has been associated with the incitement of tumorous galls and/or hairy roots in plants, whereas *Rhizobium*, *Sinorhizobium*, and *Allorhizobium* have been associated with the symbiotic induction of root nodules. However, because these features are plasmid-mediated, this is not a reliable basis for classification of these genera.

Genus I. **Rhizobium** *Frank 1889, 338*[AL]

L. David Kuykendall, John M. Young, Esperanza Martínez-Romero, Allen Kerr and Hiroyuki Sawada

Rhi.zo' bi.um. Gr. n. *rhiza* a root; Gr. n. *bios* life; M.L. neut. n. *Rhizobium* that which lives in a root.

Rods 0.5–1.0 × 1.2–3.0 µm. Nonsporeforming. Gram negative. **Motile by 1–6 peritrichous flagella.** Fimbriae have been described on some strains. **Aerobic**, possessing a respiratory type of metabolism with oxygen as the terminal electron acceptor. Optimal temperature for growth, 25–30°C; some species can grow at temperatures >40°C. Optimal pH for growth, 6–7; range pH 4–10. Generation times of *Rhizobium* strains are 1.5–5.0 h. **Colonies** are usually white or beige, circular, convex, semi-translucent or opaque, raised and mucilaginous, **usually 2–4 mm in diameter within 3–5 days on yeast-mannitol-mineral salts agar (YMA). Growth on carbohydrate media is usually accompanied by copious amounts of extracellular polysaccharide.** Pronounced turbidity develops after 2 or 3 days in aerated or agitated broth. Chemoorganotrophic, utilizing a wide range of carbohydrates and salts of organic acids as sole carbon sources, without gas formation. Cellulose and starch are not utilized. **Produce an acidic reaction in mineral-salts medium containing mannitol or other carbohydrates.** Ammonium salts, nitrate, nitrite, and most amino acids can serve as nitrogen sources. Strains of some species will grow in a simple mineral salts medium with vitamin-free casein hydrolysate as the sole source of both carbon and nitrogen, but strains of many species require one or more growth factors such as biotin, pantothenate, or nicotinic acid. Peptone is poorly utilized. Casein, starch, chitin, and agar are not hydrolyzed. **All known *Rhizobium* species include strains which induce hypertrophisms in plants as root nodules with or without symbiotic nitrogen fixation.** Some cells of symbiotic bacterial species enter root hair cells of leguminous plants (Family Leguminosae) via invagination or by wounds ("crack entry") and elicit the production of root nodules wherein the bacteria engage as intracellular symbionts, usually fixing nitrogen. Many well-defined nodulation (*nod*) and nitrogen fixation (*nif*) genes are clustered on large plasmids or megaplasmids (pSyms). Plasmid transfer between species results in the expression and stable inheritance of the particular plant-interactive properties of the plasmid-donor species. Plant host specificity is usually for a few legume genera but may, in some strains, include a wide variety of legume genera and is to some extent determined by the chemical structure of the lipochito-oligosaccharide *Nod* factors produced. These chitin-like molecules induce nodule organogenesis in the absence of bacteria. **In root nodules the bacteria occur as endophytes that exhibit pleomorphic forms, termed "bacteroids", which reduce or fix gaseous atmospheric nitrogen into a combined form utilizable by the host plant.**

The mol% G + C of the DNA is: 57–66.

Type species: **Rhizobium leguminosarum** (Frank 1879) Frank 1889, 338 (*Schinzia leguminosarum* Frank 1879, 397.)

Further descriptive information

Introductory Note This treatment of the genus *Rhizobium* also includes information on the closely related genera *Agrobacterium*, and *Sinorhizobium*. The rationale for this treatment is provided under Taxonomic Comments.

Following Bradbury (1986), strains in past literature called *Agrobacterium* biovar 1 are herein referred to as *Agrobacterium tumefaciens*. *Agrobacterium* biovar 2 strains are referred to as *Agrobacterium rhizogenes*. *Agrobacterium* biovar 3 strains are referred to as *Agrobacterium vitis* (See Table BXII.α.114 in the chapter on the genus *Agrobacterium*). Where necessary, the ability of pathogenic strains to cause crown gall tumors or the hairy root condition, previously attributed to strains using the names *"Agrobacterium tumefaciens"* and *"Agrobacterium rhizogenes"*, is indicated by reference to the tumorigenic or rhizogenic ability, respectively, of strains in species of *Agrobacterium*. Nonpathogenic strains previously named *Agrobacterium radiobacter* are referred to either as nonpathogenic strains of *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes* or merely as nonpathogenic *Agrobacterium* if the species designation has not been identified. Ti or Ri plasmids determine the pathogenic status of strains (see below). Species comprising pathogenic or nonpathogenic strains can be reported as tumorigenic as a (Ti strain) or (Ti), as rhizogenic as a (Ri strain) or (Ri), or as nonpathogenic strains of the species where relevant.

Morphology The formation of star- or rosette-shaped aggregates of cells by several *Agrobacterium* strains has been described by Beijerinck and van Delden (1902), Stapp and Knösel (1956) and Knösel (1962). Granules of poly-β-hydroxybutyrate are common in older cells, so that upon simple staining the rods appear banded. Strains of *R. leguminosarum* often contain metachromatic granules, demonstrated by staining with methylene blue, washing with dilute iodine, and staining with neutral red (Graham and Parker, 1964). Fig. BXII.α.128 shows a cell of *R. leguminosarum* biovar trifolii.

All species are motile by one to six flagella. For most species examined, insertion is peritrichous. Strains in species with a single flagellum (*R. galegae*, *R. mongolense*, *Sinorhizobium fredii*, *Sinorhizobium saheli*, *Sinorhizobium terangae*, and *Sinorhizobium xinjiangense*) also appear to have peritrichous organization expressed as polar or sub-polar insertion. Only *R. hainanense* is reported as being unambiguously polarly flagellated.

Cell wall composition The cell wall structure of *Rhizobium* is generally similar to that of other Gram-negative bacteria. The peptidoglycan consists of glutamic acid, alanine, diaminopimelic acid, and amino sugars. In addition, leucine, phenylalanine, serine, and aspartic acid have been detected in relatively large amounts in the peptidoglycan layer of several pathogenic strains. Lipopolysaccharide (LPS) cell wall composition varies from strain to strain but consistently contains 2-keto-3-deoxyoctanoic acid (KDO), uronic acids, glucosamine, glucose, mannose, rhamnose, fucose, and galactose (Carlson, 1982). The structures of LPS from a number of species have been determined, and all of them contain the unusually long 27-hydroxyoctacosanoic acid (Jeyaretnam et al., 2002; Sharypova et al., 2003). Rhizobia also have an unusually complex composition of membrane phospholipids, among them phosphatidylcholine, and under conditions of phosphorus limitation, phospholipids can be replaced by membrane lipids that do not contain phosphorus (López-Lara et al., 2003).

Fine structure As revealed by electron microscopy and biochemical analyses, cellulose-containing fibrils are formed by pathogenic *Agrobacterium* strains during their attachment to plant cells *in vitro*. These fibrils anchor the bacteria to the plant cell surface

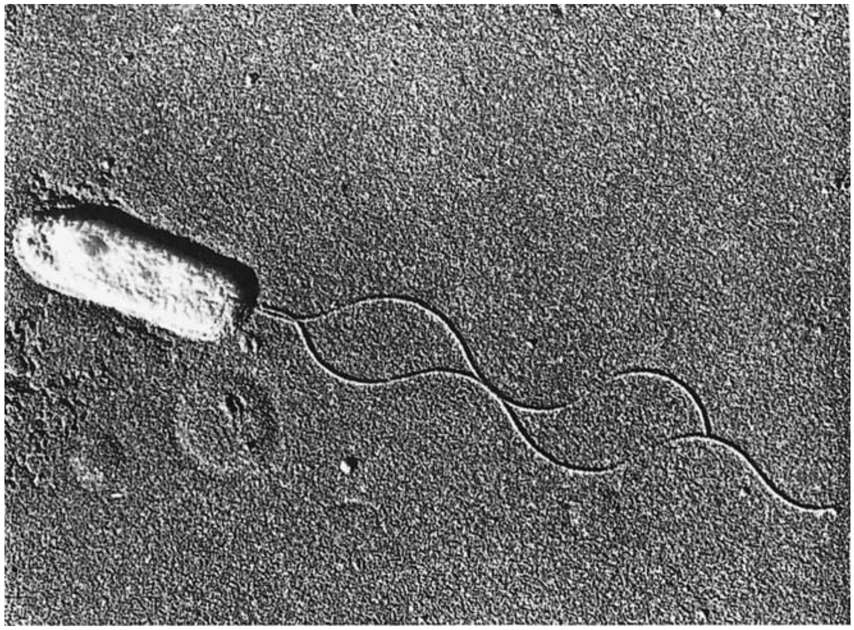

FIGURE BXII.α.128. Cell of *Rhizobium leguminosarum* biovar trifolii showing two polar flagella (× 14,000).

(Matthysse et al., 1981). Lipopolysaccharides of the outer membrane of cell envelopes play a role in the attachment of the bacteria to the wound site of the plant (Whatley et al., 1976). Smit et al. (1989) purified an adhesin that appears to mediate the first step in attachment of nodulating *Rhizobium* and pathogenic *Agrobacterium* bacterial cells to plant root hair tips.

Colonial and cultural characteristics On carbohydrate-containing solid media, the majority of *Rhizobium* strains produce circular, low convex to convex, mucous, glistening, opaque, white to beige-colored colonies, with an entire edge and a diameter of 2–4 mm after 5–6 days of incubation at 28°C.

Most strains grow rapidly on a mineral salts medium containing yeast extract and any one of a wide variety of carbohydrates (Vincent et al., 1979). Acid is usually produced to a moderate degree from carbohydrates (Norris, 1965).

Growth on carbohydrate-containing solid media may be opaque, clear or translucent (Fig. BXII.α.129) but may also exhibit small opaque areas within a clear slime. Variants that produce small colonies often fix little nitrogen symbiotically. Growth of *Agrobacterium* on nutrient agar is moderate, whereas abundant growth is obtained on media containing yeast extract and a suitable carbohydrate such as glucose, sucrose, or lactose (see Maintenance Procedures).

Almost all strains of *Rhizobium* species—but not *Agrobacterium* species—form only white colonies on yeast extract-mannitol-mineral-salts medium containing 0.0025% Congo red.

Some strains are encapsulated. All produce abundant water-soluble extracellular polysaccharide, the principal constituent of which is acidic heteropolysaccharide (80–90%). The remaining constituents, in most strains, are neutral, unbranched, β-2-linked glucans, of which some cyclics are important for nodule development (York et al., 1980; Breedveld and Miller, 1994). Certain chromosomal genes termed *chv* or *ndv* are responsible for the production of cyclic glucans essential for either virulence or nodule development in all species of *Agrobacterium* or *Rhizobium.* All strains within a species produce the same acidic heteropolysaccharide except for *R. leguminosarum* biovar phaseoli, which possesses a unique heteropolysaccharide. Curdlan production has been reported in several isolates of *R. leguminosarum* biovar trifolii (Ghai et al., 1981). The formation of water-insoluble β-1,3-glucans has been reported in some strains of pathogenic *Agrobacterium* (Nakanishi et al., 1976). The synthesis of glycogen by *Agrobacterium tumefaciens* strain B6 is regulated at the level of ADP-glucose synthesis (Eidels et al., 1970).

Nutrition and growth conditions The temperature range for growth, which is highly strain dependent, is 4–40°C; however, growth at 4°C is rare, and only certain species can grow at 40°C. The temperature maximum for *R. leguminosarum* is 38°C. All of the strains grow between 20°C and 28°C. *Agrobacterium rhizogenes* cannot grow above 30°C, whereas *Sinorhizobium saheli* and *Sinorhizobium terangae* can grow at 44°C (de Lajudie et al., 1994). The pH range for growth for the entire genus *Rhizobium* is 4–10.

Intermediates of the tricarboxylic acid cycle and several amino acids can be utilized as sole sources of carbon. The majority of *Agrobacterium tumefaciens* strains can grow on a minimal medium with nitrate or ammonium salts as the nitrogen source. *Agrobacterium rhizogenes* strains do not utilize nitrate unless biotin is supplied; some strains require both L-glutamic acid and biotin. Strains belonging to *Agrobacterium rubi* require L-glutamic acid and yeast extract (Starr, 1946; Lippincott and Lippincott, 1969; Keane et al., 1970).

Metabolism and metabolic pathways The principal mechanisms of glucose catabolism in *Rhizobium* are the Entner-Doudoroff pathway and the pentose cycle (Katznelson and Zagallo, 1957; Vardanis and Hochster, 1961; Martínez-De Drets and Arias, 1972; Arthur et al., 1973, 1975; Ronson and Primrose, 1979). It is unlikely that the Embden-Meyerhof-Parnas pathway operates in *Rhizobium* spp. because activities of fructose-1,6 diphosphate aldolase and 6-phosphofructokinase are low. Polyols are substrates for an inducible dehydrogenase that converts mannitol to fructose and arabitol to xylulose (Martínez-De Drets and Arias,

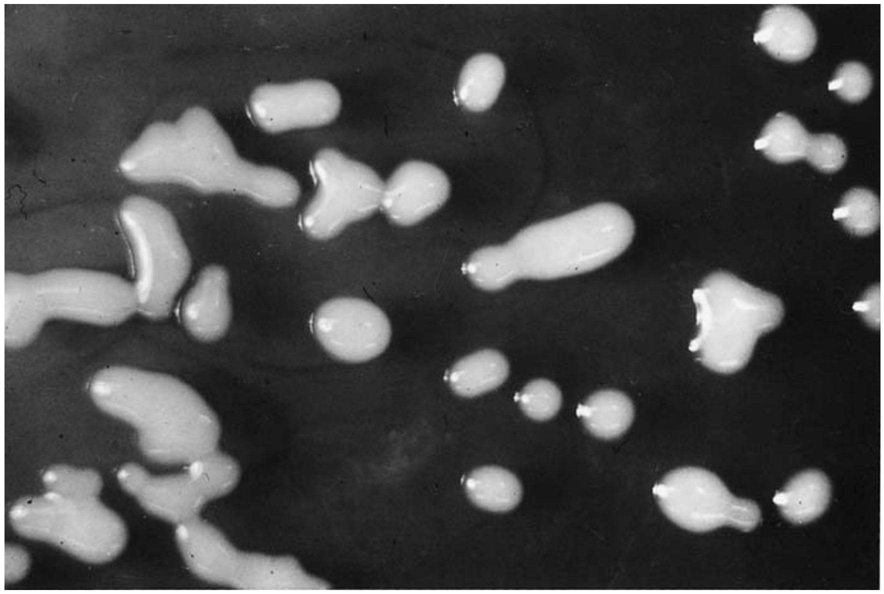

FIGURE BXII.α.129. Colonies of *Rhizobium leguminosarum* on mineral-salts mannitol agar (× 1.5).

1970). L-Arabinose is metabolized to α-ketoglutarate (Duncan, 1979).

The tricarboxylic acid cycle is operative, and the enzymes of the glyoxylate bypass are present (Johnson et al., 1966; Arthur et al., 1973; Chern et al., 1976a). Pyruvate carboxylase is an important anaplerotic enzyme (Chern et al., 1976b; Ronson and Primrose, 1979).

Glucuronic acid and glucaric acid are metabolized via 2-keto-3-deoxy-D-glucaric acid to α-ketoglutaric acid (Chang and Feingold, 1970). The initial step in the catabolism of L-sorbose by some *Agrobacterium tumefaciens* strains is the reduction to sorbitol, followed by oxidation of the latter compound to D-fructose (Van Keer et al., 1976). The majority of *Agrobacterium* strains characteristically oxidize a large number of carbohydrates (disaccharides, bionic acid, and several monosaccharides) to the corresponding 3-uloses (Bernaerts and De Ley, 1960a, b; Fukui et al., 1963; De Ley et al., 1966). The vigorous and unusual oxidation of lactose to 3-ketolactose is, so far, unique to *Agrobacterium tumefaciens* and is the basis of a simple and specific diagnostic test for the rapid differentiation of this species from other *Agrobacterium* and *Rhizobium* spp. that have been tested (Bernaerts and De Ley 1963; de Lajudie et al., 1994). These specific oxidations are catalyzed by an inducible hexopyranoside:cytochrome *c* oxidoreductase (D-glucoside 3-dehydrogenase), containing flavin adenine dinucleotide as cofactor (Hayano and Fukui, 1967; Van Beeumen and De Ley, 1968; Nakamura and Tyler, 1977). Although an "alpha-3"-ketoglucosidase was detected in a strain of *Rhizobium* (Hayano and Fukui, 1970; Hayano et al., 1973), 3-ketosucrose and 3-ketolactose are probably not involved as essential intermediates in the metabolism of sucrose and lactose, respectively (Kurowski and Pirt, 1971). Conditions have been worked out for increasing the yield of 3-ketoglycosides (Tyler and Nakamura, 1971; Fensom et al., 1974; Kurowski et al., 1975).

Anaerobic growth by nitrate reduction has been reported for *Sinorhizobium fredii* (Hynes et al., 1985) and *Sinorhizobium meliloti* (Daniel et al., 1982). *Sinorhizobium fredii* produces N_2O and *Sinorhizobium meliloti* produces N_2 as the end products of denitrification.

Rhizobium contains at least two soluble cytochromes *c*: a cytochrome c_{552} and a cytochrome c_{556}. Cytochrome c_{552} has been sequenced (Van Beeumen et al., 1980). It belongs to the cytochrome *c* sequence class IB (*sensu* Ambler, 1973) and, of all known procaryotic cytochromes *c*, shows the highest amino acid sequence homology with mitochondrial cytochrome *c* of tuna fish (Van Beeumen et al., 1980). Cytochrome c_{556} from *Rhizobium* belongs to the cytochrome *c* sequence class II (*sensu* Ambler, 1973), because its single heme group is bound near the C-terminus (Van Beeumen et al., 1980).

Auxotrophic mutants of *Rhizobium* are sometimes symbiotically defective and the isolation and study of such mutants has provided insights into the biochemical prerequisites of symbiosis (Kuykendall, 1981). For example, auxotrophy toward adenine, uracil, and leucine is often associated with symbiotic ineffectiveness in *Sinorhizobium meliloti* (Dénarié et al., 1976).

Fatty acids Fatty acid profiles have been studied for some species. Using principal components analysis of whole cell fatty acid methyl esters (FAME), Jarvis et al. (1996) reported three clusters: 1) *R. leguminosarum*, *R. etli*, *R. tropici*, *Agrobacterium rhizogenes*, *Sinorhizobium fredii*, and *Sinorhizobium meliloti*; 2) *R. galegae*, *Agrobacterium tumefaciens*, *Agrobacterium rubi*, and *Agrobacterium vitis*; and 3) *R. huakuii* and *R. loti*, (now allocated to *Mesorhizobium*). Sawada et al. (1992d) could differentiate *Agrobacterium tumefaciens*, *Agrobacterium rhizogenes*, and *Agrobacterium vitis* using fatty acid profiles. *Agrobacterium tumefaciens* could be separated from *A. vitis* based on quantitative differences in $C_{16:1}$ and $C_{18:1}$ acids, and the presence of $C_{17:0\ cyclo}$ acids. Quantitative differences in $C_{19:0\ cyclo}$, and the presence of $C_{15:0\ iso\ 3OH}$ acids and the absence of $C_{18:1\ 3OH}$ acids differentiated *Agrobacterium rhizogenes* from the other two species (Sawada et al., 1992d). Tighe et al. (2000) studied 600 strains and found that the fatty acid composition of all the fast-growing species differed from that of *Bradyrhizobium* and *Mesorhizobium*, but there were no clear differences among fast-growing genera except for the relative concentration of $C_{16:0\ 3OH}$ fatty acid, which was quantitatively lower in *Sinorhizobium* than in most *Rhizobium* strains. Species-level identification was,

however, possible in many cases, and thus the data of Tighe et al. (2000) is a valuable resource.

Genetics A circular linkage map of the *R. leguminosarum* chromosome was first constructed by Beringer and Hopwood (1976). The genome of *Sinorhizobium meliloti* has also been mapped (Kondorosi et al., 1977; Meade and Singer, 1977). These two species have similar chromosomal gene arrangements (Beringer et al., 1987). *Sinorhizobium meliloti* has a chromosome size of 3.7×10^6 bp, and its sequence has been reported (Galibert et al., 2001).

There are only incomplete comparisons of *Rhizobium* spp. by DNA–DNA reassociation. DNA–DNA reassociation data are available for the following species: *R. galegae*, *R. leguminosarum*, and *R. tropici* (Martínez-Romero et al., 1991); *Sinorhizobium fredii* and *Sinorhizobium meliloti* (de Lajudie et al., 1994); and *Sinorhizobium saheli* and *Sinorhizobium terangae* (de Lajudie et al. 1994). An early study was made of *Agrobacterium tumefaciens*, *Agrobacterium rhizogenes*, and *Agrobacterium rubi* (De Ley 1972, 1974).

Easily amplified DNA regions called amplicons, apparently controlling both adaptability and biological interactions, have been documented in *Rhizobium* genomes (Palacios et al., 1998). As these become better defined through mapping and DNA sequencing, their structure can be expected to be of particular interest.

Plasmids Plasmids and megaplasmids as large as 1600 kb can constitute as much as 50% of the total genome. Sequences of plasmids have been reported (Freiberg et al., 1997; Barnett et al., 2001; Finan et al., 2001).

Hypertrophic activity and plasmids All species (though not all strains) of *Rhizobium* and *Agrobacterium* are associated with plant hypertrophisms and, with a few exceptions, are associated with root hypertrophisms. Hypertrophy can involve formation of either nitrogen-fixing nodules in *Rhizobium* or of oncogenous (tumorous) galls or hairy roots in *Agrobacterium.* These activities are confined to particular species. Genes (pSym, pTi, and pRi) associated with hypertrophisms are usually carried on large plasmids. These genes and the associated hypertrophying activity play a central role in the ecology of these genera. Plant transformations using the agrobacterial tumorigenic system are now routine (see reviews by Kado, 1991; Zambryski, 1992; Hooykaas and Beijersbergen, 1994). Transformations in filamentous fungi have also been reported (De Groot et al., 1998).

Plasmid-regulated nitrogen fixation Some members of the *Rhizobiaceae* and *Phyllobacteriaceae* are characterized by their ability to incorporate functional genetic elements as plasmids or symbiotic islands (Sullivan and Ronson 1998) which permit them to establish pathogenic (oncogenic) or symbiotic nitrogen-fixing relationships with plants. Nitrogen-fixing symbioses involving members of the *Rhizobiaceae* are restricted to plants of the family Leguminosae (van Rhijn and Vanderleyden, 1995), with one exception. *Rhizobium* cells contain as many as 10 naturally occurring plasmids ranging in size from less than 100 kb to megaplasmids of more than 1000 kb. In some instances, the combined length of plasmids and megaplasmids approximates that of the chromosome, meaning that up to 50% of the *Rhizobium* genome is not in the chromosome. Both *nod* and *nif* genes controlling nodulating and nitrogen-fixing ability have always been found clustered together on one or more *Rhizobium* plasmids or megaplasmids called pSym. Numerous genetics studies have delineated *Rhizobium* genes essential for legume nodulation and symbiotic nitrogen fixation (Rossen et al., 1984; Török et al., 1984; Egelhoff and Long, 1985; Egelhoff et al., 1985; Jacobs et al., 1985; Debellé et al., 1986; Evans and Downie, 1986; Göttfert et al., 1986; Horvath et al., 1986; Rostas et al., 1986; Shearman et al., 1986; Aguilar et al., 1987; Fisher et al., 1987; Honma and Ausubel, 1987; Cremers et al., 1988; Davis et al., 1988; Surin and Downie, 1988; Cervantes et al., 1989; De Maagd et al., 1989; Schwedock and Long 1989, 1994; Barnett and Long, 1990; Economou et al., 1990; Honma et al., 1990; Surin et al., 1990; Baev et al., 1991, 1992; Kondorosi et al., 1991a, b; Rushing et al., 1991; Baev and Kondorosi, 1992). The nodulation-controlling genes are organized into several coordinately regulated operons. For example, the common *nodABC* operon is present in all legume symbiotic strains and can complement strains in different genera. For *R. etli*, *nodA* is separated from *nodBC* (Vázquez et al., 1991; Vázquez et al., 1993), and for *Mesorhizobium loti*, *nodB* is independent of *nodAC* (Scott et al., 1996). Others may be present in different species as allelic variants, such as *nodEF*, and these are host-specific and hence not interchangeable. Such *nod* or *hsn* genes are sometimes present only in certain strains.

pSyms are not essential for survival of the *Rhizobium* strains in soil. Non-nodulating soil bacteria identified as *Rhizobium* species have been isolated which can only form nodules after transconjugation with related symbiotic strains. Transfer of symbiotic plasmids among *Rhizobium* species has been reported under laboratory conditions and has been demonstrated by sequence comparison of natural isolates. Martínez et al. (1987) demonstrated nitrogen-fixing nodules formed by *Agrobacterium tumefaciens* carrying a conjugally transferred pSym from *R. tropici* (as *R. phaseoli* type II). Similar results were obtained for transconjugants of *Agrobacterium tumefaciens* containing pSym from *Rhizobium* strains that nodulate *Phaseolus vulgaris* (Brom et al., 1988). A pSym of *R. leguminosarum* biovar trifolii has been introduced into 15 non-nodulating bacterial isolates identified as *M. loti*, *R. leguminosarum*, *R. tropici*, *Sinorhizobium meliloti*, and four isolates related to *R. leguminosarum* (Sivakumaran et al., 1997). By comparison of *nifH* sequence type to 16S rRNA gene sequence type, Haukka et al. (1998) demonstrated that similar symbiotic genes could be found in different 16S rRNA gene backgrounds, indicating horizontal transfer across species boundaries.

There is considerable variation in the nodulating and nitrogen-fixing capacity of individual strains. In *Rhizobium* strains with the capacity for symbiotic activity, most if not all genes that specify and regulate nodulating and nitrogen-fixing abilities are carried on one or more plasmids. In this respect, members of the genus differ from *Bradyrhizobium* (see the chapter on the genus *Bradyrhizobium*), in which all symbiosis-controlling genes have been shown to be carried on the chromosome, and *Mesorhizobium* (see the chapter on the genus *Mesorhizobium*), in which many strains have symbiosis-controlling genes located on the chromosome. The systematics of these plasmid-determined symbiotic associations is reviewed in Young and Johnston (1989).

The expression of nodulation genes is controlled by the presence of flavonoids excreted by the host plant. For, example, the regulatory *nodD* gene controls *nodABC* expression. Flavonoids produced by various legumes seem to interact specifically with particular NodD proteins, which vary in structure according to *Rhizobium* species, as do the Nod Factors (NF). Compatibility between flavonoid and NodD protein is thought to be a major factor in host specificity. (For detailed reviews of nodulation and nitrogen fixation genetics and biochemistry, see Schultze et al., 1994; van Rhijn and Vanderleyden, 1995; Dénarié et al., 1996.)

Another regulation gene, *nolR*, has been reported to be common in symbiotic species of *Rhizobium* and *Sinorhizobium*. This gene was not found in species of *Azorhizobium*, *Bradyrhizobium*, *Mesorhizobium*, or *Agrobacterium* (Kiss et al., 1998). This gene repressed the expression of both *nodABCIJ* and *nodD* genes, resulting in decreased Nod factor production. Recently, a novel family of *nod* gene inducers, aldonic acids, was reported for *Sinorhizobium meliloti*, *Mesorhizobium loti*, and *Bradyrhizobium* (as *B. lupini*) strains (Gagnon and Ibrahim 1998).

Root nodules induced by some strains of symbiotic *Rhizobium* contain substances called rhizopines (Murphy et al., 1987, 1995), analogous to the opines found in pathogenic *Agrobacterium* strains (see later discussion). Those described so far are substituted scyllo-inosamines. Both synthetic and catabolic genes are located on pSym. Genes involved in synthesis are active in the symbiotic bacteroid state and catabolic genes are active in the free-living cells (Murphy et al., 1988; Dessaux et al., 1998). The likely ecological benefit of rhizopine activity for producing strains has been reported (Gordon et al., 1996). Rhizopine production has been reported for *R. leguminosarum* biovar viciae and *Sinorhizobium meliloti*. No rhizopine production was detected from isolates of *R. etli*, *R. tropici*, or *R. leguminosarum* biovar trifolii and biovar phaseoli (Wexler et al., 1995). Rhizopine synthesis (*mos*) and catabolism (*moc*) genes from *R. leguminosarum* and *Sinorhizobium meliloti* have been sequenced (Wexler et al., 1996b). Further study showed that some non-symbiotic soil bacteria, including *Arthrobacter*, *Aeromonas*, *Alcaligenes*, and *Pseudomonas*, could catabolize rhizopine. No DNA sequences homologous to *nodB* and *nodC* and no effective nodulation on *Medicago sativa* were detected in two strains that were related to *Sinorhizobium meliloti* based on partial 16S rDNA sequence analysis (Gardener and Bruijn, 1998); this result indicated that the gene(s) related to rhizopine metabolism may be carried on the chromosome or on plasmids other than pSym.

Two megaplasmids in *Sinorhizobium meliloti* are involved in the effective nodulation of alfalfa (Hynes et al., 1986). In *R. leguminosarum* (Hynes and McGregor, 1990), as in *R. etli* CFN42, plasmids other than the pSym (*nod-nif* plasmid) are required for an effective symbiosis and may carry *lps* genes (García-de los Santos and Brom, 1997; Vinuesa et al., 1999).

Plant specificity in nitrogen fixation The legume-nodulating ability of *Rhizobium* species appears to be specific to a few plant species or genera. An exception is *Sinorhizobium* sp. strain NGR234, which nodulates 112 legume genera (Pueppke and Broughton, 1999). In such instances, nodulation can occur without nitrogen fixation. Since Lerouge et al. (1990) established the chemical structure of the nodule-inducing compound produced by *Sinorhizobium meliloti*, a general hypothesis has been proposed: host specificity in all legume microsymbionts is related to the chemical structure of specific lipochitooligosaccharide Nod factors (Dénarié et al., 1992, 1996). Nodulation factors of strain NGR234 include variants of Nod factors (Price et al., 1992). Structures of Nod factors produced by several species have been described (Poupot et al., 1993, 1995; Lorquin et al., 1997; Yang et al., 1999; Snoeck et al., 2001; Pacios-Bras et al., 2002).

Plasmid-mediated plant-pathogenic (oncogenic) activity in *Agrobacterium* spp. The early literature on plasmid-mediated plant pathogenic (oncogenic) activity was reviewed by Nester et al. (1984). A recent review is given by Binns and Costantino (1998). Oncogenic (tumorigenic or rhizogenic [hairy root]) activity in the four plant-pathogenic *Agrobacterium* species is mediated by genes that are largely or wholly borne on one or more large (>150 kb) plasmids. Tumorigenic activity is conferred by Ti plasmids and rhizogenic activity is conferred by Ri plasmids. Tumorigenic genes on the Ti plasmid comprise (a) T-DNA genes, and (b) virulence (*vir*) genes. Wounding of susceptible plant tissue activates *vir* genes that facilitate the transfer of a component of the Ti (or Ri) plasmid, the T-DNA (8–22 kb). The T-DNA fragment is integrated into the plant nucleus apparently at random (Chyi et al., 1986), in one or more copies (Chilton et al., 1980; Lemmers et al., 1980; Willmitzer et al., 1980; Zambryski et al., 1980). T-DNA carries all necessary genes for tumor growth, the most important for tumorigenesis being those associated with auxin and cytokinin synthesis, which are expressed in the plant.

Comparative analysis indicates a correlation between sequence structure of the 16S–23S rRNA intergenic spacer region and the type of Ti plasmid (nopaline, vitopine, or octopine/cucumopine) present in strains of *Agrobacterium vitis* (Otten et al., 1996).

Another large Ri plasmid is involved in the hairy root disease of plants caused by rhizogenic *Agrobacterium* strains (Moore et al., 1979; White and Nester, 1980a). Little overall sequence similarity to other Ti plasmids has been detected (White and Nester, 1980b). There is one small region of conserved similarity between the Ri plasmid and an octopine Ti plasmid (pTi-B6806), but the former shows no similarity to the T-DNA region of the latter plasmid. The Ri plasmid is compatible with other Ti plasmids and thus represents a new incompatibility class of plasmids (White and Nester, 1980b).

Large plasmids that are not involved in pathogenic activity have been found in nonpathogenic strains of *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes* (Merlo and Nester, 1977; Sheikholeslam et al., 1979). In addition, large plasmids have been discovered in addition to the Ti plasmid in several tumorigenic *Agrobacterium* strains. Some strains possess an additional 2.1×10^6 base-pair linear chromosome in addition to two or more very large plasmids (Allardet-Servent et al., 1993). The sequence of the *A. tumefaciens* C58 genome was reported (Goodner et al., 2001).

Opines are unusual amino acid derivatives produced in tumor or hairy root tissues induced by pathogenic strains of *Agrobacterium* species. Opines are synthesized from common plant compounds but are not utilized by plants or by most microorganisms. They are utilized by *Agrobacterium* strains that carry the specific opine-inducing plasmids associated with oncogenicity. The opine concept as originally proposed was that specific genes associated with T-DNA permitted the synthesis of opines from plant photosynthetic products in a form whose availability as nutrients was restricted to tumorigenic strains bearing the relevant plasmid (Schell et al., 1979). At least eleven opines have been identified: octopine, lysopine, nopaline, succinamopine, leucinopine, cucumopine, heliopine, chrysopine, mikimopine, agropine, and agrocinopines (Chang et al., 1989; Dessaux et al., 1992; Chilton et al., 1995). In addition, imino acids (Moore et al., 1997), mannopine (Petit et al., 1983), and vitopine (Szegedi et al., 1988) have been reported. It is unlikely that this list is exhaustive (Moore et al., 1997). Opine catabolism by pathogenic *Agrobacterium* strains is mediated by genes, located on one or more plasmids including the Ti plasmid, that are not transferred to the plant cell nucleus (Montoya et al., 1977). Pathogenic strains can utilize more than one opine (Moore et al., 1997). Some opines can also induce conjugal transfer of the Ti plasmid to nontumorigenic strains and may contribute to the dissemination of the infectious plasmid (Gelvin 1992; Guyon et al., 1993). Analysis of

the distribution of Ti plasmids in terms of their opine genes showed that the ecology of plasmid-bearing strains is highly complex (Moore et al., 1997). In only a few samples could field outbreaks of crown gall be traced to a clonal origin of infection. In most collections, field tumors were induced by Ti plasmids of more than one opine type. Field tumors of some hosts yielded no detectable opines, even though opine-utilizing bacteria were present. Bacterial isolates from other hosts (plum and cherry) showed the best correspondence between the opine in tumors (nopaline) and the presence of bacteria that catabolized that opine. However, several unusual opine catabolic combinations were identified, including isolates that catabolized a variety of opines but were nonpathogenic. There are indications of some specificity between pathogenic *Agrobacterium* species, opine type, and host plant (Lopez et al., 1988; Sawada et al., 1992a). The opine concept (Schell et al., 1979) assumed specific utilization of opines by tumorigenic *Agrobacterium* strains bearing relevant plasmids, and that these compounds could not be utilized by other soil organisms. Since the original proposal, however, it has become clear that a wide range of soil organisms have the capacity to metabolize opines. These include *Pseudomonas* species (Beaulieu et al., 1983; Tremblay et al., 1987b) and Gram-positive coryneform bacteria (Tremblay et al., 1987a). These data collectively suggest that mechanisms explaining the involvement of opines may be more complex than the original model.

At present, oncogenic activity is associated with *Agrobacterium tumefaciens*, *Agrobacterium rhizogenes*, *Agrobacterium rubi*, and *Agrobacterium vitis*. There may be several additional pathogenic bacterial populations that also merit classification as species. Bouzar et al. (1995) records a pathogen associated with aerial infections of *Ficus benjamina*, and Sawada and Ieki (1992b) report phenotypically distinct strains isolated from affected plants.

Pathogenic host range and pathogenicity The host range of tumorigenic *Agrobacterium* strains is reported to be very wide. De Cleene and De Ley (1976) described at least 640 plant species belonging to 331 genera in 93 families of dicotyledon and gymnosperm plants as susceptible to transformation by *Agrobacterium* (Ti strains) (such as *Agrobacterium tumefaciens*). De Cleene and De Ley (1981) reported 37 plant species belonging to 30 genera in 15 families of dicotyledonous plants as susceptible to transformation by *Agrobacterium* (Ri strains) (such as *Agrobacterium rhizogenes*). None of the 250 monocotyledonous species investigated was susceptible to the disease, except some members of the orders Liliales and Arales. Bradbury (1986) listed almost 400 plant species affected by tumorigenic strains and over 50 plant species affected by rhizogenic strains.

The inference that crown gall- and hairy-root-inducing strains of *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes* have wide host ranges is based on reports of the many hosts from which the pathogens have been isolated and on the many reports of tumor induction in experimental inoculations. However, there have also been indications of host specificity within some populations (Panagopoulos and Psallidas, 1973; Anderson and Moore 1979; Moore and Cooksey 1981; Paulus et al., 1991a, b; Palumbo et al., 1998). In some instances, strains are pathogenic to a relatively narrow range of host plants (Unger et al., 1985). Furthermore, although crown gall has been reported on some host species in some countries, it is not necessarily found in these same hosts in other countries where crown gall is known. The family of Ti plasmids may have restricted host ranges in varying degrees and chromosomal background may affect specificity. It seems clear that some strains naturally infect host plants from several unrelated genera whereas others are more specific (Paulus et al., 1991b). The nature of specificity, whether it is a function of the bacterial strain or of the plasmid (Loper and Kado 1979; Close et al., 1985; D'Souza et al., 1993), has not been generally confirmed, although modifications to the Ti-plasmid have been implicated (Paulus et al., 1991a). There is no indication of host range specificity as it occurs in the pathogenic species and pathovars of *Pseudomonas* or *Xanthomonas*. Although *Agrobacterium rubi* is identified as a species isolated from galls on the canes of *Rubus* spp., the specificity of this pathogen to *Rubus* is in doubt because it has been shown to have a wide host range (Sawada et al., 1992a). *Agrobacterium vitis* is found as the predominant tumorigenic species specific to *Vitis* spp. (Thies et al., 1991), and *Agrobacterium vitis* strains have occasionally been isolated from other hosts, such as *Actinidia* (Sawada and Ieki 1992a). *Agrobacterium vitis* appears to be unique among pathogenic *Agrobacterium* species in being associated with a root decay symptom (Burr et al., 1987).

Upon infection of wounded plant tissues, tumorigenic *Agrobacterium* strains can transform plant cells into autonomously proliferating cells. In nature, the swellings mostly occur at the transition zone between the stem and the root system of the host plant, hence the name "crown gall disease." Small spherical growths or elongated ridges can occur on the stems of *Rubus* spp. such as raspberry and bramble bushes. Some oncogenic strains cause hairy root on susceptible plants (such as apple trees and roses) but cause crown gall on other plants. On some plants (e.g., *Kalanchoë*), oncogenic strains of *Agrobacterium* spp. can induce the formation of teratomata, characterized by the development of aberrant shoots, leaves, or roots developing from the tumor tissue. The type of disease produced (differentiated or undifferentiated tumors) is probably determined by both the bacterial Ti plasmid and the host plant (Gresshoff et al., 1979).

A prerequisite for tumorigenesis is the wounding of the host. Infection can occur during various stages of the life of a plant via wounds caused by growth, germination (e.g., peaches and almond), subterranean insects, or mechanical injuries (e.g., pruning, grafting, and replanting of trees in nurseries).

Tumorigenic and rhizogenic activity was initiated by *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes* at 20°C and 27°C, respectively. The latter temperature, however, was not conducive to tumorigenesis by *Agrobacterium vitis*. Temperature effects were mediated by the choice of host plant (Charest and Dijon, 1985).

Crown gall disease seldom kills plants, but growth is often impaired and stunted. Significant damage and economic loss can occur on stone fruit and grape (De Cleene, 1979).

Plasmid exchange between *Rhizobium* and *Agrobacterium* species Intergeneric transmissibility of Ti and nodulating plasmids has been demonstrated from nodulating *Rhizobium* spp. to tumorigenic *Agrobacterium* spp. (Martínez et al., 1987; Brom et al., 1988; Abe et al., 1998), and from tumorigenic *Agrobacterium* spp. to nodulating *Rhizobium* spp. (Hooykaas et al., 1977) and to *Phyllobacterium myrsinacearum* (van Veen et al., 1988); this supports a close relationship for these genera and points to promiscuous plasmid exchange between taxa. Novikova and Safronova (1992) reported transconjugants of *Agrobacterium tumefaciens* harboring the pSym genes of *R. galegae* that formed an effective symbiosis with *Medicago sativa*. The finding by Nesme et al. (1987) that crown gall that occurred in a poplar nursery was caused by naturally occurring resident mixed populations of both *Agrobacte-*

rium tumefaciens (Ti strains) and *Agrobacterium rhizogenes* (Ti strains) supports the idea that Ti plasmids may be promiscuous in the resident tumorigenic *Agrobacterium* species. Plasmid homologies do not correlate with any numerical classification of pathogenic *Agrobacterium* spp. (Currier and Nester, 1976), hence it is generally assumed that plasmid-borne Ti and Ri genes are readily transmitted within and between strains of *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes*.

Although plasmids conferring pathogenicity and nodulation are transmissible between pathogenic and nodulating genera in the laboratory, in nature these characteristics appear to be specific to the particular species. The relative specificity between particular nodulating *Rhizobium* spp. and their legume symbionts, and the pathogenic specificity indicated for *Agrobacterium vitis* and, perhaps, *Agrobacterium rubi* suggests that some plasmid incompatibilities exist, causing a restriction on transmission or subsequent gene expression. Furthermore, Bouzar et al. (1993) and Otten et al. (1996) demonstrated a correlation between the form of resident plasmids and host chromosome, suggesting possible restrictions on exchange in nature.

Agrocin and trifolitoxin activity Agrocin 84 from the nonpathogenic *Agrobacterium rhizogenes* strain 84 (ICMP 3379; NCPPB 2407) (New and Kerr, 1972; Kerr and Htay, 1974) is plasmid-encoded (Ellis et al., 1979). It is a toxic analog of an adenine nucleotide (Roberts et al., 1977) and selectively inhibits pathogenic *Agrobacterium* strains harboring a nopaline plasmid. It is effective against *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes* but not *Agrobacterium vitis* or *Agrobacterium rubi* (Ma et al., 1985; van Zyl et al., 1986; Psallidas 1988; Sawada et al., 1992a). Sensitivity towards agrocin 84 is determined by the Ti plasmid. Dipping seeds, roots, or wounded plant surfaces in suspensions of strain 84 has been used with success worldwide for the biological control of crown gall disease (Moore and Warren, 1979; Kerr, 1980). Strain 84 is available in commercial preparations as a biological control agent and has found wide application. *Agrobacterium vitis* strains are insensitive to agrocin 84. Other agrocin-producing strains, effective against *Agrobacterium vitis*, have been isolated (Staphorst et al., 1985; Chen and Xiang 1986; Webster et al., 1986; Webster and Thompson 1988; Xie et al., 1993).

Trifolitoxin (TFX) is a post-translationally modified peptide antibiotic produced by *R. leguminosarum* biovar trifolii T24 (Breil et al., 1993). TFX is toxic to non-producing strains within a distinct taxonomic group of the *Alphaproteobacteria*, and it appears to give an ecological advantage for nodulation by the producing strain. Eight genes have been identified for the production of this toxin (Triplett et al., 1994; Breil et al., 1996).

Bacteriophages Lysogeny for either active plaque-forming or defective bacteriophages is widespread in tumorigenic *Agrobacterium* spp. Morphological, biological, and physicochemical properties and genetic relationships of several of the isolated phages or phage-like particles have been determined (Beardsley, 1955; Zimmerer et al., 1966; Stonier et al., 1967; De Ley et al., 1972; Manasse et al., 1972; Vervliet et al., 1975). Virulent bacteriophages of *Rhizobium* were the subject of numerous studies published prior to 1950 (Allen and Allen, 1950), but *Agrobacterium* phages, although not as extensively studied in earlier times, have more recently been isolated from sewage and soil (Roslycky et al., 1963; Boyd et al., 1970a, b).

The range of hosts susceptible to a particular *Rhizobium* bacteriophage is highly variable. In some instances, it is limited to relatively few strains within a single host species; in others, it may cross taxonomic boundaries. Cross-infection studies of *Sinorhizobium meliloti* and *Sinorhizobium fredii* (Hashem et al., 1996) indicate that bacteriophage lysis is not usually sufficiently specific to identify species or individual strains. Some strains of *Rhizobium* are lysogenic. Bacteriocins have been reported (Roslycky, 1967; Venter et al., 2001), as well as a parasitic *Bdellovibrio*.

Antigenic structure Early serological studies indicated that strains belonging to *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes* could be distinguished from each other by serological reactions (Keane et al., 1970; Lopez, 1978). Alarcón et al. (1987) and Sawada et al. (1992c) found serological heterogeneity between these species and with *Agrobacterium vitis*. *Rhizobium* spp. show extensive cross-reaction with *Agrobacterium* strains (Graham, 1971).

Most serological reactions (agglutination, gel diffusion, precipitation, and fluorescent antibody) show strain specificity and have traditionally been of great value in identifying particular strains of *Rhizobium* in nodules of field plants or in laboratory investigations. The agglutination reaction, using crushed nodule extracts, is the most widely used for field work because of its simplicity, although it is complicated by cross-reactions and autoagglutination. Surface antigens, although useful for strain recognition, are limited in their usefulness for species identification. Early work, such as that of Vincent and Humphrey (1970), who reported on the antigen structure in the "biovars" of *R. leguminosarum*, should now be reinterpreted in the light of modern taxonomic revisions of the species. Sawada et al. (1992b) differentiated several serogroups in *Agrobacterium vitis* using a slide agglutination test.

Ecology *Rhizobium* occurs worldwide in soils and especially in the rhizosphere of plants. As many as 10^6–10^7 cells/g soil of symbiotic *Rhizobium* have been reported. *Rhizobium* strains capable of degrading 2-sulfonato-fatty-acid-methyl-esters (Masuda et al., 1995) and *Agrobacterium* strains capable of utilizing phthalate (Nomura et al., 1989) were reported as common soil inhabitants in contaminated soils. The identification of these strains as authentic rhizobia and agrobacteria needs confirmation.

Natural interactions between *Rhizobium* strains within the rhizosphere are complex, as indicated by the extent to which different *Rhizobium* populations are shown to compete in the infection processes. Agrocin-producing strains have a proven role in competing with tumorigenic *Agrobacterium* strains to inhibit infection. A similar competitive process occurs when attempts are made to nodulate seedling legumes with effective *Rhizobium* strains. Naturally occurring strains that are nonefficient in nitogen fixation can be more effective in infecting and nodulating plants, thereby limiting plant growth (Triplett and Sadowsky, 1992). Strains of *Rhizobium* that are non-nodulating and occurring naturally in soils have been well documented (Soberón-Chávez and Nájera, 1989; Segovia et al., 1991). Symbiotic *Rhizobium leguminosarum* biovar trifolii strains have been reported as natural endophytes in the roots of rice (Yanni et al., 1997), and *R. etli* strains, as endophytes of maize (Gutiérrez-Zamora and Martínez-Romero, 2001). Plant-pathogenic *Agrobacterium* species have also been isolated from a crown gall tumor on alfalfa (Palumbo et al., 1998).

Although bacteria within the genus *Rhizobium* have been shown to have a worldwide distribution, unique species may be isolated from limited geographic regions, normally related to the distribution of their hosts (Martínez-Romero and Caballero-Mellado, 1996). *Rhizobium* species may have been spread interna-

tionally with inoculated legume plants, with seed (Pérez-Ramírez et al., 1998), or soil. Caballero-Mellado and Martínez-Romero (1999) reported that soil fertilization limited the genetic diversity of *Rhizobium* in bean nodules. Vance (1998) reviewed agronomic aspects of commercial inoculants that are used to enhance legume crop cultivation.

Agrobacterium strains have also been reported in a variety of human clinical specimens (CDC group Vd-3) (Lautrop, 1967; Riley and Weaver, 1977; Gilardi, 1978a; Rubin et al., 1980). They are usually 3-ketolactose-positive and nonpathogenic to tomato. It is believed that these clinical isolates occur either as incidental inhabitants in the patient or as contaminants introduced during sample manipulation. The authenticity of these strains as true *Agrobacterium* spp. needs to be confirmed.

Antibiotic sensitivity *Rhizobium* strains are resistant to a variable spectrum of antibiotics (Davis, 1962). Most are susceptible to tetracycline. Although there is wide strain-to-strain variation in resistance, *Rhizobium* strains are intrinsically more sensitive than *Bradyrhizobium* to tetracycline, penicillin G, viomycin, vancomycin, and streptomycin. Streptomycin-resistant mutants, which are usually effective as nodulating strains, are important in ecological field studies on strain competition. In general, wild-type *Agrobacterium* tumorigenic species have been reported to be sensitive to chlorotetracycline, gentamicin, neomycin, novobiocin, oxytetracycline, and tetracycline (Kersters et al., 1973) but are commonly resistant to nalidixic acid. Growth is inhibited by low concentrations (3–780 μg/ml of medium) of metacycline, doxycycline, sigmamycin (tetracycline + oleandomycin), and triacetyloleandomycin (Goedert, 1973).

Enrichment and Isolation Procedures

Although *Rhizobium* strains are common soil inhabitants, they are best isolated from freshly excised legume root nodules. Identification is relatively easy if strains are isolated from host plant nodules. Isolation is difficult if strains are isolated directly from the soil or if strains are non-infective, unless they have unique genetic markers. Isolation of symbiotic species from soil generally requires the use of trap hosts, which are leguminous plants grown in the soil and from which nodules are selected for subsequent isolation of rhizobia. Nodules collected in the field can be temporarily stored in small vials containing silica gel held under a cotton plug.

In order to isolate symbionts, healthy root nodules—with a small portion of root attached if they are very small (<1.0 mm)—are surface sterilized by exposure to commercial 3% H_2O_2 solution or 5% commercial hypochlorite (3% available chlorine) solution for 5–60 min depending on their size. This treatment is followed by a wash in sterile water. The nodules are crushed in a small drop of sterile 0.05% peptone or 0.1M phosphate and a loopful of the suspension is streaked onto surface-dried plates of yeast extract-mannitol agar (YMA)[1] prepared without $CaCO_3$. Alternatively, a small loopful of the crushed nodule suspension can be streaked onto successive plates of agar medium. Large nodules can be sliced with a sterile scalpel blade and portions of the interior removed with a needle. Bacteria can readily be isolated from young galls and nodules on different parts of plants. Isolation from older hypertrophying tissue is more difficult. Incubation is at 28°C for 3 or more days. Well-isolated, white, mucoid, glistening, hemispheric colonies are restreaked onto fresh plates for subsequent confirmation, which requires reinfection of the original host under careful aseptic conditions where uninoculated controls are devoid of nodules. If heavy fungal contamination is expected, the agar medium used for initial isolation should contain 0.002% actidione. *Rhizobium* strains grow poorly on 0.04% peptone/1% glucose mineral salts agar and show little pH change. This medium can serve as a useful contamination check: colony formation in 2 days at 28°C and a marked pH change are not characteristic of *Rhizobium*.

1. Yeast extract-mannitol agar (YMA) contains (g/l of distilled water): D-mannitol, 10.0; KH_2PO_4, 0.5; $MgSO_4 \cdot 7H_2O$, 0.2; NaCl, 0.1; $CaCO_3$, 4.0; yeast extract (Difco), 0.4; agar, 15.0; pH 6.8–7.0. Sterilize at 121°C for 15 or 30 min depending on the volume. The $CaCO_3$ is omitted for the preparation of pour plates or for liquid medium.

Maintenance Procedures

YMA slant cultures in sealed containers can be stored for 2–3 years or longer at 2°C. Cultures usually survive for around 2 months at 15°C. Long-term storage at −20°C or −80°C is recommended: turbid suspensions from fresh broth cultures are mixed with equal volumes of sterile 80% glycerol in water and allowed to stand for 1 hr at room temperature before storing in small aliquots in the freezer. Individual aliquots are thawed as required. Norris (1963) described a preservation method using small porcelain beads which, after inoculation and drying over silica gel, can be used individually to inoculate YMB for subsequent recovery of the bacteria.

Stock cultures of pathogenic species may be routinely maintained on agar slants in screw-capped vials at 4°C for 2 months on YMA or on either of the following media (in g/l of tap water): (a) glucose, 20; yeast extract, 10; $CaCO_3$, 20; and agar, 20; or (b) glucose, 10; yeast extract, 10; $(NH_4)_2SO_4$, 1.0; KH_2PO_4, 0.25; and agar, 20.

Lyophilized cultures stored at 4°C remain viable for at least 25 years.

Procedures for Testing Special Characters

Carbohydrate and organic acid utilization have been determined using inoculated plates of the medium of Elkan and Kwik (1968). On the dried surface of these plates are placed absorbent paper discs previously saturated with a 10% solution of the organic compound and slowly dried. During incubation at 28°C the plates are examined daily using indirect lighting against a black, nonreflecting background.

API Biotype galleries (BioMerieux, La Balme-les-Grottes, France) and similar standardized systems to test for the utilization of standard ranges of substrates are increasingly used to obtain reproducible biochemical data.

Details on the methods used to assess nodulation response under greenhouse or growth room conditions are given by Vincent (1970), and Somasegaran and Hoben (1994) have produced an excellent methods book for the novice researcher of symbiotic species. Moore et al. (1988) have provided useful advice for performing inoculation tests for pathogenicity studies and summarize recipes for diagnostic media and tests.

Sawada et al. (1995) have reported a method for detecting the presence of Ti and Ri plasmids by specific amplification of components using the polymerase chain reaction.

Differentiation of the genus *Rhizobium* from other genera

Members of *Rhizobium* are distinguished from those in the related genera *Mesorhizobium* and *Phyllobacterium* by differences in growth rate, fatty acid profiles, and 16S rDNA sequence. Members of

Rhizobium are not distinguished from those in the related genera *Allorhizobium* or *Sinorhizobium* by any phenotypic characters except those that form the individual species circumscriptions. The genus *Agrobacterium* is distinguished from the genera containing nitrogen-fixing species, including *Rhizobium*, only because its members have oncogenic capabilities. *Rhizobium* is distinguished from *Sinorhizobium* not only based on differences in their 16S rDNA sequences but also on the basis of other gene sequences (Gaunt et al., 2001) and by *nolR* gene hybridization (Toledo et al., 2003).

The features that differentiate nodulating strains of *Rhizobium* species from morphologically and physiologically similar organisms are given in Tables BXII.α.112 and BXII.α.113. Strains of nonpathogenic agrobacteria and non-nodulating rhizobia can be isolated from soils and are difficult to allocate to genera or species based on characteristics reported in Table BXII.α.112. It is necessary to resort to specific molecular probes for reliable identification.

Taxonomic Comments

Overviews of the relationships of bacterial nitrogen-fixing genera are given in Young (1992, 1994), Martínez-Romero (1994), Lindström et al. (1995, 1998), Martínez-Romero and Caballero-Mellado (1996), and Young and Haukka (1996).

At that time of publication of the first edition of *Bergey's Manual of Systematic Bacteriology*, the family *Rhizobiaceae* comprised *Rhizobium* (Jordan, 1984a), *Bradyrhizobium* (Jordan, 1984a), *Phyllobacterium* (Knösel, 1984a), and *Agrobacterium* (Kersters and De Ley, 1984a).

Since then, the relationships of nodulating, nitrogen-fixing species have been investigated by comparative analysis of 16S rDNA sequence data. Sequences of the type strains, obtained from international databases, have been subjected to various forms of algorithmic and parsimonious analysis in order to establish their phylogenetic relationships (Sawada et al., 1993; Willems and Collins 1993; de Lajudie et al., 1994, 1998b, 1998a; Nour et al., 1995; Rome et al., 1996; Young and Haukka 1996; Amarger et al., 1997; Tan et al., 1997; Lindström et al., 1998). Comparison of these analyses with others that have been published (Rome et al., 1996; Jarvis et al., 1997; de Lajudie et al., 1998a, b; van Berkum et al., 1998; Wang et al., 1998), and with Fig. BXII.α.130 of this chapter, shows how much results can vary depending on the selection of sequences and the form of analysis. Notwithstanding, all data clearly support the separation of *Bradyrhizobium* Jordan 1982 (now assigned to the family *Bradyrhizobiaceae*; Kuykendall, this volume) and *Azorhizobium* Dreyfus et al., 1988 (now assigned to the family *Hyphomicrobiaceae*; Kuykendall, this volume) as distantly related to all the other pathogenic and nodulating species. These latter species are allocated to the closely related families, *Rhizobiaceae* and *Phyllobacteriaceae*. Nitrogen-fixing and oncogenic (hypertrophying) species in *Agrobacterium*, *Rhizobium*, and *Sinorhizobium* are assigned to the *Rhizobiaceae* and species of *Mesorhizobium* (Jarvis et al., 1997; Chen and Kuykendall, this volume) are assigned to the *Phyllobacteriaceae* (Chen and Kuykendall, this volume).

The family *Rhizobiaceae* includes symbiotic and pathogenic species in the genera *Agrobacterium*, *Rhizobium*, and *Sinorhizobium*. Species allocated to these genera are found in two or three clusters. One cluster comprises *Sinorhizobium*: *Sinorhizobium fredii* (the type species), *Sinorhizobium arboris*, *Sinorhizobium kostiense*, *Sinorhizobium medicae*, *Sinorhizobium meliloti*, *Sinorhizobium saheli*, *Sinorhizobium terangae*, and *Sinorhizobium xinjiangense*. *S. arboris* and *S. kostiense* were only recently described (Nick et al., 1999). The second cluster is more heterogeneous and may be considered to be represented by two subgroups. Subgroup 2a includes *R. leguminosarum* (the type species), *R. etli*, *R. gallicum*, *R. giardinii*, *R. hainanense*, *R. mongolense*, *R. tropici*, and *Agrobacterium rhizogenes*. Subgroup 2b includes *R. galegae*, *R. huautlense*, *Agrobacterium tumefaciens* (the type species), *Agrobacterium rubi*, *Agrobacterium vitis*, and *Allorhizobium undicola* (the type species). All these species have base differences amounting to less than 7% of the total 16S rDNA sequence. The extent of statistical support for individual branches and their relative positions depend on the form of phylogenetic analysis and the selection of sequences. Eardly et al. (1996), Martínez-Romero and Caballero-Mellado (1996), and Young and Haukka (1996) note anomalies in sequence analyses that are attributable to recombination events between species, a conclusion supported but qualified by Wernegreen and Riley (1999). As yet the significance and implications of recombination on the inference of phylogenetic relationships are unclear.

The family also contains, as outliers to the rhizobial species, strains named *Blastobacter* spp. and *"Liberibacter"* spp., which do not have symbiotic or pathogenic characteristics. Other strains of *Blastobacter* spp. are to be found in the families *Methylobacteriaceae* (four strains), *Bradyrhizobiaceae* (one strain), and *Sphingomonadaceae* (one strain). *Blastobacter aggregatus* ATCC 43293 and *Blastobacter capsulatus* ATCC 43294 in the *Rhizobiaceae* are therefore perhaps incorrectly named. The new genus *"Liberibacter"* represents strains of the fastidious organism that is the pathogen of citrus greening disease. This organism appears to be relatively distantly related to *Rhizobium*.

When first proposed, *Sinorhizobium* (Chen et al., 1988b) was based on only a small number of nutritional and biochemical tests, and its validity was questioned by Jarvis et al. (1992) on the basis of partial 16S rDNA sequence analysis and on the interpretation of numerical data. This genus has since been examined in greater detail and an emended circumscription of the genus has been produced (de Lajudie et al., 1994). However, this circumscription does not delineate a taxon distinct from *Rhizobium*, and the polyphasic data reported (PAGE of total proteins and carbon source utilization tests) do not support a coherent taxon. Moreover, the protein data show *Sinorhizobium fredii* (the type strain) as an outlier to the other species, and carbon source utilization data show *Sinorhizobium* species intermingled with *Azorhizobium*, *Bradyrhizobium*, and *Rhizobium*. Support for this genus, distinct from *Rhizobium*, is based on comparative 16S rDNA sequence data alone (de Lajudie et al., 1994).

Allorhizobium, is a monospecific genus established because—as indicated by its name—comparative analysis of 16S rDNA sequence data for *Allorhizobium undicola* indicated that this organism belonged to an outlying branch (de Lajudie et al., 1998b). The closest neighboring species in their analysis was *Agrobacterium vitis*. The species *Allorhizobium undicola* is well defined based on DNA–DNA reassociation, PAGE of total proteins, and carbon source utilization tests. As with *Sinorhizobium*, the circumscription of the genus does not delineate a taxon distinct from *Rhizobium*, and the polyphasic data do not support a close relationship between *Allorhizobium undicola* and *Agrobacterium vitis* and other agrobacteria. In proposing a new genus, rather than either nominating the species as a nitrogen-fixing member of *Agrobacterium ex tempore* or allocating it to *Rhizobium ex tempore*, the authors are committed to a nomenclature in which either *Agrobacterium vitis* is renamed *Allorhizobium vitis* or is recognized in its own monospecific genus. While monospecific genera can sensibly be named

TABLE BXII.α.112. Characteristics of *Rhizobium*, *Agrobacterium*, *Allorhizobium*, and *Sinorhizobium* species[a,b]

Characteristics	*Rhizobium leguminosarum*	*Rhizobium etli*	*Rhizobium galegae*	*Rhizobium gallicum*	*Rhizobium giardinii*	*Rhizobium hainanense*	*Rhizobium huautlense*	*Rhizobium mongolense*	*Rhizobium tropici*	*Agrobacterium tumefaciens*	*Agrobacterium rhizogenes*	*Agrobacterium rubi*	*Agrobacterium vitis*	*Allorhizobium undicola*	*Sinorhizobium fredii*	*Sinorhizobium medicae*	*Sinorhizobium meliloti*	*Sinorhizobium saheli*	*Sinorhizobium terangae*	*Sinorhizobium xinjiangense*

[a]For symbols see standard definitions; (+), weak reaction.

[b]Carbon source utilization data is from de Lajudie et al. (1994) and de Lajudie et al. (1998a). Data for *R. leguminosarum* are from Amarger et al. (1997).

[c]Substrates which gave positive reactions by strains of all species: L-arabinose, D-cellobiose, D-fructose, D-galactose, D-glucose, L-histidine, inositol, D-mannose, rhamnose, ribose, sorbitol, D-turanose, and D-xylose. Fumarate, glycerol, lactose, L-malate, maltose, mannitol, sucrose, succinate, and trehalose were substrates for which only one species expressed variable negative reactions.

[d]Substrates which gave negative reactions by strains of all species: adipate, D-("alpha")-alanine, DL-2-aminobutyrate, amylamine, azelate, benzoate, benzylamine, butylamine, caprate, *n*-caprate, caprylate, citraconate, diaminobutane, esculin, ethylamine, glycine, glycogen, heptanoate, histamine, *o*-hydroxybenzoate, inulin, isophthalate, isovalerate, itaconate, DL-kynurenine, levulinate, maleate, mesaconate, L-methionine, DL-norvaline, oxalate, pelargonate, phenylacetate, phthalate, pimelate, sebacate, spermine, starch, suberate, terephthalate, D-tryptamine, tryptophan, urea, and *n*-valerate. 2-Aminobenzoate, 3-aminobenzoate, 4-aminobenzoate, L-cysteine, fumarate, methyl-D-mannoside, L-norleucine, and sucrose were substrates for which only one species expressed variable positive reactions.

[e]Data are included only where information is available for two or more strains.

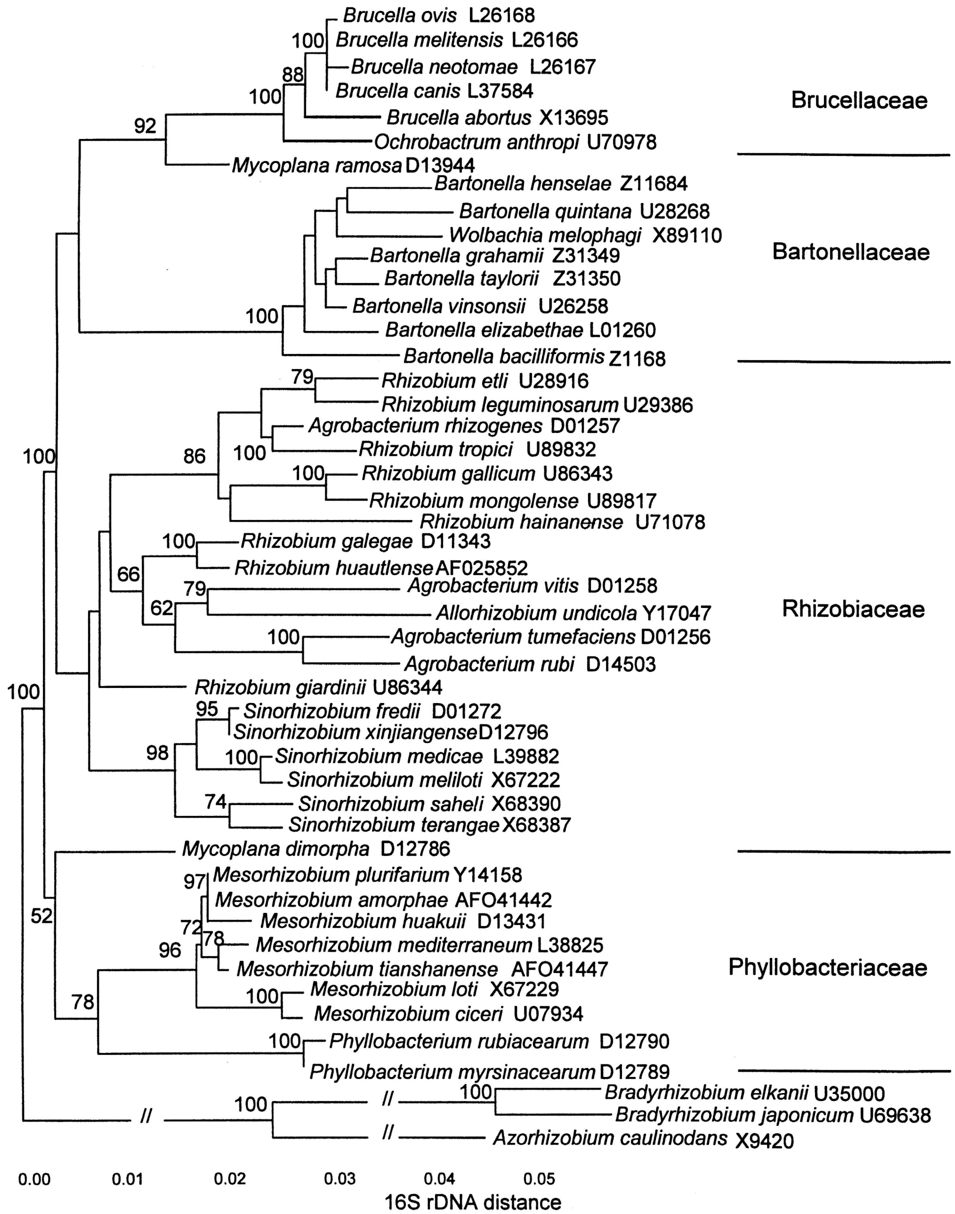

FIGURE BXII.α.130. Neighbor-joining tree expressing the relationships of genera within the *Rhizobiaceae* (*Agrobacterium, Allorhizobium, Rhizobium,* and *Sinorhizobium* and related families) based on 16 S rDNA sequences. Bootstrap probabilities (as percentages) are determined from 1000 resamplings.

when there is clear justification based on a unique circumscription of the taxon, the practice of naming taxa when they are merely outlying members of larger clades must be questioned. In such cases, where the description of the genus is indistinguishable from adjacent genera and where the species description forms the basis of the generic description, there is no basis for forestalling an on-going process of naming monospecific genera across the clade. This approach to classification implies the creation of many genera containing small numbers of species with circumscriptions indistinguishable from *Rhizobium.*

In regard to "rhizobia," legume plants are represented by more than 14,000 species (Jordan 1984a; Lindström et al., 1998), of which fewer than 1% have been investigated to establish the identity of their associated nitrogen-fixing bacterial species. Considering the relatively close relationships of taxa within the *Rhizobiaceae,* it is highly probable that new taxa will be characterized that will be intermediate between the present named species and genera (*Agrobacterium, Rhizobium,* and *Sinorhizobium*). Intermediate taxa can be expected to obscure the apparent deep branches between currently named genera (Martínez-Romero and Caballero-Mellado, 1996).

Murray et al. (1990) have made clear the expectation that at the generic level, taxa should be supported with phenotypic descriptions. Proposed minimal standards for *Agrobacterium* and *Rhizobium* require that generic as well as species names should be based on both phenotypic and phylogenetic data (Graham et al., 1991). Phylogenetic divisions can only be understood as generating distinct genera where these have evolved into discrete phenotypic groups. Genera differentiated solely on sequence data have the same nomenclatural status as taxa erected as *Candidatus,*

as described by Murray and Stackebrandt (1995). Furthermore, 16S rDNA sequence data cannot be accepted uncritically where there is evidence of recombination within sequences (Eardly et al., 1996; Martínez-Romero and Caballero-Mellado, 1996; Young and Haukka, 1996).

With the exception of the 16S rDNA-based discrimination of *Sinorhizobium* as a distinct clade, the generic circumscriptions of *Agrobacterium*, *Allorhizobium*, *Rhizobium*, and *Sinorhizobium* contain no demonstrated characteristics by which these genera can be supported as distinct taxa. Multiple character analysis towards a phenetic (Goodfellow and O'Donnell, 1993; Goodfellow et al., 1997) or polyphasic (Vandamme et al., 1996b) classification aims to produce coherent taxa with relevant circumscriptions. Electrophoretic protein patterns, and numerical analysis of nutritional and biochemical data (de Lajudie et al., 1994) gave no support for segregation of species into the separate genera *Agrobacterium*, *Rhizobium*, and *Sinorhizobium*. Terefework et al. (1998) and de Lajudie et al. (1998a) provide data showing that various pathogenic and nodulating, symbiotic bacteria belonging to the genera *Agrobacterium* and *Rhizobium* are interspersed on subbranches of 16S or 23S phylogenetic trees. Analysis of fatty acid profiles showed that these three genera were closely related (Jarvis et al., 1996), but that species of *Mesorhizobium* formed a distinct group. More recently, Tighe et al. (2000) showed that the concentration of $C_{16:0\ 3OH}$ fatty acid was generally somewhat lower in *Sinorhizobium* than *Rhizobium*. 16S rDNA sequence data clearly show that *Agrobacterium* spp. (Willems and Collins, 1993) are closely related to *Rhizobium* spp. such as *Rhizobium galegae* (Lindström, 1989), and the recently described *Rhizobium huautlense* (Wang et al., 1998). *Agrobacterium rhizogenes* is always found among authentic *Rhizobium* spp. Many past studies have suggested the need for amalgamation of *Agrobacterium* and *Rhizobium* (Graham 1964, 1976; Heberlein et al., 1967; De Ley, 1968; White, 1972; Kerr, 1992; Sawada et al., 1993). It has long been clear that pathogenic (*Agrobacterium*) and nitrogen-fixing (*Rhizobium*) species are interspersed, and there seems to be a paucity of justification for the on-going separation of these genera. *Agrobacterium* is a polyphyletic genus that is an artificial amalgamation of plant-pathogenic species (Young et al., 2001).

The four named genera—*Agrobacterium*, *Allorhizobium*, *Rhizobium*, and *Sinorhizobium*—are closely related in genomic and phenotypic terms. It has recently been proposed by the authors of this treatment that *Agrobacterium*, *Allorhizobium*, and *Rhizobium* be amalgamated into a single genus, *Rhizobium*, based on their close genomic and phenotypic similarity (Young et al., 2001). We maintain that *Allorhizobium* is an artificial genus and in phylogenetic terms is part of the *Agrobacterium*/*Rhizobium* cluster. Indeed it seems clear that its creation was only justified based on the anomalous state of *Agrobacterium* nomenclature at the time it was proposed by de Lajudie et al., (1998a). The branches between *Agrobacterium* and *Rhizobium* on the one hand and *Sinorhizobium* on the other suggest an evolutionary divergence that could be interpreted as preliminary to the formation of new genera. At present these two clades are probably incipient genera and merit no more than recognition as subgenera.[2]

2. Since the completion of this manuscript, a proposal to include species of *Agrobacterium*, *A. radiobacter*, *A. rhizogenes*, *A rubi*, *A. vitis*, and *Allorhizobium undicola* in *Rhizobium* with an emended description of the genus, has been made (Young et al., 2001), as a more natural polyphasic, interpretation of the the taxonomy of the family *Rhizobiaceae*. The status of the genus *Sinorhizobium* is considered to need further evaluation.

Differentiation of the species of the genus *Rhizobium*

Morphological, biochemical, and nutritional data are given in Tables BXII.α.112 and BXII.α.113. Nutritional data have been reported for only about half of *Rhizobium* species (Table BXII.α.113). Data are included here only if more than one strain for each species has been reported. Some recently named species have been established largely using comparative 16S rDNA sequence analyses. Phenotypic descriptions of these species, as well as a comprehensive comparative investigation of the whole genus, are needed.

The phenotypic descriptions of the symbiotic nodule-forming *Rhizobium* species are based on D.C. Jordan's treatment in the first edition of *Bergey's Manual of Systematic Bacteriology* in 1984 and on original descriptions of new species. The phenotypic description of *Agrobacterium* is based on studies by De Ley et al. (1966), Lippincott and Lippincott (1969), Keane et al. (1970), White (1972), Kersters et al. (1973), Panagopoulos and Psallidas (1973), Kerr and Panagopoulos (1977), Süle (1978), Panagopoulos et al. (1978), Holmes and Roberts (1981), Sawada and Ieki (1992b), de Lajudie et al. (1994), and Amarger et al. (1997).

List of species of the genus Rhizobium

1. **Rhizobium leguminosarum** (Frank 1879) Frank 1889, 338[AL] (*Schinzia leguminosarum* Frank 1879, 397.)
le.gu.mi.no.sa' rum. M.L. fem. n. *Leguminosae* old family name of the legumes; M.L. gen. pl. n. *leguminosarum* of legumes.

The characteristics are as given for the genus and listed in Tables BXII.α.112 and BXII.α.113. The cells have either 1 or 2 polar flagella or 2–6 peritrichous flagella. Growth does not occur at 39–40°C. The pH range for growth is 4.5–9.0. Growth does not occur in YMA containing 2% NaCl. Pantothenate and, for some strains, thiamine are required as growth factors. Well characterized genetically. Three biovars of *R. leguminosarum* have been defined, biovar trifolii (previously classified as *Rhizobium trifolii* Dangeard 1926[AL]), biovar phaseoli, and biovar viceae, based on nodulating specificity. Selected strains of biovar phaseoli have been elevated to the status of species as *R. etli*, *R. gallicum*, *R. giardinii*, *R. mongolense*, and *R. tropici*. Residual strains representing *R. leguminosarum* need to be re-examined and the description of the species needs to be emended.

R. leguminosarum nodulates with some, but not necessarily all, *Lathyrus* spp., *Lens* spp., temperate species of *Phaseolus* (*P. vulgaris*, *P. angustifolius*, *P. multiflorus*), *Pisum* spp., *Trifolium* spp., and *Vicia* spp.

The mol% G + C of the DNA is: 59–63 (T_m).

Type strain: ATCC 10004, DSM 30132, NCIB 11478, USDA 2370.

GenBank accession number (16S rRNA): U29386.

2. **Rhizobium etli** Segovia, Young, and Martínez-Romero 1993, 376[VP]
et' li. L. n. *etl* bean; N.L. gen. n. *etli* of bean.

The characteristics are as given for the genus and listed

in Table BXII.α.112. Fast growing: colonies are 2–4 mm in diameter after 2–4 d on peptone–yeast extract agar. No growth occurs on Luria broth medium or on peptone yeast-extract medium lacking calcium. Growth occurs on a minimal medium containing malate as a carbon source. Maximum temperature for growth is 37°C. Selected strains of *R. leguminosarum* biovar phaseoli were differentiated as this new species on the basis of differences in protein profiles, antibiotic resistance profiles, serological types, DNA–DNA reassociation data, plasmid profiles, exopolysaccharide structures, and multilocus enzyme electrophoresis.

The species contains two named biovars: *Rhizobium etli* biovar phaseoli and biovar mimosae (Wang et al., 1999a). The species nodulates and fixes nitrogen in association with *Phaseolus vulgaris* and some other legumes, such as *Mimosa affinis*. Nonsymbiotic strains are included in the species.

The mol% G + C of the DNA is: 59-63 (T_m).

Type strain: CFN 42, ATCC 51251, ICMP 13642, USDA 9032.

GenBank accession number (16S rRNA): U28916.

3. **Rhizobium galegae** Lindström 1989, 365[VP]
ga.le′gae. M.L. fem. gen. n. *galegae* of *Galega*, a genus of leguminous plants.

The characteristics are as given for the genus and listed in Tables BXII.α.112 and BXII.α.113. Motile by 1–2 polar or subpolar flagella. Relatively slow growing. Colonies on YMA are more than 1.0 mm in diameter after 7 d at 28°C. Growth does not occur on YMA containing 2% NaCl. Maximum temperature for growth is 33–37°C. Most strains form a serum zone and give an alkaline reaction in litmus milk. Hydrolyzes urea but does not precipitate calcium glycerophosphate or reduce nitrate. Requires pantothenate as a vitamin supplement or growth factor, but not thiamine. Utilizes relatively few organic substrates as sole sources of carbon (Table BXII.α.113). A preliminary report gave information on this species (Lindström and Lehtomäki, 1988). Nodulates *Galega orientalis* and *Galega officinalis* and is reported to be specific to these species.

The mol% G + C of the DNA is: 63 (T_m).

Type strain: HAMBI 540, ATCC 43677, DSM 11542, ICMP 13643, LMG 6214.

GenBank accession number (16S rRNA): D11343, X67226.

4. **Rhizobium gallicum** Amarger, Macheret, and Laguerre 1997, 1005[VP]
gal′li.cum. L. adj. *gallicum* pertaining to Gallia; the country of origin, France.

The characteristics are as given for the genus and listed in Table BXII.α.112. Relatively fast growing. Colonies are 2–4 mm in diameter within 2–3 d at 28°C. Growth does not occur on YMA containing 1% NaCl. Resistant to nalidixic acid. Separated from other *Rhizobium* species by cluster analysis of phenotypic data. The status of *R. gallicum* as an authentic species is supported by amplified 16S rDNA restriction analysis, comparative 16S rDNA sequence analysis, DNA–DNA reassociation, and nutritional data.

Two biovars, *R. gallicum* biovar gallicum and *R. gallicum* biovar phaseoli, are established based on nodulating specificity. *R. gallicum* biovar gallicum nodulates and fixes nitrogen in association with *Leucaena leucocephala*, *Macroptilium atropurpureum*, *Onobrychis viciifolia*, and *Phaseolus* spp. whereas *R. gallicum* biovar phaseoli nodulates *Phaseolus* spp. only.

The mol% G + C of the DNA is: not available.

Type strain: R602sp, MSDJ1109.

GenBank accession number (16S rRNA): AF008130, U86343.

5. **Rhizobium giardinii** Amarger, Macheret, and Laguerre 1997, 1005[VP]
giar.di′ni.i. N.L. gen. n. *giardinii* of Giardini, a Brazilian microbiologist who isolated the organism.

The characteristics are as given for the genus and listed in Table BXII.α.112. Relatively fast growing. Colonies are 2–4 mm in diameter within 2–3 d at 28°C. Growth does not occur on YMA containing 2% NaCl. Resistant to nalidixic acid. The status of *R. giardinii* as an authentic species is supported by amplified 16S rDNA restriction analysis, DNA–DNA hybridization, and comparative 16S rDNA sequence analysis.

Two biovars, *R. giardinii* biovar giardinii and *R. giardinii* biovar phaseoli, are established based on nodulating specificity. *R. giardinii* biovar giardinii nodulates *Phaseolus* spp., *Leucaena leucocephala*, and *Macroptilium atropurpureum*, but does not fix nitrogen with *Phaseolus vulgaris*. *R. giardinii* biovar phaseoli nodulates *Phaseolus* spp. and is weakly efficient in fixing nitrogen in association with that host.

The mol% G + C of the DNA is: not available.

Type strain: H152, MSDJ0144.

GenBank accession number (16S rRNA): U86344.

6. **Rhizobium hainanense** Chen, Tan, Gao, Li, and Wang 1997b, 872[VP]
hai.na.nen′se. M.L. neut. adj. *hainanense* pertaining to Hainan Province in China.

The characteristics are as given for the genus and listed in Table BXII.α.112. Motile by a single polar flagellum. Relatively fast growing, with a generation time of 2–4 h. Colonies are 2–4 mm in diameter after 3 d growth on yeast extract mannitol agar. Temperature optimal for growth, 25–30°C. Strains can grow at 40°C. Optimal pH for growth, 6–8; pH range, 5–10. Grows on YMA containing 2% NaCl.

The status of *R. hainanense* as an authentic species is supported by cluster analysis of phenotypic features, DNA–DNA reassociation data, and comparative 16S rDNA sequence analysis.

Nodulates *Acacia sinicus*, *Arachis hypogaea*, *Centrosema pubescens*, *Desmodium gyroides*, *D. sinuatum*, *D. triquetrum*, *D. heterophyllum*, *Macroptilium lathyroides*, *Stylosanthes guianensis*, *Tephrosia candida*, *Uraria crinita*, and *Zornia diphylla*.

The mol% G + C of the DNA is: 59–63 (T_m).

Type strain: I66, CCBAU 57015, DSM 11917, ICMP 13690.

GenBank accession number (16S rRNA): U71078.

7. **Rhizobium huautlense** Wang, van Berkum, Beyene, Sui, Dorado, Chen and Martínez-Romero 1998, 696[VP]
hu.aut.len′se. N.L. adj. *huautlense* of Huautla, the region in Mexico where the organisms were isolated.

The characteristics are as given for the genus and listed in Table BXII.α.112. Relatively fast growing, with a generation time of 2.0–2.2 h. Colonies are 2–4 mm in diameter within 2–3 d at 28°C. Grows at 40°C. Growth does not occur on YMA containing 2% NaCl. Requires thiamine as a growth factor. Comparative sequence analysis of 16S rDNA indicates that this species is closely related to *R. galegae*. These

two species are differentiated based on multilocus enzyme electrophoresis, DNA–DNA reassociation, size of compatible Sym plasmids, and a small number of other features. Nodulates *Sesbania herbacea*, *S. rostrata*, and *Leucaena leucocephala*.

The mol% G + C of the DNA is: 57–59 (T_m).

Type strain: S02, ICMP 13551, USDA 4900.

GenBank accession number (16S rRNA): AF025852.

8. **Rhizobium lupini** (Schroeter 1886) Eckhardt, Baldwin and Fred 1931, 273[AL] (*Phytomyxa lupini* Schroeter 1886, 135.)
lu.pi'ni. M.L. masc. n. *Lupinius* generic name of lupine; M.L. gen. n. *lupini* of *Lupinus*.

A limited description is given in Jordan and Allen (1974). Jordan (1984a) recognized the affinities of this species with *Bradyrhizobium* species but felt that evidence was lacking to propose the transfer of *R. lupini* to the genus. Since then comparative sequence analyses of 16S rDNA from nodulating strains of *Lupinus* support transfer of the species; however, the 16S rDNA sequence of the type strain, which has unfortunately been contaminated with *B. japonicum* but still contains another distinct species (van Berkum et al., 1998), appears not to have been analyzed. The status of this species clearly needs work.

Nodulates *Lupinus* spp. and *Ornithopus* spp. Limited nodulation of *Glycine* spp. and the cowpea miscellany.

The mol% G + C of the DNA is: not available.

Type strain: ATCC 10319, DSM 30140.

9. **Rhizobium mongolense** van Berkum, Beyene, Bao, Campbell and Eardly 1998, 21[VP]
mon.go.len'se. L. neut. adj. *mongolense* pertaining to Inner Mongolia, the region where the bacteria were isolated.

The characteristics are as given for the genus and listed in Table BXII.α.112. Motile by a single polar or subpolar flagellum. Relatively fast growing: colonies 1–3 mm in diameter within 3–5 days on arabinose-gluconate agar. No growth occurs on YMA containing 1% NaCl or at pH values below 4.0. Resistant to bacitracin, cefuperazone, and penicillin G. *R. mongolense* shares 99.2% similarity in its 16S rDNA sequence with *R. gallicum* (van Berkum et al., 1998), and it may therefore be a junior synonym of *R. gallicum*. Isolated from *Medicago ruthenica*. Nodulates *Medicago ruthenica* and *Phaseolus vulgaris*.

The mol% G + C of the DNA is: not available.

Type strain: USDA 1844 (ICMP 13688).

GenBank accession number (16S rRNA): U89817

10. **Rhizobium tropici** Martínez-Romero, Segovia, Mercante, Franco, Graham and Pardo 1991, 424[VP]
tro'pi.ci. M.L. gen. n. *tropici* of the tropic (of Cancer).

The characteristics are as given for the genus and listed in Tables BXII.α.112 and BXII.α.113. Motile by peritrichous flagella. Relatively fast growing, with a doubling time of 1.6–2.0 h. Colonies are 2–4 mm in diameter within 2–4 days at 30°C on mannitol–yeast extract agar and peptone yeast-extract agar. Can grow at 40°C. Growth occurs at pH 4.5–7. Does not produce 3-ketolactose. Utilizes a range of organic substrates as sole sources of carbon (Table BXII.α.113).

Previously classified as Type II strains of *Rhizobium leguminosarum* biovar phaseoli. This species comprises Type A and Type B strains, which may represent two distinct species. Distinguished from *Rhizobium leguminosarum* by host range, *nif* gene organization, high temperature tolerance, and extreme acid tolerance, and are said to be more symbiotically stable. Distinguished from other *Rhizobium* species by DNA–DNA reassociation, multilocus enzyme electrophoresis profiles, in biochemical tests, and 16S rDNA sequence comparison.

Forms nodules on *Phaseolus vulgaris*, *Leucaena* spp., and with other legume species. Type A strain CFN299 also nodulates *Amorpha fruticosa*.

The mol% G + C of the DNA is: 60–62 (T_m).

Type strain: ATCC 49672, ICMP 13646, IFO 15427, LMG 9503, USDA 9030.

GenBank accession number (16S rRNA): U89832, X77125.

Genus II. **Agrobacterium** *Conn 1942, 359*[AL]*

JOHN M. YOUNG, ALLEN KERR AND HIROYUKI SAWADA

A.gro.bac.te'ri.um. Gr. n. *agros* a field; Gr. dim. neut. n. *bakterion* a small rod; M.L. neut. n. *Agrobacterium* a small field rod.

Rods 0.6–1.0 × 1.5–3.0 μm, occurring singly or in pairs. Nonsporeforming. Gram negative. **Motile by 1–4 peritrichous flagella. Aerobic**, possessing a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Some strains are capable of anaerobic respiration in the presence of nitrate. Most strains are able to grow under reduced oxygen tensions in plant tissues. Optimal temperature for growth: 25–28°C. Colonies are usually convex, circular, smooth, nonpigmented to light beige. **Growth on carbohydrate-containing media is usually accompanied by copious extracellular polysaccharide slime.** Catalase positive. **Usually oxidase positive** and urease positive. Indole is not produced. Chemoorganotrophs, utilizing a wide range of carbohydrates, salts of organic acids, and amino acids as carbon sources, but not cellulose, starch, agar, or chitin. **Produce an acid reaction in mineral salts media containing mannitol and other carbohydrates.** Ammonium salts and nitrates can serve as nitrogen sources for strains of some species; others require amino acids and additional growth factors. 3-ketoglycosides are produced by the majority of strains belonging to *A. tumefaciens*. **Strains of some species in this genus invade the crown, roots, and stems of a great variety of dicotyledonous and some gymnospermous plants via wounds, causing transformation of the plant cells into autonomously proliferating tumor cells.** Onco-

**Editorial Note:* Young et al. (2001) have proposed the transfer of the type species of the genus *Agrobacterium*, *A. tumefaciens*, as well as the species *A. rhizogenes*, *A. rubi*, and *A. vitis* to the genus *Rhizobium*.

genicity is correlated with the presence of a large tumor-inducing plasmid. Habitat: soil. Oncogenic strains occur mainly in soils previously contaminated with diseased plant material. Some non-oncogenic *Agrobacterium* strains have been isolated from human clinical specimens.

The mol% G + C of the DNA is: 57–63.

Type species: **Agrobacterium tumefaciens** (Smith and Townsend 1907) Conn 1942, 359[AL] (*Bacterium tumefaciens* Smith and Townsend 1907, 672; *Agrobacterium radiobacter* (Beijerinck and van Delden 1902) Conn 1942, 359; *Agrobacterium radiobacter* biovar radiobacter (Beijerinck and van Delden 1902) Keane, Kerr and New 1970, 594; *Agrobacterium radiobacter* biovar tumefaciens (Smith and Townsend 1907) Keane, Kerr and New 1970, 594; *Agrobacterium radiobacter* pathovar *tumefaciens* (Smith and Townsend 1907) Young, Dye, Bradbury, Panagopoulos and Robbs 1978, 156.)

Further descriptive information

Introductory note on nomenclature used in this chapter Following Bradbury (1986), strains in past literature called *Agrobacterium* biovar 1 are herein referred to as *A. tumefaciens*. *Agrobacterium* biovar 2 strains are referred to as *A. rhizogenes*. *Agrobacterium* biovar 3 strains are referred to as *A. vitis*. Where necessary, the ability of pathogenic strains to cause crown gall tumors or the hairy root condition, previously attributed to strains using the names *"Agrobacterium tumefaciens"* and *A. rhizogenes*, is indicated by reference to the tumorigenic or rhizogenic capacity respectively of strains in species of *Agrobacterium*. Nonpathogenic strains previously named *A. radiobacter* are referred to as nonpathogenic strains of *A. tumefaciens* and *A. rhizogenes* or as nonpathogenic *Agrobacterium* if the species designation has not been identified. Ti or Ri plasmids determine the pathogenic status of strains (See below). Species comprising pathogenic or nonpathogenic strains are reported as tumorigenic as a (Ti strain) or (Ti); as rhizogenic as a (Ri strain) or (Ri); or as nonpathogenic strains of the species where relevant. Table BXII.α.114 explains the relationships of names in the literature.

Acid is produced in mineral salts media from L-arabinose, cellobiose, D-fructose, D-glucose, lactose, maltose, melezitose, L-rhamnose, trehalose, D-xylose, adonitol, arabitol, ethanol, mannitol, salicin, and other carbohydrates.

Plant diseases associated with agrobacteria are commonly known as crown gall, hairy root, cane gall, and grapevine gall. Strains of some species possess a wide host range (*A. rhizogenes* and *A. tumefaciens*), whereas others (*A. rubi* and *A. vitis*) possess a limited host range, perhaps confined to single plant genera. The tumors are self-proliferating and can be transmitted by grafting.

Tumor induction is correlated with the presence of a large tumor-inducing plasmid (Ti-plasmid) in the bacterium. Hairy root induction is associated with the presence of an Ri plasmid. Both plasmids are involved in similar mechanisms of symptom production. Some strains lack oncogenic plasmids and are nonpathogenic.

The molecular size of the *Agrobacterium* genome ranges from 3.0 to 3.6×10^9 bp.

Additional information about agrobacteria can be found in the chapter on the genus *Rhizobium*.

Enrichment and Isolation Procedures

Several selective media have been described for the isolation of *Agrobacterium* species from soil and crown gall tissues (Moore et al., 1988). The medium of Schroth et al. (1965)[1] is a general medium for the isolation of *A. tumefaciens*. Medium 1A[2] of Brisbane and Kerr (1983) can be used for most *Agrobacterium tumefaciens* strains. Medium 2E of Brisbane and Kerr (1983)[3] is used for *Agrobacterium rhizogenes*; erythritol was selected as the sole carbon source in this medium because *Agrobacterium tumefaciens* strains cannot utilize it (see Table BXII.α.113 in the chapter on the genus *Rhizobium*). Agrobacteria can be isolated from soil and from young crown gall tissues by spreading 0.1 ml of the appropriate dilution of soil or extracts of gall tissue with an L-shaped glass rod over one of the surface-dried media in Petri dishes, which are subsequently incubated at 27°C. Typical convex, glistening, and circular colonies with an entire edge are transferred for storage and identification.

Other selective media were described by Clark (1969), Kado and Heskett (1970), and Moore et al. (1980). A selective medium[4] has been developed for *Agrobacterium vitis* (Roy and Sasser 1983).

Procedures for Testing Special Characters

Pathogenicity No single host plant will serve for the assay of virulence of tumorigenic strains of *Agrobacterium* because the host range of some strains is restricted (Panagopoulos and Psallidas, 1973; Anderson and Moore, 1979) (see above). Sunflower (*Helianthus annuus*) may be host to the widest range of tumorigenic strains. Young vigorously growing plants are recommended. Stems of 1–2 week-old sunflower plants are inoculated with sterile needles or sharpened sterile toothpicks dipped in colonies or heavy ($>10^8$ cfu/ml) aqueous bacterial suspensions prepared from 2-d-old cultures on any medium producing satisfactory growth. Pathogenicity can usually be recorded within a week after inoculation. The young stems of various varieties of the following plants can also be used: tobacco (*Nicotiana tabacum*), tomato (*Lycopersicon esculentum*) and *Kalanchoë daigremontiana* (Anderson and Moore, 1979). Tumor formation can be rather slow, taking from 2–4 weeks. As positive and negative controls, wounded plants should be inoculated with known pathogenic and nonpathogenic *Agrobacterium* strains. Inoculated plants should be

---

1. The medium of Schroth et al. (1965) consists of (g/l of distilled water): agar, 20.0; mannitol, 10.0; $NaNO_3$, 4.0; $MgCl_2$, 2.0; calcium propionate, 1.2; $MgHPO_4 \cdot 3H_2O$, 0.2; $MgSO_4 \cdot 7H_2O$, 0.1; $NaHCO_3$, 0.075; and magnesium carbonate, 0.075. The pH is adjusted to 7.1 with 1 N HCl. After the medium is autoclaved and cooled to 50–55°C, the following compounds are added aseptically to give final concentrations of (mg/l): berberine, 275; sodium selenite, 100; penicillin G (1625 U/mg), 60; streptomycin sulfate, 30; cycloheximide, 250; tyrothricin, 1.0; and bacitracin (65 U/mg), 100.

2. Medium 1A of Brisbane and Kerr (1983) contains (g/l of distilled water): L (−) arabitol, 3.04; NH_4NO_3, 0.16; KH_2PO_4, 0.54; K_2HPO_4, 1.04; $MgSO_4 \cdot 7H_2O$, 0.25; sodium taurocholate, 0.29; crystal violet (0.1% w/v aqueous), 2 ml; and agar, 15.0. Autoclave; cool to 50°C, then add 1 ml of a filter-sterilized 2% solution of cycloheximide and 6.6 ml of a filter-sterilized 1% solution of Na_2SeO_3.

3. Medium 2E for *Agrobacterium rhizogenes* strains (Brisbane and Kerr, 1983) consists of (g/l of distilled water): NH_4NO_3, 0.16; erythritol, 3.05; KH_2PO_4, 0.54; K_2HPO_4, 1.04; $MgSO_4 \cdot 7H_2O$, 0.25; sodium taurocholate, 0.29; yeast extract (1% w/v aqueous), 1 ml; malachite green (0.1% w/v aqueous), 5 ml; agar, 15. Autoclave; cool to 50°C, then add 1 ml of a filter-sterilized 2% solution of cycloheximide and 6.6 ml of a filter-sterilized 1% solution of Na_2SeO_3.

4. The medium for *Agrobacterium vitis* of Roy and Sasser (in Moore et al., 1988) contains (g/l): adonitol, 4.0; KH_2PO_4, 0.7; K_2HPO_4, 0.9; $MgSO_4 \cdot 7H_2O$, 0.2; NaCl, 0.2; H_3BO_3, 1.0; yeast extract, 0.14; agar, 15; chloranthanil (Bravo 500; 4% aqueous), 0.5 ml. Adjust to pH 7.2, autoclave; cool to 50°C and add the following as filter-sterilized solutions: triphenyltetrazolium chloride, 80 mg; D-cycloserine, 20 mg; trimethroprim (in acidified water), 20 mg. Colonies of *Agrobacterium vitis* have a dark red center with white margins. Comparison with an authentic strain is recommended.

TABLE BXII.α.114. Relationships between different proposed nomenclature for the genus *Agrobacterium*

Species names based on natural classification		Species names based on pathogenicity	
Names used in this text (after Holmes and Roberts, 1981; Bradbury, 1986; Holmes, 1988)	After Keane et al. (1970); New and Kerr (1972); Kerr and Panagopoulos (1977); Panagopoulos et al. (1978)	Allen and Holding, 1974; Approved Lists (Skerman et al., 1980)	After Kersters and De Ley, 1984a
A. tumefaciens (Ti strain or Ti)	*A. radiobacter*[a] biovar tumefaciens (biotype 1)	*A. tumefaciens*	*A. tumefaciens* (biovar 1)
A. tumefaciens (Ri strain or Ri)	*A. radiobacter* biovar rhizogenes (biotype 1)	*A. rhizogenes*	*A. rhizogenes* (biovar 1)
A. tumefaciens (nonpathogenic)	*A. radiobacter* biovar radiobacter (biotype 1)	*A. radiobacter*	*A. radiobacter* (biovar 1)
A. rhizogenes (Ti strain or Ti)	*A. radiobacter* biovar tumefaciens (biotype 2)	*A. tumefaciens*	*A. tumefaciens* (biovar 2)
A. rhizogenes (Ri strain or Ri)	*A. radiobacter* biovar rhizogenes (biotype 2)	*A. rhizogenes*	*A. rhizogenes* (biovar 2)
A. rhizogenes (nonpathogenic)	*A. radiobacter* biovar radiobacter (biotype 2)	*A. radiobacter*	*A. radiobacter* (biovar 2)
A. rubi (Ti strain or Ti)[b]	*A. radiobacter* biovar tumefaciens (biotype 2)	*A. rubi*	*A. rubi*
A. vitis (Ti strain or Ti)[b]	*A. radiobacter* biovar tumefaciens (biotype 3)	*A. vitis*	*A. tumefaciens* (biovar 3)
A. vitis (nonpathogenic)	NR[c]	NR	NR

[a]Use of the species epithet *radiobacter* in place of *tumefaciens* is now not considered acceptable in terms of the Code (Sawada et al., 1993; Bouzar, 1994).

[b]Only tumorigenic (Ti) capability has been reported for this species.

[c]NR, not recorded.

kept in a greenhouse at 20–27°C. When no greenhouse facilities are available, disks of carrot roots (*Daucus carota*) are also useful (Klein and Tenebaum, 1955; Lippincott and Lippincott, 1969). This is a convenient procedure, provided that at least 10 slices from different carrot roots are inoculated per strain and that proper controls are included, because false positive responses (cambial swellings) occasionally occur. Because pathogenic strains belonging to *A. vitis* and isolated from grapevines usually display a restricted host specificity, pathogenicity tests for these strains should be performed on the green tender shoots of grapevines (Panagopoulos and Psallidas, 1973; Panagopoulos et al., 1978).

The root-inducing ability of *A. rhizogenes* (Ri strains) is usually tested by the carrot disk assay (Lippincott and Lippincott, 1969; Moore et al., 1979) or on *Kalanchoë daigremontiana* (White and Nester, 1980b). The interpretation of such experiments is sometimes difficult because some tumorigenic strains are known to induce typical hairy root symptoms on *Kalanchoë* plants (De Cleene and De Ley, 1981).

Differentiation of the genus *Agrobacterium* from other genera

See Table BXII.α.112 in the chapter on the genus *Rhizobium*. Apart from phenotypic characters that distinguish them as individual species, there are no common distinct characters that differentiate these species as separate from members of the genus *Rhizobium*.

Taxonomic Comments

Inferred phylogenies based on comparative analyses of 16S rDNA sequence data show that plant-pathogenic *Agrobacterium* spp. are intermingled with fast-growing *Rhizobium* spp., together with *Allorhizobium undicola*. The genus itself is established only based on pathogenicity characteristics of its species. Apart from pathogenicity tests and nomenclatural problems posed by the confusing species epithets, the generic taxonomic relationships of *Agrobacterium* spp. are discussed fully and further descriptive information is given in the chapter on *Rhizobium*.

Nomenclatural problems *Agrobacterium tumefaciens* (Smith and Townsend 1907) Conn 1942 (type species) was the name given to strains of *Agrobacterium* capable of inducing tumorigenic reactions in many host genera (although some of these strains, isolated from *Vitis* spp., appeared to be specific to grape). *Agrobacterium rhizogenes* (Riker et al., 1930) Conn 1942 is comprised of strains capable of inducing a hairy-root (rhizogenic) reaction in host plants. *Agrobacterium radiobacter* (Beijerinck and van Delden 1902) Conn 1942 consisted of nonpathogenic *Agrobacterium* strains, and *A. rubi* (Hildebrand 1940) Starr and Weiss 1943 contained strains capable of inducing tumorigenic reactions in *Rubus* spp. Although *A. rhizogenes* and *A. tumefaciens* comprised populations from soil and from a large number of dicotyledonous hosts, *A. rubi* was represented by isolates from *Rubus* which appeared to be specific to that host in nature. This classification was predominantly, and for some species solely, based on the phytopathogenic behavior of these bacteria. Though of practical use and widely supported as a special purpose classification, it bears no relationship to, and is inconsistent with, natural classifications of *Agrobacterium* as now understood.

When Smith and Townsend and Riker et al. first proposed the names *A. tumefaciens* and *A. rhizogenes*, they followed the custom of giving names which reported a distinctive character of the species—in this instance their pathogenic symptoms. However, the tumorigenic and rhizogenic characters are carried on different plasmids, with the consequence that the pathogenic characters are separately transmissible between species. The result is that both species *A. tumefaciens* and *A. rhizogenes* are represented by strains which may be either tumorigenic, rhizogenic, or—if lacking either kind of plasmid—nonpathogenic. Notwithstanding customary naming, in this extreme example apparently distinctive features are not characteristic of all members of the taxon, are found in these related taxa, and are mobile.

Although it was believed in the past that the different path-

ogenic reactions would be supported by physiological reactions that would justify species discriminations (Burkholder and Starr, 1948), this assumption has long been shown to be false (Young et al., 1992). Although the establishment of these species (*A. rhizogenes* and *A. tumefaciens*) based on distinct pathogenic characters was supported by Kersters and De Ley (1984a) and by subsequent workers, others have supported an alternative nomenclature based on natural classification. Holmes and Roberts (1981) and Holmes (1988) proposed a rational and consistent nomenclature for these taxonomic groups, which is used here. Bradbury (1986) also supported this classification but it has not found widespread acceptance for reasons that will be discussed below.

The classification of *Agrobacterium* species has been thoroughly studied using the following techniques: (a) numerical analysis of phenotypic characteristics (White, 1972; Kersters et al., 1973; Holmes and Roberts, 1981); (b) biochemical and physiological tests (Keane et al., 1970; Kersters et al., 1973; Kerr and Panagopoulos, 1977; Süle, 1978; Holmes and Roberts, 1981); (c) fatty acid methyl ester profiles (Sawada et al., 1992d; Jarvis et al., 1996); (d) DNA–DNA reassociation (De Ley, 1972 ,1974); (e) measurements of the thermal stability of DNA–DNA hybrids (De Ley et al., 1973); and (f) comparison of electrophoretograms of soluble proteins (Kersters and De Ley, 1975). The results obtained by the above mentioned methods corroborated each other and indicated that the genus *Agrobacterium* consisted of at least three genetically and phenotypically different groups or clusters. These groups corresponded to biovars 1, 2, and 3 of Keane et al. (1970). Recently, this number has been increased to four, possibly five, groups now recognized as species (see below).

Species recognized based on their overall phenotypic and genomic relatedness are given below under the List of the species of the genus *Rhizobium* according to the type strains allocated to each species population.

Bradbury (1986), Holmes and Roberts (1981), Holmes (1988), and Young et al. (1992) have supported use of the names *A. tumefaciens* and *A. rhizogenes*, in accord with natural classification, recognizing pathogenic strains according to their tumorigenic, rhizogenic, and nonpathogenic states. However, the epithet *tumefaciens* has become so entrenched as the name for pathogenic populations of *Agrobacterium* spp. with tumorigenic capabilities in a special purpose classification, that it is difficult for it also to be used unambiguously for its proper purpose in natural classification. Attempts to resolve the difficulty by recognizing *A. radiobacter* in place of *A. tumefaciens* (Young et al., 1978; Kersters and De Ley, 1984a; Sawada et al., 1993) cannot be adopted easily because *A. tumefaciens*, the type species, has been conserved over *A. radiobacter* (Judicial Commission, 1970). Bouzar (1994) sought clarification of the proposal of Sawada et al. (1993) which, with the response of Sawada et al. (Bouzar 1994), the Judicial Commission of the ICSB deemed to have resolved the matter (L.G. Wayne, personal communication). The practical and usual solution to this nomenclatural confusion has been to use an artificial classification and informal nomenclature in which the species names *A. tumefaciens* or *A. rhizogenes* are applied to the pathogenic plasmid-borne states, and the terms biotype or biovar are applied to the natural species groups.

If the genus *Agrobacterium* continues to be differentiated from *Rhizobium* in the future, then the use of a natural classification that recognizes *Agrobacterium* species will probably require a radical change of nomenclature by application of the Code (Lapage et al., 1992). For instance, the name *A. tumefaciens* could be rejected (Rule 23a) as a *nomen ambiguum*; a name that has been used with different meanings and has thus become a source of error (Rule 56a). Rejection would also require the designation of a new type species. The obvious candidate is *A. radiobacter*. A more radical option could involve the application of new names (and a new type species), extending the proposal of Kersters and De Ley (1984a). For both these proposals, it would be necessary to make a Request for an Opinion to the Judicial Commission of the ICSB. The four named genera—*Agrobacterium*, *Allorhizobium*, *Rhizobium*, and *Sinorhizobium* —are closely related in genomic and phenotypic terms. It has recently been proposed that *Agrobacterium*, *Allorhizobium*, and *Rhizobium* be amalgamated into a single genus, *Rhizobium*, based on their close genomic and phenotypic similarity (Young et al., 2001) (see *Rhizobium* chapter in this volume).

Elsewhere, the application of pathovars in terms of the Standards for Naming Pathovars (Dye et al., 1980) has been proposed (Young et al., 1978; Kersters and De Ley, 1984a). However, the fact that most pathogenicity genes are carried on a plasmid means that the pathogenic character of any strain is unstable. This lack of stability would make uncertain the application of pathovar names to particular strains, most notably to pathotype strains. For pathogenic strains in *Agrobacterium* therefore, this formal special purpose nomenclature (Dye et al., 1980) seems inappropriate. Species comprising pathogenic or non-pathogenic strains could be reported as tumorigenic, as a Ti strain or Ti, as rhizogenic, as a Ri strain or Ri, or as nonpathogenic strains of the species, where relevant.

List of species of the genus Agrobacterium

1. **Agrobacterium tumefaciens** (Smith and Townsend 1907) Conn 1942, 359[AL] (*Bacterium tumefaciens* Smith and Townsend 1907, 672; *Agrobacterium radiobacter* (Beijerinck and van Delden 1902) Conn 1942, 359; *Agrobacterium radiobacter* biovar radiobacter (Beijerinck and van Delden 1902) Keane, Kerr and New 1970, 594; *Agrobacterium radiobacter* biovar tumefaciens (Smith and Townsend 1907) Keane, Kerr and New 1970, 594; *Agrobacterium radiobacter* pathovar *tumefaciens* (Smith and Townsend 1907) Young, Dye, Bradbury, Panagopoulos and Robbs 1978, 156.)
tu.me.fa' ci.ens. L. n. *tumor* a swelling tumor; L. v. *facere* to make, to produce; M.L. part. adj. *tumefaciens* tumor producing.

The characteristics are as described for the genus and as listed in Tables BXII.α.112 and BXII.α.113 in the chapter on the genus *Rhizobium*. Temperature optimal for growth 25–28°C and grows at 37°C. Grows in media containing 2% NaCl. Produces 3-ketolactose. Has no growth factor requirements. Utilizes a relatively wide range of organic substrates as sole sources of carbon (see Table BXII.α.113 in the chapter on the genus *Rhizobium*). The status of *A. tumefaciens* as an authentic species with the *Rhizobium* clade is supported by comparative 16S rDNA sequence analysis.

This species corresponds to biotype 1 of Keane et al. (1970), group I of White (1972), cluster 1 of Kersters et al. (1973), biovar 1 of Willems and Collins (1993) and of Sawada et al. (1993). *A. tumefaciens* comprises 3-ketolactose-positive, tumorigenic strains, as well as hairy root-forming

strains and nonpathogenic strains. It includes the type strain of *A. tumefaciens*, a tumorigenic strain, as well as the type strain of *A. radiobacter*, a nonpathogenic strain.

Ti or Ri plasmids determine the pathogenic status of strains. The species comprises pathogenic or nonpathogenic strains, which can be reported as tumorigenic, as a Ti strain or Ti, as rhizogenic as a Ri strain or Ri, or as nonpathogenic strains of the species where relevant. Pathogenic strains have a wide, and perhaps complex, host range.

An alternative special purpose nomenclature involves naming strains according to their pathogenic character, as *A. tumefaciens*, *A. rhizogenes*, or *A. radiobacter* for tumorigenic, rhizogenic and nonpathogenic strains, respectively, and classifying them as *Agrobacterium* biovar 1.

The epithet *tumefaciens* takes precedence in *Agrobacterium* because it is the designated type species of this genus.

The mol% G + C of the DNA is: 57–63 (T_m).

Type strain: ATCC 23308, DSM 30205, ICMP 5856, LMG 187, NCPPB 2437.

GenBank accession number (16S rRNA): D01256, D14500, M11223.

2. **Agrobacterium rhizogenes** (Riker, Banfield, Wright, Keitt and Sagen 1930) Conn 1942, 359[AL] emend. Sawada, Ieki, Oyaizu and Matsumoto 1993, 701 (*Bacterium rhizogenes* Riker, Banfield, Wright, Keitt and Sagen 1930, 536; *Agrobacterium radiobacter* biovar rhizogenes (Riker, Banfield, Wright, Keitt and Sagen 1930) Keane, Kerr and New 1970, 594; *Agrobacterium radiobacter* pathovar *rhizogenes* (Riker, Banfield, Wright, Keitt and Sagen 1930) Young, Dye, Bradbury, Panagopoulos and Robbs 1978, 156.)
rhi.zo'ge.nes. Gr. n. *rhiza* a root; Gr. v. *gennao* to make, to produce; M.L. adj. *rhizogenes* root-producing.

The characteristics are as described for the genus and as listed in Tables BXII.α.112 and BXII.α.113 in the chapter on the genus *Rhizobium.* Temperature optimal for growth 25–28°C. Does not grow at 35°C. Does not grow in media containing 2% NaCl. Does not produce 3-ketolactose. Requires biotin as a growth factor. Utilizes a relatively wide range of organic substrates as sole sources of carbon (Table BXII.α.113). The status of *A. rhizogenes* as an authentic species in the genus *Rhizobium* is supported by numerical analysis of nutritional and biochemical data and by comparative 16S rDNA sequence analysis.

This species corresponds to biotype 2 of Keane et al. (1970), group III of White (1972), and cluster 2 of Kersters et al. (1973). It comprises 3-ketolactose-negative, tumorigenic, rhizogenic, and nonpathogenic strains.

Ti or Ri plasmids determine the pathogenic status of strains. The species comprises pathogenic or nonpathogenic strains, which can be reported as tumorigenic, as a Ti strain or Ti, as rhizogenic as a Ri strain or Ri, or as nonpathogenic strains of the species where relevant. Pathogenic strains have a wide, and perhaps complex, host range.

An alternative special purpose nomenclature involves naming strains according to their pathogenic character, as *A. tumefaciens*, *A. rhizogenes*, or *A. radiobacter* for tumorigenic, rhizogenic, and nonpathogenic strains, respectively, and classifying them as *Agrobacterium* biovar 2.

The mol% G + C of the DNA is: 59–63 (T_m).

Type strain: ATCC 11325, DSM 30148, ICMP 5794, IFO 13257, LMG 150, NCPPB 2991.

GenBank accession number (16S rRNA): D01257, D14501.

3. **Agrobacterium rubi** (Hildebrand 1940) Starr and Weiss 1943, 316[AL] (*Phytomonas rubi* Hildebrand 1940, 694.)
ru'bi. L. n. *Rubus* generic name of blackberry; L. gen. n. *rubi* of *Rubus*

The characteristics are as described for the genus and as listed in Table BXII.α.112 in the chapter on the genus *Rhizobium.* Temperature optimal for growth 25–28°C. Does not grow at 35°C (Sawada and Ieki, 1992b); grows at 37°C (Kerr, 1992). Does not grow in media containing 2% NaCl. Does not produce 3-ketolactose. Growth rate on ordinary media is characteristically slower than for the other species. Requires L-glutamic acid, biotin, pantothenate, and nicotinic acid (present in yeast extract) as growth factors. The status of *A. rubi* as an authentic species is supported by numerical analysis of nutritional and biochemical data and by comparative 16S rDNA sequence analysis.

So far, pathogenic strains of this species have been reported only from *Rubus* spp.

Tumorigenic strains bearing Ti plasmids determine the pathogenic status of strains. Isolated from aboveground cane galls on *Rubus* spp. (black raspberry, boysenberry). The natural host range is apparently limited to *Rubus* spp., but artificial inoculations indicate a wider host range (Anderson and Moore, 1979).

The mol% G + C of the DNA is: 57.6–58.8 (T_m).

Type strain: ATCC 13335, CFBP 1317, ICMP 6428, IFO 13261, LMG 156, NCPPB 1854.

GenBank accession number (16S rRNA): D14503, X67228.

4. **Agrobacterium vitis** Ophel and Kerr 1990, 240[VP]
vi'tis. L. fem. n. *vitis* wine plant; L. gen. fem. n. *vitis* of the wine plant.

The characteristics are as described for the genus and as listed in Tables BXII.α.112 and BXII.α.113 in the chapter on the genus *Rhizobium.* Temperature optimal for growth 25–28°C. Does not grow at 35°C. Grows in medium containing 2% NaCl. Does not produce 3-ketolactose. Strains require biotin for growth. Produces acid from adonitol and mannitol, but not from alpha-methyl-D-glucoside, erythritol, dulcitol, melezitose, or arabitol. Utilizes relatively few organic substrates as sole sources of carbon (Table BXII.α.113).

The status of *A. vitis* as an authentic species is supported by numerical analysis of nutritional and biochemical data and by comparative 16S rDNA sequence analysis. The species comprises strains previously referred to as *Agrobacterium* biovar 3 *sensu* Kerr and Panagopoulos (1977) as described by Süle (1978) and Panagopoulos et al. (1978). *A. vitis* strains have been isolated from grapevines in many countries including Greece and Hungary (Panagopoulos et al., 1978), People's Republic of China (Ma et al., 1985), Australia (Ophel and Kerr, 1990), Japan (Sawada et al., 1990), France, Germany, and the United States (Otten et al., 1996), Korea, and, to date, the geographic distribution of the pathogen has reflected that of the host. Many strains of this species display a limited host range. So far, pathogenic strains of this species have been reported largely from *Vitis*

spp. although Sawada and Ieki (1992a) report an *A. vitis* strain (as biovar 3) from *Actinidia*.

Ti plasmids determine the pathogenic status of strains. The species comprises pathogenic or nonpathogenic strains, which can be reported as tumorigenic, as Ti strain or Ti, or nonpathogenic strains of the species where relevant. Strains are generally isolated from *Vitis* spp. grape, but they have occasionally been isolated from other dicotyledonous plant species.

The mol% G + C of the DNA is: 59 (T_m).

Type strain: ATCC 49767, ICMP 10752, LMG 8750, NCPPB 3554.

GenBank accession number (16S rRNA): D01258, D14502, U45329, X67225.

Other Organisms

A small group of yellow-pigmented, 3-ketolactose-positive bacteria, including *"Chromobacterium folium"* (*"Chromobacterium lividum"*) strains NCTC 10590 and 10591, that were considered to constitute another distinct group of agrobacteria (Holmes and Roberts, 1981) have since been classified as *Sphingomonas yanoikuyae* (Takeuchi et al., 1995).

Marine, star-shaped, aggregate-forming bacteria named *A. ferrugineum* Ahrens and Rheinheimer 1967, *A. gelatinovorans* Ahrens 1968 (as *A. gelatinovorum*), and *A. stellulatum* Stapp and Knösel 1954 were not included in the Approved Lists. However, Rüger and Höfle (1992) reported phenotypic and genotypic data which did "not definitely support exclusion of marine strains from *Agrobacterium*." As an *ex tempore* measure they proposed these species, together with *A. atlanticum* Rüger and Höfle 1992 and *A. meteori* Rüger and Höfle 1992, as members of the genus *Agrobacterium*.

A comparative analysis of 16S rDNA sequence data has shown the marine *Agrobacterium* spp. to cluster in two subdivisions in the *Alphaproteobacteria*. *A. stellulatum* and *"A. kieliense"* were in the "alpha-2" subdivision, but were more distant from *Rhizobium* than genera of the *Bartonellaceae*, *Brucellaceae*, and *Phyllobacteriaceae*. *A. meteori*, *A. atlanticum*, *A. ferrugineum*, and *A. gelatinovorans* were in the "alpha-3" subdivision (Uchino et al., 1997). Following a reinvestigation of phenotypic characters and of inferred phylogenies based on comparative analyses of 16S rDNA sequences, Uchino et al. (1998) allocated the marine agrobacteria as follows: *Ruegeria atlantica* (Rüger and Höfle 1992) Uchino et al. 1999^{VP} (syn: *Agrobacterium meteori* Rüger and Höfle 1992), *Ruegeria gelatinovorans* (Rüger and Höfle 1992) Uchino et al. 1999 (as *R. gelatinovora*^{VP}), *Stappia stellulata* (Rüger and Höfle 1992) Uchino et al. 1999^{VP}. *Agrobacterium ferrugineum* is a member of an unidentified genus in the alpha-3 sub-group of the *Proteobacteria*.

An unnamed *Agrobacterium* species has been reported from *Ficus benjamina* (Bouzar et al., 1995). Identity as a new species is based on the presence of a unique 16S rRNA domain, on differences in nutritional profiles, and on an unusual opine metabolism. Tumorigenic and nonpathogenic strains have been isolated.

Genus III. **Allorhizobium** *de Lajudie, Laurent-Fulele, Willems, Torck, Coopman, Collins, Kersters, Dreyfus and Gillis 1998a, 1288*^{VP}*

L. David Kuykendall and Frank B. Dazzo

Al.lo.rhi.zo' bi.um. Gr. adj. *allos* other; M.L. neut. n. *Rhizobium* a bacterial generic name; M.L. neut. n. *Allorhizobium* the other *Rhizobium*, to refer to the fact that it is phylogenetically separate from other *Rhizobium* species.

Rods 0.5–0.7 × 2.0–4.0 µm. Nonsporeforming. Gram negative. Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. **Relatively fast growing**; colonies 0.5–3.0 mm develop in 1–2 days on yeast–mannitol–mineral salts agar, and pronounced turbidity develops after 1–2 days in agitated broth media. Chemoorganotrophic. **A wide range of carbohydrates, organic acids, and amino acids are used as sole carbon sources for growth. Ketolactose is not produced from lactose. Growth on carbohydrate media is usually accompanied by extracellular polysaccharide production.** At the molecular level, the genus can be distinguished from related species in other genera by SDS-PAGE whole cell protein analysis, ITS PCR-RFLP, and 16S rRNA gene sequencing. **Initiates the production of root nodules, in which the bacteria occur as nitrogen-fixing intracellular symbionts.** Exhibits specificity to certain temperate-zone and tropical-zone leguminous plants (family Leguminoseae).

The mol% G + C of the DNA is: 60.1.

Type species: **Allorhizobium undicola** De Lajudie, Laurent-Fulele, Willems, Torck, Coopman, Collins, Kersters, Dreyfus and Gillis 1998a, 1288.

Further descriptive information

Like most legume-nodulating bacteria, these organisms are Gram-negative rods but, compared with most of the fast-growing *Rhizobium*, bacteria isolated from nodules of *Neptunia natans* growing in India are even faster growing, developing approximately 2 mm colonies in 2 d on yeast mannitol agar (Vincent, 1970). Colonies are beige, round, creamy, and smooth; like most *Rhizobium* species, this organism, motile in liquid medium, also produces copious slime, which is composed of extracellular polysaccharides (de Lajudie et al., 1998a). Utilizes a wide range of carbohydrates, organic acids, and amino acids for carbon and energy sources (see Table BXII.α.113 in the chapter on the genus *Rhizobium*).

In the aquatic environment, symbiotic infection of *Neptunia* occurs by wound or "crack" entry, rather than via root hairs, followed by formation of infection threads that penetrate host nodule cells and release the endosymbionts (Subbao-Rao et al., 1995). Thus, nodules are formed at the base of lateral and adventitious roots, wherein the bacteria occur as intracellular symbionts that fix N_2.

**Editorial Note:* Young et al. (2001) have proposed the transfer of the type and only species of *Allorhizobium*, *A. undicola*, to the genus *Rhizobium*.

This species exhibits host specificity, since no isolates have been found which can nodulate *Sesbania rostrata*, *Sesbania pubescens*, *Sesbania grandiflora*, *Vigna ungiuculata*, or *Macroptilium atrpurpureum* (de Lajudie et al., 1998a). This species forms nodules on the temperate-zone *Medicago sativa* (alfalfa) and a number of tropical-zone (*Neptunia natans*, *Acacia senegal*, *Acacia seyal*, *Acacia tortilis* subsp. *radiana*, *Lotus arabicus*, *Faidherbia albida*) leguminous plants of the family Leguminoseae (Subbao-Rao et al., 1995; de Lajudie et al., 1998a).

Enrichment and Isolation Procedures

This organism can be isolated from fresh nodules. A sample of water or soil can be used to inoculate seeds of the host plant *Neptunia natans* that have been surface-sterilized and scarified with concentrated sulfuric acid for about 5 min, followed by several rinses with sterile water. Plants are grown aseptically, so that uninoculated controls are devoid of nodules. Fahraeus plant growth medium is recommended (Fåhraeus, 1957). Nodules formed are surface sterilized in 50% Clorox for a few minutes, followed by several sterile water rinses. The contents of squashed nodules can be streaked on YEM for isolation.

Maintenance Procedures

Lyophilized cultures stored at 4°C are recommended.

Differentiation of the genus *Allorhizobium* from other genera

See Table BXII.α.112 in the chapter on the genus *Rhizobium*. Apart from phenotypic characters that distinguish *Allorhizobium undicola* as an individual species, there are no common distinct characters that differentiate *Allorhizobium* from members of the genus *Rhizobium*, *Agrobacterium*, or *Sinorhizobium*.

Taxonomic Comments

Inferred phylogenies based on comparative analyses of 16S rDNA sequence data show that *Allorhizobium undicola* is intermingled with fast-growing *Rhizobium* spp. and plant pathogenic *Agrobacterium* spp. (Young et al., 2001). Further, the circumscription of the genus does not delineate a taxon distinct from *Rhizobium* (Young et al., 2001). *Allorhizobium* is a monospecific genus established because—as indicated by its name—the data for *Allorhizobium undicola* represented an outlying branch in the particular comparative analysis of 16S rDNA sequence data (de Lajudie et al., 1998a). The closest neighboring species in this analysis is *Rhizobium vitis* (formerly *Agrobacterium vitis*). Comparison of this analysis with others that have been published (Sawada et al., 1993; Willems and Collins, 1993; de Lajudie et al., 1994, 1998b, a; Nour et al., 1995; Rome et al., 1996; Amarger et al., 1997; Chen et al., 1997b; Jarvis et al., 1997; Tan et al., 1997; van Berkum et al., 1998; Wang et al., 1998) and with Fig. BXII.α.130 of the chapter on the genus *Rhizobium* shows how much results can vary depending on the selection of sequences and upon the form of analysis. The species *R. undicola* is well defined based on DNA–DNA reassociation, PAGE of total proteins, and carbon source utilization tests. Further taxonomic comments are given in the chapter on the genus *Rhizobium*.

List of species of the genus Allorhizobium

1. **Allorhizobium undicola** De Lajudie, Laurent-Fulele, Willems, Torck, Coopman, Collins, Kersters, Dreyfus and Gillis 1998a, 1288.
   un.di' co.la. L. n. *unda* water; L. n. *cola* dweller; M.L. n. *undicola* water dweller, referring to the isolation of these strains from nodules of the aquatic plant *Neptunia natans*.

   The characteristics are as described for the genus and listed in Tables BXII.α.112 and BXII.α.113 in the chapter on the genus *Rhizobium*. Exhibits specificity to some temperate-zone (*Medicago sativa*) and some tropical-zone (*Neptunia natans*, *Acacia senegal*, *Acacia seyal*, *Acacia tortilis* subsp. *raddiana*, *Lotus arabicus*, *Faidherbia albida*) leguminous plants (family Leguminoseae) and incites the production of root nodules wherein the bacteria occur as intracellular symbionts. No strain has been found to nodulate *Sesbania rostrata*, *Sesbania pubescens*, *Sesbania grandiflora*, *Vigna unguiculata*, or *Macroptilium atropurpureum*. Wound or crack-entry infection of *Neptunia* occurs, rather than infection via root hairs in the aquatic environment. The closest relative is *Agrobacterium vitis* (96.2% 16S ribosomal RNA similarity).

   The mol% G + C of the DNA is: 60.1 (T_m).
   Type strain: ORS 992, LMG 11875.
   GenBank accession number (16S rRNA): Y17047.

Genus IV. **Carbophilus** *Meyer, Stackebrandt and Auling 1994, 182[VP] (Effective publication: Meyer, Stackebrandt and Auling 1993, 393)*

Ortwin O. Meyer

car.bo.phi' lus. L. masc. *carbo* carbon; M.L. part. *philus* loving, loving carbohydrates and other carbonaceous substrates.

Rod-shaped cells with slightly tapered ends, 0.7–0.9 × 0.9–1.7 μm. Motility variable; when present, it is by means of up to five peritrichous flagella. Flagellation is maximal in the late exponential growth phase, when more than 80% of the cells are flagellated. Formation of aggregates is rare. **Gram negative.** Colonies are white to cream colored. Organic growth factors are not required. **Aerobic**, having a strictly respiratory type of metabolism, with oxygen as the terminal electron acceptor. Neither denitrification nor reduction of nitrate to nitrite has yet been observed. **Facultatively chemolithoautotrophic**. CO is utilized as a substrate under aerobic chemolithoautrophic conditions. Chemoorganoheterotrophic substrates encompass a wide variety of the salts of organic acids (except citrate), amino acids, sugars, and sugar alcohols (see Table 1 of Meyer et al., 1993). Suitable nitrogen sources are ammonia, hydroxylamine, nitrate, and urea (Frunzke and Meyer, 1990). Dinitrogen is not fixed. Not phototrophic. Not methanogenic. Isolated from soil at the city of Moscow (Russia).

The mol% G + C of the DNA is: 62.8 (T_m).

Type species: **Carbophilus carboxidus** (ex Nozhevnikova and

Zavarzin 1974) Meyer, Stackebrandt and Auling 1994, 182 (Effective publication: Meyer, Stackebrandt and Auling 1993, 393.)

Further descriptive information

CO-oxidizing *Carbophilus carboxidus* grows with CO as energy source and CO_2 as carbon source under aerobic chemolithoautotrophic conditions, with a generation time of about 40 h (Cypionka et al., 1980). *C. carboxidus* is an exception among the aerobic CO-oxidizing bacteria in that strains capable of growing at the expense of H_2 plus CO_2 are not known. The electron transport system of *C. carboxidus* contains *b*-, *c*-, and *a*-type cytochromes at levels similar to those of other aerobic, respiratory bacteria (Cypionka and Meyer, 1983b). The *o*-type cytochrome b_{536} serves as alternative CO-insensitive terminal oxidase.

C. carboxidus contains the megaplasmids pHCG1-a (558 kb), pHCG1-b (428 kb), and pHCG1-c (129 kb) (Kraut and Meyer, 1988). The structural genes for CO dehydrogenase (*coxLMS*) and ribulosebisphopshate carboxylase (*cbbL*) are plasmid encoded (Kraut et al., 1989).

For appropriate media, cultivation and growth conditions, type of CO dehydrogenase, and enrichment and isolation procedures, refer to the genus *Oligotropha*.

Differentiation of the genus *Carbophilus* from other genera

The ability to utilize CO under aerobic chemolithoautotrophic conditions occurs only in the genera *Carbophilus*, *Oligotropha*, *Bradyrhizobium*, and *Zavarzinia*. A property that separates *Carbophilus carboxidus* from all other aerobic carboxidotrophic bacteria is its inability to grow chemolithoautotrophically on H_2 and CO_2. The genus *Carbophilus* can be differentiated from *Oligotropha* and *Zavarzinia* by its peritrichous flagellation, the wide variety of organic substrates utilized, particularly sugars, and a different profile of fatty acids and polyamines (see Table 1 of Meyer et al., 1993). *C. carboxidus* does not fix N_2. *Carbophilus* is differentiated from *Nitrobacter* by the inability to utilize ammonium as an energy source for chemolithoautotrophic growth. It is differentiated from *Agrobacterium* by not being infectious to plants.

Taxonomic Comments

The genus *Carbophilus* with the single species *C. carboxidus* has been allocated to the class *Alphaproteobacteria* in the phylum *Proteobacteria* (Fig. BXII.α.185 in the genus *Oligotropha*) on the basis of 16S ribosomal RNA cataloging, the presence of signature oligonucleotides in 16S rRNA catalogues (see Table 5 of Auling et al., 1988), the presence of ubiquinone Q-10 as the major quinone (see Table 3 of Auling et al., 1988), the presence of *sym*-homospermidine and putrescine as the major polyamines (see Table 4 of Auling et al., 1988), and the presence of *cis*-11,12-octadecenoic acid as the main fatty acid and 11-methyl-*cis*-11,12-octadecenoic acid as diagnostic fatty acid (see Table 3 of Auling et al., 1988). The position of *Carbophilus* is in an individual line of descent within the *Alphaproteobacteria* together with the nitrilotriacetic acid utilizing members of the genus *Chelatobacter* (Meyer et al., 1993). The 16S rRNA similarity coefficient of 0.78 separating these two taxa is lower than those found to delineate phenotypically well-described and phylogenetically coherent genera, such as *Bradyrhizobium*, *Rhizobium*, or *Nitrobacter* (Meyer et al., 1993).

List of species of the genus Carbophilus

1. **Carbophilus carboxidus** (ex Nozhevnikova and Zavarzin 1974) Meyer, Stackebrandt and Auling 1994, 182[VP] (Effective publication: Meyer, Stackebrandt and Auling 1993, 390.)

car.box′ idus. L. n. connected with carbon oxides.

The description is as given for the genus. The strain carboxydobacterium Z-1171 was isolated from soil near a stream at Neskuchny Garden, city of Moscow, Russia; it was originally described as *"Achromobacter carboxydus"* and later as *"Alcaligenes carboxydus"* (Nozhevnikova and Zavarzin, 1974; Zavarzin and Nozhevnikova, 1976, 1977; Zavarzin, 1978; Cypionka et al., 1980; Meyer and Schlegel, 1983).

The mol% G + C of the DNA is: 62.8 (T_m).

Type strain: ATCC 51424, CIP 105722, DSM 1086, Z-1171.

Genus V. **Chelatobacter** *Auling, Busse, Egli, El-Banna and Stackebrandt 1993b, 624[VP]* *(Effective publication: Auling, Busse, Egli, El-Banna and Stackebrandt 1993a, 109)*

Thomas W. Egli and Georg Auling

Che.la′ to.bac.ter. Gr. n. *chele* claw; M.L. v. *chelato* to form claw-like complexes with divalent cations, i.e., to chelate; M.L. masc. n. *bacter* equivalent of Gr. neut. n. *bakterion* rod or staff; M.L. masc. n. *Chelatobacter* chelating rod.

Rods 0.7–0.9 × 1–2 µm, often pleomorphic and budding. L-, Y-, and X-shaped forms occur. Gram negative. **Motile, usually by two or three subpolar flagella. Obligately aerobic.** Optimal growth temperature, 28–30°C; no growth at 41°C and 4°C. Slow growers with all substrates tested so far (μ_{max} <0.25 h^{-1}). Poly-β-hydroxybutyrate is accumulated. All strains are sensitive to β-lactam antibiotics but resistant to nalidixic acid. **The metal-chelating aminopolycarboxylic acid nitrilotriacetic acid (NTA) can be utilized as a sole source of carbon/energy and nitrogen.** A great variety of sugars, acids, alcohols, and methylated amines are utilized. Vitamins are not required. Ubiquinone Q-10 is present. The main polyamine present is *sym*-homospermidine; putrescine and spermidine occur as major polyamines and spermine as a minor polyamine.

The mol% G + C of the DNA is: 62–63.

Type species: **Chelatobacter heintzii** Auling, Busse, Egli, El-Banna and Stackebrandt 1993b, 624 (Effective publication: Auling, Busse, Egli, El-Banna and Stackebrandt 1993a, 110.)

Further descriptive information

Cell morphology All the strains isolated so far are of similar morphology, although they differ slightly with respect to their physiological properties (Egli et al., 1988). Generally the cells are motile, usually by two to three subpolar flagella (Fig. BXII.α.131a); however, for one strain (TE 10) peritrichously flag-

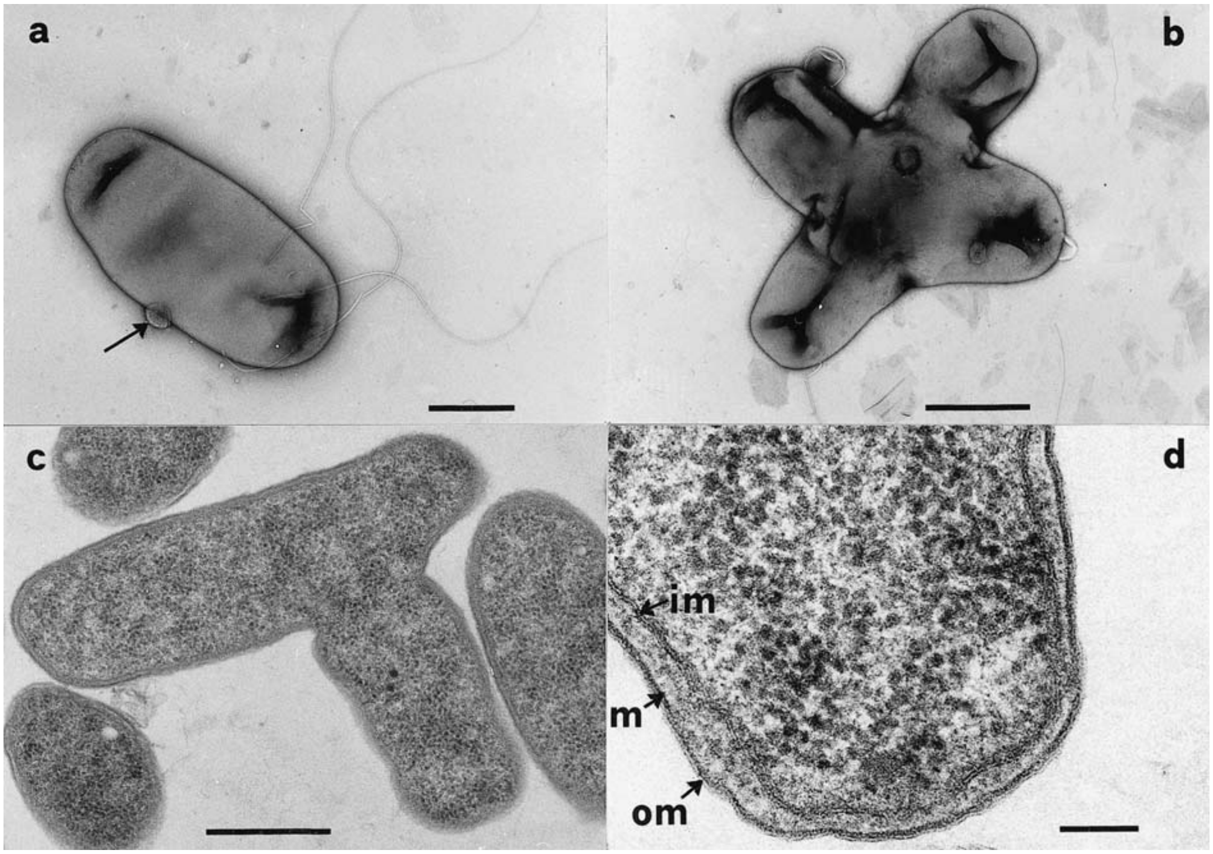

FIGURE BXII.α.131. Electron micrographs of *Chelatobacter heintzii* strains. (*a*), negatively stained cell of isolate TE 8 with the subpolar location of flagella and the initiation of cell budding (*arrow*). Bar = 0.5 μm. (*b*), negatively stained cell of isolate TE 8 demonstrating pleomorphism. Bar = 0.5 μm. (*c*), thin-sectioned cells of isolate TE 7 exhibiting pleomorphism. Bar = 0.5 μm. (*d*), higher magnification of thin-sectioned cell of isolate TE 6 demonstrating the Gram-negative cell wall with inner membrane (*im*), murein layer (*m*), and outer membrane (*om*), Bar = 0.1 μm.

ellated cells were also observed (Wehrli and Egli, 1988). The proportion of cells that are motile depends on the growth phase and substrate. In addition to cells dividing normally by binary fission, L-, Y-, and X-shaped cells are frequently detected in thin-sectioned, freeze-fractured, and negatively stained preparations (Fig. BXII.α.131b, c). In addition, bud-like structures are often observed where growth of daughter cells is obviously initiated (Fig. BXII.α.131a, b). The significance of this pleomorphism and whether or not it is dependent on nutritional or particular environmental conditions is still unknown; however, it does not result from growth with the metal-chelating compound NTA because pleomorphic cells are also observed during growth in complex media.

All isolates exhibit a peptidoglycan layer of 4–6 nm thickness (Wehrli and Egli, 1988) and an outer membrane (Fig. BXII.α.131d). The outer membrane is always closely associated with the underlying murein layer, and this is probably the reason why in freeze-fractured cells breakage occurs exclusively at the inner membrane and not at the outer membrane as well, as has been observed with most other Gram-negative bacteria (Wehrli and Egli, 1988).

Colony morphology Strains that grew well on Plate Count Agar (PCA, from Difco, Detroit, MI) exhibited round and smooth, beige-brown colonies that had a diameter of 2–3 mm after 4–5 days of growth. However, most of the strains grew faster and reliably on 0.2 × PCA broth solidified with 1.5% agar (see below), and on this medium the colonies of all isolates were similar: round, light-beige, slightly translucent and small in size (1.0–1.5 mm in diameter after 4–5 days). The colonies were round and volcano- or sometimes fried-egg-like, frequently with one or two concentric rings (Fig. BXII.α.132a, b, c, e). Colonies grown on NTA-containing media were white, tough, and pinpoint in size at the early stages of development (Fig. BXII.α.132b, viewed with a stereo-microscope with incident light); later a brown center developed and finally (4–5 days after streaking out) the whole colony turned black and polygonal as shown in Fig. BXII.α.132d (viewed with transmitted light).

Cultural characteristics The chemically defined medium (SM) used for isolation of *Chelatobacter heintzii* strains in both batch and chemostat culture (Egli et al., 1988; Egli and Weilenmann, 1989) contained (g/l distilled water): $MgSO_4 \cdot 7H_2O$, 1.0 g; $CaCl_2 \cdot 2H_2O$, 0.2 g; $Na_2HPO_4 \cdot 2H_2O$, 0.41 g; KH_2PO_4, 0.26 g; 1 ml of the trace element stock solution described by Pfennig et al. (1981) with NTA as the chelating agent (5.2 g/l); and 1 ml of a vitamin stock solution. The vitamin solution contains (per liter): pyridoxine·HCl, 100 mg; thiamine·HCl, riboflavin, nicotinic acid, D-calcium pantothenate, *p*-amino benzoic acid, lipoic acid, nicotinamide, and vitamin B_{12}, 50 mg each; biotin, 20 mg; and folic acid, 20 mg. This medium was supplemented with either NTA or other carbon and/or nitrogen sources (up to a maximum of 5 g/l carbon). For growth with carbon sources that contained no nitrogen, the SM was supplemented with NH_4Cl, 0.54 g/l.

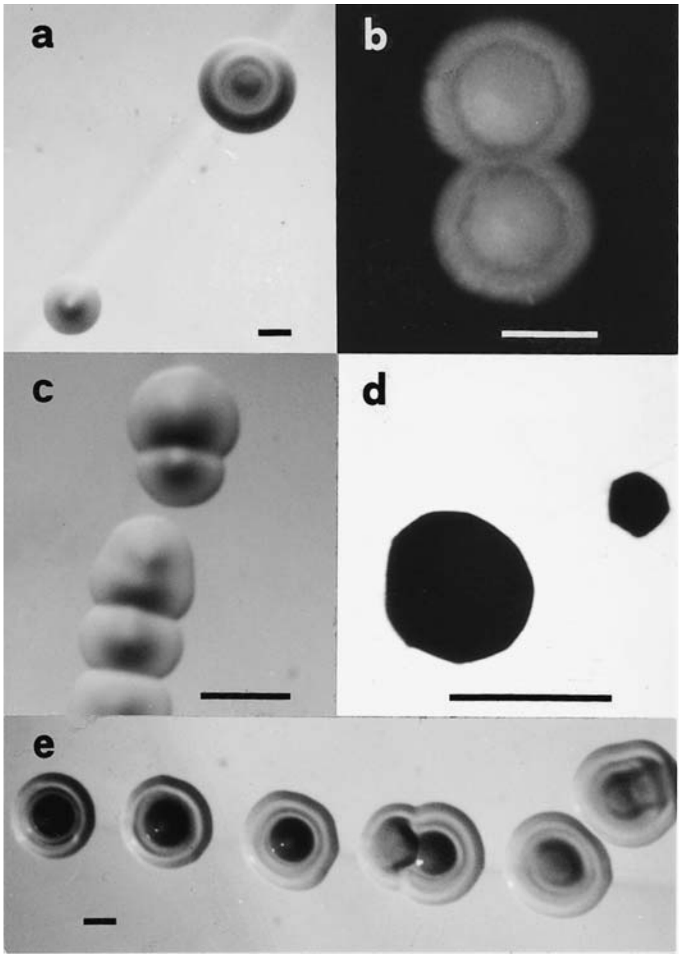

FIGURE BXII.α.132. Morphology of *Chelatobacter heintzii* colonies. (*a*), PCA-grown strain TE 8. (*b*), NTA-grown strain TE 8. (*c*), PCA-grown strain TE 9. (*d*), colony of NTA-grown strain TE 9 after 7 days, note the polygonal shape of the colonies. (*e*), colonies of PCA-grown strain TE 4. Bars = 0.5 mm.

For isolation and growth on agar plates this medium is supplemented with 1.5% agar plus NTA (0.5 g/l). For isolation, and in early experiments, vitamins were included in the medium, but later it was found that for growth of all strains of *Chelatobacter heintzii*, vitamins can be omitted.

Growth characteristics Isolates differed with respect to their growth on media containing high nutrient concentrations. Most of the strains grew poorly and only after heavy inoculation on PCA plates of the original concentration. However, faster growth occurred on diluted (10–20% of the original concentration) PCA medium broth amended with 1.5% agar, although the colonies obtained were smaller.

Growth in batch culture with NTA as the only carbon/energy and nitrogen source results in the excretion of ammonia, causing an increase in pH of the culture medium. Under such conditions growth ceases at approximately pH 9 and, after transfer into new medium, the cells exhibit extended lag phases (often 5–10 d) until growth resumes. Growth with mixtures of utilizable carbon sources plus NTA resulted in a simultaneous utilization of the two substrates and in faster growth than with NTA alone. For example, during simultaneous utilization of glucose plus NTA, a maximum specific growth rate of 0.17 h^{-1} was reported for strain TE 8 compared to 0.11 h^{-1} during growth with NTA alone (Table BXII.α.115).

Nutritional and physiological characteristics The nutritional and physiological characteristics of different strains of *Chelatobacter heintzii* are listed in Table BXII.α.116. All strains utilized acetate, benzoate, citrate, glycollate, lactate, malate, propionate, pyruvate, succinate, *n*-butanol, ethanol, glycerol, *iso*-propanol, *n*-propanol; the sugars *N*-acetylglucosamine, arabinose, D-cellobiose, esculin, D-fructose, galactose, gentiobiose, D-glucose, inositol, D-maltose, mannitol, D-mannose, rhamnose, D-ribose, D-sorbitol, sucrose, D-xylose, L-alanine, L-arginine, L-aspartate, L-glutamate, L-glycine, L-lysine, L-phenylalanine, L-proline, L-serine, and acetamide. No strain grew with: adonitol, aniline, arabitol, dimethyl formamide, dimethyl sulfoxide, erythritol, [S,S]-ethylene diamine disuccinate, formate, gluconate, N-(2-acetamido)-iminodiacetate, D-lactose, malonate, methane, methanol, methyl acetamide, methyl diethyl amine, *n*-decane, oxalate, phenol, tetraethyl ammonium chloride, triethanol amine, tris-hydroxymethyl amino methane, urea, xylene, and H_2/CO_2.

In addition, none of the strains produced gas from glucose, indole or H_2S, was able to ferment sugars, to hydrolyze DNA, to fix N_2, to denitrify with NTA or with glucose, to produce acid from glucose or ethanol, to grow on mannitol (*Rhizobium*) agar, or was acid fast. For all strains, growth was slightly affected by the presence of 1% NaCl and no growth occurred with 10% NaCl.

Metabolism and metabolic pathways A key nutritional feature of members of the genus *Chelatobacter* is their ability to grow with the chelating agent NTA as the only source of carbon, energy and nitrogen. The biochemistry of NTA utilization has been studied mainly in *Chelatobacter heintzii* ATCC 29600 (Egli, 1994) and is shown in Fig. BXII.α.133. After transport into the cell, two enzymatic steps are sufficient to transform NTA into the central metabolites glycine and glyoxylate. Transport of NTA is most probably energy-dependent (summarized in Bucheli-Witschel and Egli, 2001). Recently, it was suggested that free NTA (and not a metal-NTA complex) is the form that is transported (Bolton et al., 1996). This implies that the equilibrium between free NTA and metal-complexed NTA will be crucial for the transport of

TABLE BXII.α.115. Maximum specific growth rate of three NTA-utilizing strains during batch growth with various substrate combinations[a,b]

Substrate	*Chelatobacter heintzii* TE 8	*Chelatobacter heintzii* TE 9	*Chelatococcus asaccharovorans* TE 1
NTA	0.11	0.1	0.07
NTA/acetate	0.15	0.13	0.13
NTA/glucose	0.17	0.13	0.07
NH_4^+/acetate	0.19	0.23	0.12

[b]Growth rates (h^{-1}) measured at 30°C, pH 6.8–7.0, and substrate concentrations of 250 mg/l.

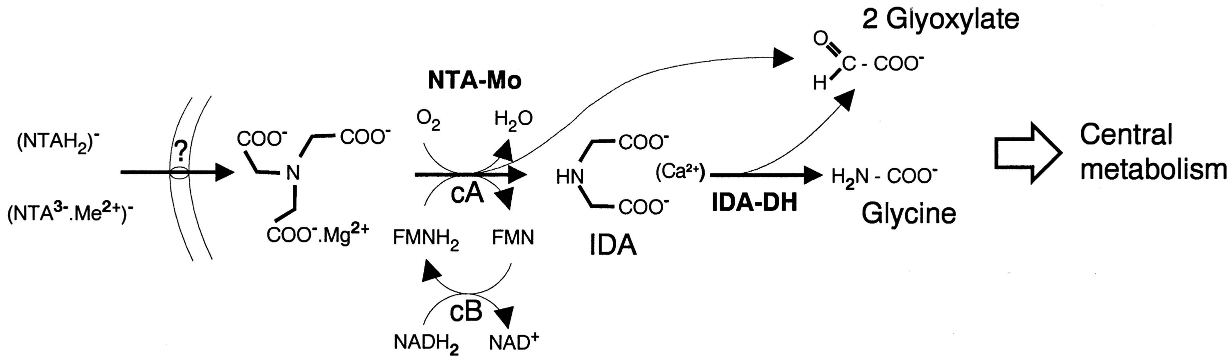

FIGURE BXII.α.133. Metabolic pathway for NTA in *Chelatobacter heintzii* ATCC 29600. *IDA*, membrane-bound iminodiacetate dehydrogenase; *NTA-Mo*, NTA monooxygenase, component A (*cA*) and B (*cB*), respectively. Note that the function of cB can be taken over by other FMN-reducing oxidoreductases.

this compound into the cell and that labile metal-NTA complexes should be degraded preferentially.

NTA monooxygenase The first intracellular step is catalyzed by a monooxygenase (NTA-Mo). NTA-Mo was originally isolated as a two component system, consisting of component cA and a FMN-containing protein cB with both components being present as dimers (Uetz et al., 1992). Immunological studies indicated that both cA and cB are present in all *Chelatobacter heintzii* strains tested so far (Table BXII.α.116; Uetz, 1992). It was demonstrated recently that cA acts as an independent monooxygenase whereas cB is supplying the enzyme with $FMNH_2$ and that FMN oxidoreductases from distantly related organisms and enzyme systems can supply cA with $FMNH_2$(Witschel et al., 1997). The substrate specificity of NTA-Mo is very narrow, so far NTA complexed with Mg^{2+} is the only compound that is known to be accepted (Uetz et al., 1992). Neither free NTA nor Ca^{2+}-complexed NTA is accepted as a substrate. Both components have been cloned and sequenced from *Chelatobacter heintzii* ATCC 29600 (see below).

Iminodiacetate dehydrogenase A membrane-bound iminodiacetate dehydrogenase (IDA-DH) which is present in all presently known NTA-degrading strains, was found to be the second enzyme in the catabolism of NTA (Uetz and Egli, 1993). The enzyme differs from succinate dehydrogenase and experiments with IDA-DH extracted from membranes and reconstituted in artificial membrane vesicles indicated that it feeds electrons abstracted from IDA into the electron transfer chain at the level of ubiquinone.

Regulation of NTA-degrading enzymes Recently, regulation of the ability to degrade NTA and the expression of NTA-Mo was studied under different growth conditions in carbon-limited continuous culture (Bally, 1994; Bally et al., 1994; Egli, 1995; Bally and Egli, 1996). NTA was consumed simultaneously with easily degradable carbon substrates such as, e.g., glucose and the extent of expression of NTA-Mo was dependent on the ratio of NTA:glucose in the feed medium (and, hence, the ratio of the two carbon sources consumed by the cell). Significant expression of NTA-Mo was only observed when the contribution of NTA to the total carbon consumed by the culture was higher than 1%. The experiments indicate that in wastewater treatment plants or the natural environment, NTA-degrading bacterial cells are probably not growing with NTA as a single carbon source but with mixtures of NTA plus naturally available carbon substrates, and that NTA-degrading enzymes are probably rarely fully induced under environmental growth conditions. These results are supported by studies from real and model wastewater treatment plants (Bally, 1994) showing that in plants receiving more than 1% of their organic carbon as NTA, both components of NTA-Mo were expressed, whereas in plants receiving only little NTA it was not detectable. Nevertheless, in both systems the fraction of NTA-degrading cells (as assessed with cell surface antibodies) was similar, indicating that under such conditions probably the induction of the catabolic enzymes was more responsible for successful degradation of NTA than the enrichment of NTA-degrading bacterial cells (Egli, 1995).

Genetics With regard to catabolic genes, in *Chelatobacter heintzii* ATCC 29600 the genes for the components cA and cB of NTA-Mo (see above) have been cloned and sequenced recently (Knobel et al., 1996). Two open reading frames (most probably chromosomally encoded) oriented divergently with an intergenic region of 307 bp could be assigned to the two components. The deduced gene products of *ntaA* showed significant homology only to SoxA (involved in dibenzothiphene degradation) and SnaA (involved in pristamycin synthesis), whereas that of *ntaB* shared weak homology in one domain with other NADH:FMN oxidoreductases. Unfortunately, these homologies give no conclusive answer yet with respect to the possible evolutionary origin of NTA-Mo. Additionally, an open reading frame was found downstream of *ntaA* which shares considerable homology in the N-terminal region with the GntR class of bacterial regulator proteins and, therefore, may encode a regulatory protein involved in the regulation of *ntaA* and *ntaB* expression. This information was recently confirmed (Xu et al., 1997). Hybridization experiments with different gene probes from *Chelatobacter heintzii* ATCC 29600 indicate that *ntaA* is highly conserved in the different strains investigated so far (even in *Chelatococcus asaccharovorans*), whereas *ntaB* was not detected in all strains. This confirms the recent observation that probably any FMN-reducing oxidoreductase can supply FMNH to NTA-Mo, i.e., component A (Witschel et al., 1997; Xu et al., 1997).

Antigenic structure Polyclonal antibodies (α-*Cb* and α-*Cc*) have been raised against whole cells (El-Banna, 1989; Wilberg et al., 1993) and isolated cell walls (Bally, 1994) of NTA-utilizing *Chelatobacter* and *Chelatococcus* strains. In Ouchterlony double diffusion or indirect immunofluorescence tests, the antisera raised against the two central NTA-utilizing *Chelatobacter* strains, i.e., *Chelatobacter heintzii* strains TE 6 and ATCC 29600, did not cross-react with cell homogenates from both *Chelatococcus asaccharovorans* strains. Similarly, the antiserum raised against *Chelatococcus asaccharovorans* strain TE 2 did not cross-react with homogenates

TABLE BXII.α.116. Physiological properties of NTA-utilizing, obligately aerobic strains of *Chelatobacter heintzii* and *Chelatococcus asaccharovorans*[a,b,c]

[a]Symbols: +, positive result obtained with seven or more of the nine strains; (+), weakly positive result; −, negative result obtained with seven or more of the nine strains; d, three to six strains out of nine strains tested differed in their reaction (results of individual strains in Egli et al., 1988).

[b]Data from Egli et al. (1988) and Egli and Weilenmann (1989).

[c]Many of the tests were performed with both NTA-grown cells and cells grown on PCA plates.

[d] *Chelatobacter heintzii* strains TE 4–TE 10 and ATCC 27109 and ATCC 29600; *Chelatococcus asaccharovorans* strains TE 1 and TE 2. All strains were enriched in batch culture, except for *Chelatobacter heintzii* strain TE 4.

[e]Only cells grown on NTA-agar plates were positive; cells grown on PCA plates were negative.

[f]Test performed with API-20B.

[g]As in e, except for strain ATCC 27109 that gave positive results on NTA as well as PCA plates.

[h]TE 6 and ATCC 29600 were slightly positive.

[i]ATCC 29600 was positive, TE 4 and 9 were slightly positive.

[j]ATCC 29600 was positive.

[k]PCA-grown cells of strain TE 5 were negative.

[l]ATCC 27109 was negative.

[m]PCA-grown cells of strains TE 4–8 and 10 were weakly positive, those of strain TE 9 were negative.

[n]CA grown cells of TE 4 and 9 were negative.

[o]Results from Uetz (1992).

[p]TE 10 and ATCC 27109 were slightly positive.

[q]ATCC 27109 was positive.

[r]TE 4–8 were only slightly positive.

[s]+, formation of black colonies; −, no growth.

[t]TE 9 and ATCC 27109 were positive.

[u]TE 4 and TE 10 were negative.

[v]TE 10 and ATCC 29600 were negative.

[w]TE 9 and 10, ATCC 27109, and ATCC 29600 were weakly positive.

[x]TE 4 and 10 were negative.

[y]TE 4 was negative.

[z]ATCC 29600 was positive; TE 4 and TE 9 were slightly positive.

of the two central strains of *Chelatobacter heintzii* (Wilberg et al., 1993).

Cross-reaction of α-*Cb* was also tested with a variety of bacteria that were expected to co-exist with members of *Chelatobacter* in the same habitat. No cross reaction was observed for *Agrobacterium tumefaciens*, *Alcaligenes faecalis*, *Azotobacter chroococcum*, *Bradyrhizobium japonicum*, *Comamonas acidovorans*, *Comamonas testosteroni*, *Escherichia coli* ML30, *Klebsiella pneumoniae*, NTA-utilizing strain TE 11 (denitrifying), *Paracoccus denitrificans*, *Pseudomonas fluorescens*, *Pseudomonas putida*, *Rhizobium leguminosarum*, *Rhizobium meliloti* and *Rhodobacter* sp. (Wilberg et al., 1993). A slight cross-reaction was observed with *Carbophilus carboxidus* DSM 1086, *Aminobacter aminovorans* NCIB 9039, *Chelatobacter heintzii* strains TE 4 to TE 10, and *Ralstonia eutropha*. Highly specific antibodies were prepared from outer membrane fractions of *Chelatobacter heintzii* ATCC 29600 using a depletion method (Bally, 1994). The only bacteria still exhibiting significant cross-reaction with the purified antibodies were *Rhizobium phaseoli* and *Carbophilus carboxidus*.

Antibiotics and drug resistance The susceptibility of NTA-utilizing *Chelatobacter heintzii* and *Chelatococcus asaccharovorans* strains towards a range of antibiotics was tested (Auling et al., 1993a) and a summary of the results is provided in Table BXII.α.117. All *Chelatobacter heintzii* strains were resistant to nalidixic acid and sensitive towards penicillin G, ampicillin, carbenicillin, deoxycycline, vancomycin, and novobiocin. It has not yet been determined whether this extreme sensitivity towards β-lactam antibiotics is a property that allows the differentiation of *Chelatobacter* spp. from close neighbors. However, the resistance of all strains towards nalidixic acid might be used to isolate such strains with a medium amended with this antibiotic.

TABLE BXII.α.117. Resistance of *Chelatobacter heintzii* and *Chelatococcus asaccharovorans* towards a range of different antibiotics[a,b]

Antibiotics[c]	*Chelatobacter heintzii*[d]	*Chelatococcus asaccharovorans*[e]
β-Lactams:		
Penicillin G, 10U	S	S
Ampicillin, 10 μg	S	d
Carbenicillin, 100 μg	S	S
Cephaloridine, 30 μg	S	R
Cephalexin, 30 μg	d	R
Aminoglycosides:		
Streptomycin, 10 μg	d	R
Neomycin, 30 μg	S	S
Kanamycin, 30 μg	d	S
Gentamycin, 10 μg	S	S
Tobramycin, 10 μg	d	S
Other antibiotics:		
Tetracycline, 30 μg	S	S
Doxycycline, 30 μg	S	S
Erythromycin, 15 μg	S	S
Chloramphenicol, 30 μg	d	d
Rifampicin, 30 μg	S	S
Polymyxin B, 300 U	d	S
Novobiocin, 30 μg	S	S
Vancomycin, 30 μg	S	R
Nalidixic acid, 30 μg	R	R
Trimethoprim, 1.25 μg; + sulfamethoxazole, 23.75 μg	d	R

[a]Symbols: S, at least eight or all strains sensitive; R, at least eight or all strains resistant; d, strains differed in their reaction.

[b]Data from Auling et al. (1993a).

[c]Absolute amount of antibiotic used in test.

[d]Nine *Chelatobacter heintzii* strains were tested (TE 4 to 10, ATCC 27109, ATCC 29600).

[e]Two *Chelatococcus asaccharovorans* strain were tested (TE 1 and TE 2).

Ecology Data collected so far with surface antibodies (Wilberg et al., 1993; Bally, 1994) and 16S rRNA probes (Neef, 1997) indicate that members of the genus *Chelatobacter* are ubiquitously distributed in the environment. This is supported by the ready isolation of *Chelatobacter* strains from soil, sediment, surface and wastewater. Even in an environment with little chance of having ever been exposed to NTA, i.e., a small pristine alpine stream that contained no detectable NTA (<0.2 μg/l), cells cross-reacting with antibodies raised against *Chelatobacter heintzii* ATCC 29600 were detected at 1.2×10^5 cells per liter (corresponding to 0.27% of the total bacterial population) (Bally, 1994). In nutrient-rich environments such as eutrophic surface waters or wastewater treatment plants, the total number of cross-reacting cells generally increased by several orders of magnitude. For example, both Wilberg et al. (1993) and Bally (1994) reported numbers of NTA-degrading *Chelatobacter* cells in aerated tanks of several Swiss wastewater treatment plants in the range of 10^{10} cells/l (corresponding to 0.1–1% of the total bacterial population). Similar figures were recently reported using a molecular probe specific for the 16S rRNA of *Chelatobacter heintzii* ATCC 29600 (Neef, 1997).

Polyamines and ubiquinones All *Chelatobacter heintzii* strains contained *sym*-homospermidine as the main, putrescine and spermidine as major, and spermine as minor polyamine compounds (Auling et al., 1993a). Ubiquinone Q-10 was present in all strains. As it has been frequently stated that NTA is utilized by specialized pseudomonads, this polyamine and quinone profile allows *Chelatobacter heintzii* to be clearly distinguished from the true (fluorescent) *Pseudomonas* spp., which contain putrescine and spermidine as the main polyamines and ubiquinone Q-9 (Auling et al., 1991, 1993a).

Soluble protein patterns The soluble protein pattern for *Chelatobacter heintzii* has been compared to that of *Chelatococcus asaccharovorans* (Auling et al., 1993a). *Chelatobacter* and *Chelatococcus* strains exhibited clearly different patterns. Among the different *Chelatobacter* strains, the protein patterns were highly similar, except for two isolates (strains TE 4 and 7). Although the soluble protein patterns of strains TE 4 and 7 were virtually identical, the two strains differed considerably with respect to their nutritional and physiological properties (Egli et al., 1988).

Miscellaneous comments In the 1970s, eutrophication of surface waters by phosphorus from detergents and agriculture stimulated discussion about banning sodium tripolyphosphate (STPP) from laundry detergents and replacing it with nonphosphorus-containing metal-chelating agents such as aminopolycarboxylic acids (Mottola, 1974; Tiedje, 1980; Anderson et al., 1985). Aminopolycarboxylic acids are metal-sequestering compounds used in large amounts in a variety of domestic and industrial applications including cleaning agents, agricultural fertilizers, for water treatment and descaling of boilers, in the photographic industry, the dying of textiles, during pulp and paper production, for metal finishing and rubber processing, or in food, pharmaceuticals, and cosmetics (McCrary and Howard, 1979; Egli, 1988; Egli et al., 1990). Aminopolycarboxylic acids include both man-made (e.g., ethylenediaminetetraacetic acid [EDTA] and nitrilotriacetic acid [NTA]) and microbially synthesized (e.g., *S,S*-ethylenediaminedisuccinic acid) compounds. The most extensively used synthetic chelating agents are EDTA and NTA. All applications are water based and therefore their susceptibility to biodegradation during wastewater treatment and in the aquatic environment is an important criterion for assessing their environmental impact and toxicity (Anderson et al., 1985). Of all the synthetic chelating agents, NTA and EDTA have received the most attention, NTA because of its controversial application in laundry detergents as a substitute for sodium tripolyphosphate, and EDTA because of its slow biodegradability and its ubiquitous presence in aqueous systems (Tiedje, 1980; Wolf and Gilbert, 1992).

It was soon established that elimination of NTA, one of the most promising substitutes for STPP, from wastewater and natural waters was exclusively brought about by microbial action. This was the motivation for setting up the first enrichment cultures to isolate NTA-degrading microorganisms (Focht and Joseph, 1971; Cripps and Noble, 1973; Enfors and Molin, 1973a, b; Tiedje et al., 1973; Kakii et al., 1986). Most of these isolates were identified based on rather superficial characterization and assigned to the genus *Pseudomonas*, although the isolation of NTA-utilizing nonpseudomonads was also reported (Egli et al., 1990). However, with the exception of the two strains deposited at the ATCC (strains ATCC 29600 and 27109), none of these isolates seems to be available anymore. Despite the poor characterization of these isolates, the (probably false) conclusion was drawn that the biodegradation of NTA was primarily a trait inherent to specialized *Pseudomonas* strains (Tiedje, 1980; Anderson et al., 1985). From the description given in the original publications and the fact that the two ATCC strains were described as similar, it seems highly likely that most of these isolates were the first *Chelatobacter* strains isolated from the environment. Today the ubiquitous occurrence of members of the genus *Chelatobacter* and *Chelatococcus* (Wilberg et al., 1993; Bally, 1994) gives a strong indication that these bacteria are a major component of the NTA-degrading microbial community in wastewater treatment plants and aerobic environments.

Other strains reported to grow at the expense of NTA have included *Bacillus*, *Listeria*, *Rhodococcus*, and yeast species (Egli, 1994). However, most of these strains have been poorly characterized and were lost. Nevertheless, these reports suggest that the ability to utilize NTA is probably not restricted to *Chelatobacter* and *Chelatococcus* species. This is supported by the recent finding of an EDTA-degrading isolate (clearly different from *Chelatobacter* and *Chelatococcus*) that was also able to metabolize NTA (Witschel et al., 1997).

Enrichment and Isolation Procedures

From soil, wastewater, or surface waters, strains belonging to the genus *Chelatobacter* can be easily enriched in either batch or chemostat cultures using NTA as the only source of carbon, energy, and nitrogen (Egli et al., 1988; Egli and Weilenmann, 1989). All of the presently known strains of *Chelatobacter* are resistant towards nalidixic acid (Table BXII.α.117). This might be used to isolate such strains with a medium containing this antibiotic.

Maintenance Procedures

All strains can be maintained in a freeze-dried condition. Alternatively, cultures grown in SM with NTA and amended with either glycerol (15%, v/v) or DMSO (50%, v/v) can be stored in liquid nitrogen. However, with either method revival of cultures may take a while. Best results have been obtained when streaking cultures from liquid nitrogen directly onto agar plates with SM containing NTA as the only carbon and nitrogen source. When maintaining cultures on selective NTA agar plates, it is recommended to transfer them to new plates at least every week because growth leads to an increased pH in and around the colonies. Cells stored under such conditions exhibit long lag phases (up to several weeks) before they restart growing. Liquid cultures

behave similarly. Long lag times and irreproducible growth can be avoided by transferring the cells to fresh medium whilst they are still growing exponentially. Note that concentrations of NTA that are too high, combined with low buffering capacity of the medium or no pH control, may lead to an early cessation of growth.

Procedures for Testing Special Characters

Growth with NTA as the only source of carbon, energy, and nitrogen is a key property of *Chelatobacter*. Consumption of NTA can be measured either by the disappearance of dissolved organic carbon (DOC) paralleled by the excretion of ammonia, or via the consumption of NTA. A HPLC method specially developed for the analysis of NTA in culture media and cell extracts has been described by Schneider et al. (1988).

Differentiation of the genus *Chelatobacter* from other genera

The presently available information indicates that members of the genus *Chelatobacter* are most likely closely related to members of the genus *Aminobacter*. The nutritional and physiological properties that allow separation of the two genera are listed in Table BXII.α.118.

Taxonomic Comments

The presence of ubiquinone Q-10 (Egli et al., 1988), and the characteristic polyamine pattern with *sym*-homospermidine as the main, and putrescine and spermidine as major components (Auling et al., 1993a), clearly allocates members of the genus *Chelatobacter* to the *Alphaproteobacteria*, and to the family *Rhizobiaceae* (D. Kuykendall, personal communication). The polyamine pattern indicates a relationship to *Phyllobacterium* (Auling et al., 1991) but distinguishes *Chelatobacter* from *Ochrobactrum*. A weak serological cross-reaction with *Aminobacter aminovorans* (Green and Gillis, 1989; Urakami et al., 1992) and even less with *Carbophilus carboxidus* (Meyer et al., 1993), formerly *"Alcaligenes carboxydus"* (Auling et al., 1988), was observed (Wilberg et al., 1993). Oligonucleotide catalogs indicated the latter as the nearest neighbor of *Chelatobacter* (Auling et al., 1993a). Meanwhile, 16S rDNA sequence data allow grouping of *Chelatobacter* with *Mesorhizobium* (Jarvis et al., 1997), 4-chloro-2-methylphenol-degrading (Lechner et al., 1995) members of *Defluvibacter* (Fritsche et al., 1999a), two species of *Pseudaminobacter* (Katayama-Fujimura et al., 1983, 1984b; Kämpfer et al., 1999), and *Aminobacter* (Urakami et al., 1992).

The genus presently comprises nine strains and contains only

[a]Data collected from Egli et al. (1988), Egli and Weilenmann (1989), Green and Gillis (1989), and Urakami et al. (1992).

[b]Symbols: +, positive; −, negative; d, individual strains differ in their properties; nd, not reported.

[c]Most data from Green and Gillis (1989) (including the strains NCIB 9039, 11590, and 11591, later assigned to this species by Urakami et al., 1992).

[d]Data from Urakami et al. (1992).

[e]Strains tested in our laboratory were *A. aminovorans* NCIB 9039, *A. aganoensis* DSM 7051, *A. niigataensis* DSM 7050.

[f]From Egli et al. (1988), differing from Kämpfer et al. (1999).

[g]TE 4 and 10 are negative.

[h]Plate count agar, nutrient broth, peptone water, or PYG broth.

[i]TE 5 and 9, ATCC 27109, and 29600 are positive.

[j]TE 7 and 8 are positive, TE 4 and 5 slightly positive.

[k]TE 9 and 10 and ATCC 29600 are negative.

[l]ATCC 27109 negative.

[m]From Kämpfer et al. (1999). Strains used were *Chelatobacter heintzii* DSM 6450[T], *Aminobacter aminovorans* DSM 7048[T], *A. aganoensis* DSM 7051[T], and *A. niigataensis* DSM 7050[T].

a single species, *Chelatobacter heintzii.* Based on DNA–DNA hybridization studies (Auling et al., 1993a), the genus is divided into two groups, A1 and A2 (Fig. BXII.α.134). However, this division does not reflect the nutritional and physiological properties of the different *Chelatobacter* isolates (see Table BXII.α.116). The reference strain for DNA homology cluster A1 is *C. heintzii* strain ATCC 29600, which is also the type strain of the species. Strain *C. heintzii* TE 6 is the central strain of the DNA homology cluster A2.

The increasing availability of new relatives of *Chelatobacter* may require a change in its nomenclatural status in the future; a clustering of *Chelatobacter* with *Aminobacter* was recently proposed by Kämpfer et al. (2002). However, any revision based on phylogenetic considerations will meet with problems, since the related taxa are located within the notoriously "shallow" branch formerly known as the "alpha-2" branch of the *Proteobacteria.*

Acknowledgments

We are indebted to Ernst Wehrli for supplying us with excellent electron micrographs. In addition, we thank D. Kuykendall for allowing us to include unpublished information. TE would like to thank H.U. Weilenmann and all the students that have contributed to the study of NTA-utilizing microorganisms. Furthermore, the generous financial support of research on NTA in the laboratory of TE by grants from the Swiss National Science Foundation, Lever AG Switzerland and Unilever Port Sunlight, the Research Commission of ETH Zürich, and by EAWAG is gratefully acknowledged.

Auling et al., Systematic and Applied Microbiology *16:* 104–112, 1993, ©Urban & Fischer Verlag, Jena.)

List of species of the genus Chelatobacter

1. **Chelatobacter heintzii** Auling, Busse, Egli, El-Banna and Stackebrandt 1993b, 624[VP] (Effective publication: Auling, Busse, Egli, El-Banna and Stackebrandt 1993a, 110.)
heintz'i.i. M.L. gen. n. *heintzii* of Heintz; named after the chemist W. Heintz who was the first to synthesize the chelating agent NTA (Heintz 1862, 1865) and to describe some of its properties.

The characteristics are as described for the genus and listed in Tables BXII.α.115, BXII.α.116, and BXII.α.117.
The mol% G + C of the DNA is: 62–63 (T_m).
Type strain: ATCC 29600, DSM 10368.

Additional Remarks: All NTA-utilizing *Chelatobacter heintzii* strains described here have been deposited at the German Collection of Microorganisms and Cell Cultures (DSM), Braunschweig, Germany, where they have been assigned the following numbers: TE 4, DSM 6463; TE 5, DSM 6464; TE 6, DSM 6465; TE 7, DSM 6466; TE 8, DSM 6449; TE 9, DSM 6450; TE 10, DSM 6451. The other strains are available from the American Type Culture Collection, Rockville, MD, U.S.A., i.e., the strain isolated by Tiedje et al. (1973), namely *Chelatobacter heintzii* ATCC 29600 (also available from DSM under accession number DSM 10368) and ATCC 27109 (originally isolated by Focht and Joseph, 1971).

Genus VI. **Ensifer** *Casida 1982, 343[VP]*

David L. Balkwill

En' si.fer. L. adj. *ensifer* sword-bearing; M.L. masc. *Ensifer* sword bearer.

Rods 0.7–1.1 × 1.0–1.9 µm, occurring singly or in pairs. **Reproduction by budding at one pole of the cell**, with the bud then elongating to produce **asymmetric polar growth**. **Attaches endwise to various living Gram-positive and Gram-negative host bacteria and may cause lysis of the host cells. Host cells are not required for growth.** Gram negative, but may stain poorly. **Motile by a tuft of three to five subpolar flagella.** Aerobic; does not grow anaerobically in the presence of light. Optimal growth occurs at 27°C; good growth occurs at 20°C and 37°C. Not heat resistant. Weakly catalase positive. Nitrate and nitrite are reduced. Nitrification is negative for nitrite and ammonia. The **metabolism of glucose and galactose is oxidative**. Growth is inhibited by 4% NaCl but not by 2.5% NaCl. Grows well on most media. Definite but slow growth on soil extract agar and on 1.5% Noble agar in distilled water. Agar is not hydrolyzed. Utilizes a variety of organic carbon sources. A segment of the *Ensifer* 16S rDNA sequence (TACGGAGACGTTT, corresponding to positions 1009 through 1021 in the *Escherichia coli* 16S rDNA sequence; Brosius et al., 1978) might represent a signature sequence for this genus, as it did not match any other bacterial sequences available in public databases as of June, 2003.

The mol% G + C of the DNA is: 67 (T_m) and 63 (Bd).
Type species: **Ensifer adhaerens** Casida 1982, 343.

Further descriptive information

E. adhaerens was originally designated as strain A (Casida, 1980). Growth of *E. adhaerens* is initiated by budding at one pole of the cell, after which the bud elongates to produce asymmetric polar growth (Fig. BXII.α.135). This growth usually widens to equal the diameter of the mother cell. The daughter cell eventually separates from the mother cell by binary fission. Either the mother and daughter cells are the same size, or the daughter cell is smaller.

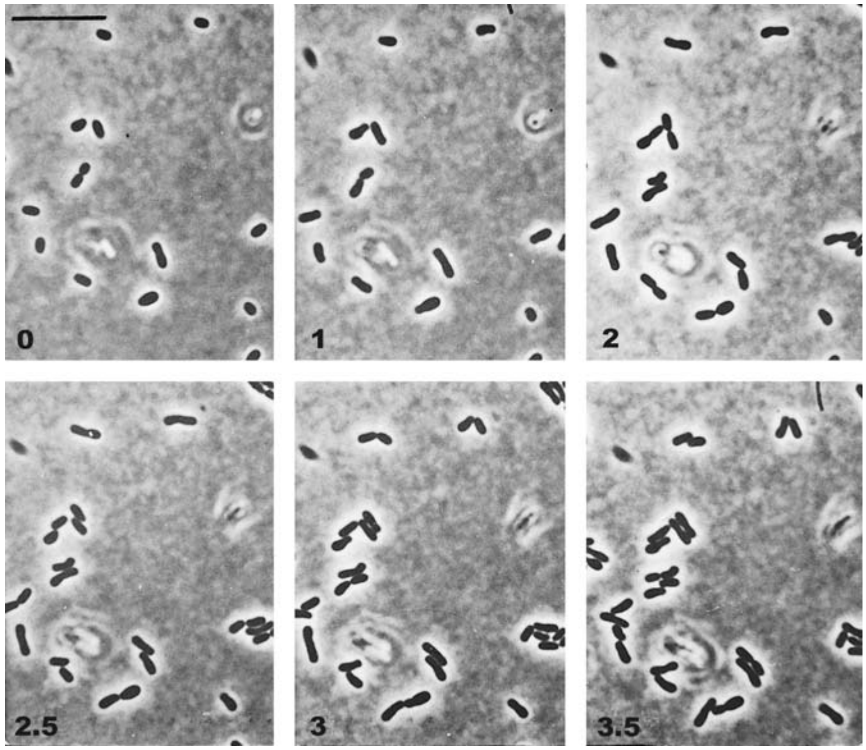

FIGURE BXII.α.135. Growth of *Ensifer adhaerens* on full-strength heart infusion agar. Incubation was for 0, 1, 2, 2.5, 3, and 3.5 h. Phase-contrast microscopy of a slide culture. Bar = 10 μm. (Reproduced with permission from L.E. Casida, Jr., International Journal of Systematic Bacteriology *32:* 339–345, 1982, ©International Union of Microbiological Societies.)

Measurements from electron micrographs indicate that some of the nonattached daughter cells are 20–30% smaller (length or width or both) than the nondividing mother cells. There is no tube or filament between mother and daughter cells during binary fission. After fission, growth resumes as new buds at the newly formed poles of both the mother and daughter cells. There does not appear to be any requirement for a rest or maturation period before growth resumes. Bud formation does not always occur at the pole of the cell; buds sometimes form on the side of a mother cell in old cultures.

The budding and division processes of *E. adhaerens* are similar to those of *Rhodopseudomonas blastica* (Eckersley and Dow, 1980). However, the latter organism is photosynthetic, grows anaerobically in the light, and divides only when the mother and daughter cells are of equal size. Moreover, the daughter cell must undergo an obligate period of maturation before it initiates growth.

A bar of darkly stained material is frequently visible along the side of the cell in whole-cell preparations of *E. adhaerens* that are stained with uranyl acetate and observed by electron microscopy. This bar becomes wider near one or both poles of the cell. When cells of *E. adhaerens* are attached to host cells, such as those of *Micrococcus luteus*, this bar often extends between the *E. adhaerens* cell and the host cell. The chemical composition of the bar is not known. In addition, it is not readily apparent in whole-cell preparations negatively stained with phosphotungstic acid instead of uranyl acetate, and it has not been located unequivocally in thin-sectioned material.

When *E. adhaerens* is grown in the presence of *M. luteus* (or some other sensitive bacterium) on agar medium, large numbers of *E. adhaerens* cells attach endwise to *M. luteus* cells. The *E. adhaerens* cells are situated side by side, closely packed, in a picket fence arrangement. When the prevailing nutrient and pH conditions (in soil or on laboratory media; pH 6 is optimal) are satisfactory, this arrangement eventually results in lysis of the *M. luteus* cells. There is no specialized morphological structure on the *E. adhaerens* cell for attachment purposes. Rosettes are not formed.

E. adhaerens is not an obligate predator. It grows well on most media in the absence of potential host cells. In fact, the overall growth of *E. adhaerens* usually does not increase as a result of tracking (Casida, 1980) or lysis of *M. luteus* cells. However, some increased growth of *E. adhaerens* does occur when both organisms are placed on Noble agar with or without 0.1% glucose. Thus *E. adhaerens* probably benefits from this interaction only if the nutritive value of the medium is very low, a situation that is comparable to the presumed low availability of nutrients occurring in soils that have not recently received organic matter. In soil, *E. adhaerens* cells attach directly to host cells, so that even the small amounts of lytic factor produced under low-nutrient conditions can be used effectively in lysing host cells. On agar media, this lytic factor is diffusible and can act on host cells at a distance from the *E. adhaerens* cells.

E. adhaerens produces colonies 10–15 mm in diameter after 6 d on heart infusion agar prepared at one-tenth of the recommended strength (but containing 1.5% agar). These colonies are grayish white, circular with undulate margins, convex, slimy, moist, and opaque (but may appear almost translucent because of excessive slime production). Growth on agar slants is abundant, opaque, grayish white, smooth, flat, slimy, and moist. Pellicle and sediment (with little turbidity) are produced in a broth medium containing 0.5% peptone, 0.1% yeast extract, and 0.1% glucose.

Definite but slow growth occurs during sequential transfers on 1.5% Noble agar in distilled water. Host cells are not required,

and the agar is not hydrolyzed. This growth is equivalent to that obtained on soil extract agar. Good growth is obtained on a synthetic medium containing 0.1% glucose, 0.1% NH_4NO_3, 0.1% KH_2PO_4, 0.1% NaCl, 0.1% $MgSO_4 \cdot 7H_2O$, 0.1% L-glutamic acid, and 1.5% agar (pH 7.0). *E. adhaerens* utilizes a variety of organic carbon sources including glucose, galactose, mannose, rhamnose, xylose, mannitol, sorbitol, glycerol, L-glutamic acid, L-alanine, L-asparagine, and L-glutamine. Acetate is used only slowly and does not inhibit glucose utilization. *E. adhaerens* grows on pure gelatin without hydrolysis. Starch is not hydrolyzed. Good growth occurs on blood agar, with no hemolysis. Good growth also occurs on desoxycholate agar, initially appearing whitish purple and then changing to buff.

The metabolism (Hugh and Leifson, 1953) of glucose and galactose is oxidative. No growth occurs under petrolatum. Gas is not produced in the absence of petrolatum; only trace amounts of acid, if any, are produced.

E. adhaerens cells do not survive 30 s of heating in tap water at 71°C.

Thirteen lytic phages for *E. adhaerens* were isolated from soil by Germida and Casida (1983) and used for phage typing of eight *E. adhaerens* host strains. The phages were also used in assays to monitor *E. adhaerens* predatory activity against other bacteria in soil (see below).

The habitat for *E. adhaerens* is soil. The numbers of *E. adhaerens* cells in soils can be estimated (Casida, 1980) by gently applying dilutions of soil to the surfaces of pregrown lawns of *M. luteus* cells (one-tenth-strength heart infusion agar, with 1.5% agar). After continued incubation, *E. adhaerens* produces small, thin, transparent colonies that appear as small moist areas that expand and coalesce. These colonies are not visible by transmitted light. The plates must be viewed from above, using light arriving at an oblique angle. The *E. adhaerens* colonies are on the surface of the *M. luteus* lawn. Under these conditions, they neither penetrate the lawn nor lyse the *M. luteus* cells. The cell numbers of specific *E. adhaerens* strains in soil can also be estimated with a most probable number (MPN) method that combines phage analysis with a dilution frequency procedure (Makkar and Casida, 1987b). A small (but known) number of lytic phage specific for the strain to be enumerated is added to each soil dilution. A tenfold or greater increase in PFU after a suitable incubation period is then taken to indicate that *E. adhaerens* host cells were present in a dilution. This method is capable of detecting *E. adhaerens* strains in soils even when they are present in very low numbers.

E. adhaerens has been isolated from a range of soil types. However, the strains from different soils do not necessarily cross-react when tested by phage typing (Germida and Casida, 1983). The predatory activity of *E. adhaerens* and its host range can be detected and followed in soils with the indirect phage analysis procedure of Germida and Casida (1983). Some bacteria, such as a myxobacterium and a *Streptomyces* predatory bacterium, succumb to *E. adhaerens* attack in soil but do not do so in laboratory cultures.

Indigenous *E. adhaerens* cells in soil attack only certain species of bacteria that are added to the soil. Studies using indirect phage analysis (Germida and Casida, 1983; Zeph, 1986; Zeph and Casida, 1986) have shown that *E. adhaerens* attacks *Agromyces ramosus*, *Micrococcus luteus*, a *Myxococcus* species soil isolate, *Staphylococcus aureus*, and two *Streptomyces* soil strains (C2 and 34). *E. adhaerens* does not attack *Actinomyces humiferus*, *Agrobacterium tumefaciens*, *Arthrobacter globiformis*, *Azotobacter vinelandii*, *Bacillus stearothermophilus*, *Bacillus subtilis*, *Bacillus thuringiensis*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Rhizobium leguminosarum*, *Salmonella typhi*, or *Sinorhizobium meliloti*. However, in a few instances *E. adhaerens* will attack another bacterial predator, such as the *Myxococcus* soil isolate that is itself attacking certain of the above bacteria (Germida and Casida, 1983).

E. adhaerens is a component of a sequence of three predatory bacteria in soil that respond naturally when host cells, such as those of *M. luteus*, are added to the soil (Casida, 1980). A *Streptomyces* predator responds quickly with growth and attack on *M. luteus*. This is followed by growth of *E. adhaerens*, which attaches to and lyses both *M. luteus* and the streptomycete. Finally, a myxobacterium (*Myxococcus*) multiplies and attacks residual *M. luteus* cells but is, in turn, attacked by *E. adhaerens*. *E. coli* is not attacked directly by *E. adhaerens* in soil. Instead, the *E. coli* cells activate germination of the myxobacterium microcysts so that *E. coli* is destroyed, and this is followed by *E. adhaerens* attack on the myxobacterium (Germida and Casida, 1983; Liu and Casida, 1983).

E. adhaerens can also activate *Bacillus* spores (Mormak and Casida, 1985). In laboratory cultures, *E. adhaerens* cells promote a reversible germination of *B. subtilis* spores that does not proceed beyond the activation stage. Indigenous *E. adhaerens*-like bacteria promote the same type of limited spore germination in unamended soil. However, spores associated with *E. adhaerens*-like bacteria in soils that have been nutritionally enriched by incubation with ground alfalfa progress further in the germination process, and some of them may germinate fully, as implied by the eventual appearance of ghosted vegetative cells. There is no direct evidence that the indigenous *E. adhaerens*-like bacteria attack the germinated spores in nutritionally enriched soil, and cells of *E. adhaerens* do not attack vegetative cells of *B. subtilis* in laboratory cultures. Mormak and Casida (1985) have suggested that because small quantities of dipicolinic acid, calcium, and certain amino acids are released during spore activation, *E. adhaerens* and other soil bacteria may utilize these compounds for small amounts of growth or for maintaining cell viability.

E. adhaerens attaches to other bacteria in soil, but it also attaches to other bacteria (or does not become detached) during the preparation of dilutions of soil for plating of other soil organisms. Therefore, it may be in the colonies of the other soil organisms, and it may not be apparent that this is the case. *E. adhaerens* is difficult to remove from cultures of other bacteria unless the other organisms will grow on media containing 4% NaCl. *E. adhaerens* does not grow in the presence of 4% NaCl.

Germida et al. (1985) have reported that *E. adhaerens* can be used to bioassay for plant-available manganese in soils. The assay is specific for manganese, and the results correlate significantly with plant yields.

Enrichment and Isolation Procedures

Variations of two procedures can be used for enrichment and isolation of *E. adhaerens*. In the first procedure, washed *M. luteus* cells, or cells of some other host organism, are added to natural soil, followed by the addition of enough water to adjust the soil water content to 50–60% of the soil's moisture-holding capacity. Alternatively, the cells are mixed with soil and sand in a soil percolation device (Germida and Casida, 1983), and water is percolated through the column of soil. Incubation is for 4–6 days at 25–27°C. After incubation, dilutions of soil are plated on desoxycholate agar or MacConkey agar. The dilutions of soil may also be spread carefully over the surfaces of pregrown lawns of *M. luteus* (on one-tenth strength heart infusion agar, with 1.5% agar), after which the *M. luteus* plates are incubated further. (See previous description for the appearance of the resulting *E. adhaerens* colonies.)

In the second isolation procedure, *M. luteus* cells, or cells of

some other host organism, are applied as a smear to a sterile glass slide. The cells are allowed to become just dry at room temperature. They are then immediately placed in contact with natural soil. The slides can be partially buried in soil, either outdoors or in the laboratory. They are placed vertically in the soil, so that only the top 2 cm (approximately) protrudes. Water is added to the soil at intervals to maintain a range of 40–65% of moisture-holding capacity. Alternatively, a sterile glass ring 11 mm high × 25 mm in diameter (e.g., as cut from a test tube) may be placed on the smear and filled with soil. The soil is tamped lightly to ensure direct contact with the smear. Moisture-holding capacity is adjusted to 65%, and incubation is at 27°C in sterile Petri plates. Additional water is added as needed. The incubation time for the *M. luteus* host cells is 3–4 d. After completion of the incubation of these slides, or of buried slides, the soil is gently removed to expose the area of the slide surface where the *M. luteus* smear was placed. An inoculating loop that has been heated and plunged into agar while still hot is touched against this area of the slide. The loop is then streaked through a lawn of *M. luteus* cells or onto the surfaces of plates of desoxycholate or MacConkey agar without bacterial lawns.

Maintenance Procedures

E. adhaerens survives well on refrigerated slants of heart infusion agar made up at one-tenth strength (with 1.5% agar). It can also be lyophilized by common procedures used for aerobes.

Differentiation of the genus *Ensifer* from other genera

The genus *Ensifer* is separated from other genera of aerobic, motile, nonphotosynthetic, Gram-negative rods by its method of multiplication. It reproduces by budding at one pole of the cell, with the bud then elongating to produce asymmetric polar growth. Separation of the cells occurs by binary fission, after which growth resumes immediately as new buds at the newly formed poles of both the mother and daughter cells.

In addition to the above, *E. adhaerens* attaches with one of its poles to various species of Gram-positive and Gram-negative bacteria. If enough *E. adhaerens* cells are present, they will position themselves side by side in a picket fence arrangement around the host bacterium. *M. luteus* is a good host organism for demonstrating this behavior. Depending on the species of the host involved in the interaction, *E. adhaerens* may proceed to kill and lyse the host if the pH and background nutritional level are suitable.

E. adhaerens can be differentiated, or even removed, from some other genera of bacteria by using a medium containing 4% NaCl. *E. adhaerens* does not grow in the presence of 4% NaCl but can grow in the presence of 2% NaCl.

The 16S rDNA sequence for *E. adhaerens* differs from those of all species of *Sinorhizobium* (the most closely related genus according to phylogenetic analyses) at positions 658, 659/746, 747, and 1012/1017, and from those of all but one species of *Sinorhizobium* at positions 1010/1019 and 1011/1018 (see below for details). The segment of the *E. adhaerens* 16S rDNA sequence from positions 1009 through 1021 did not match any bacterial sequences in public databases (as of June, 2003) and, therefore, may be unique to *Ensifer*.

Taxonomic Comments

E. adhaerens-like bacteria have been isolated from several soils. These bacteria have the characteristics of *E. adhaerens*, but do not demonstrate a cross-reaction with strains A or 7A when they are examined by phage typing. These *E. adhaerens*-like bacteria are considered to be strains of *E. adhaerens*, with the lack of cross-reaction being due to strain specificity of the particular bacteriophages that have been used.

16S rDNA sequences have been determined for two strains of *E. adhaerens*: ATCC 33212^T and ATCC 33499 (Balkwill, unpublished data; GenBank accession numbers AF191739 and AF191738, respectively). Phylogenetic analyses of these sequences with distance matrix (Fig. BXII.α.136), parsimony, and maximum likelihood methods indicated that *E. adhaerens* should be placed in the *Rhizobiaceae*. Within this family, *E. adhaerens* is most closely related to the genus *Sinorhizobium*. Similarities between the sequences for *E. adhaerens* and those for validly published species of *Sinorhizobium* are high (98.2% to 99.0%). On the other hand, the *Sinorhizobium* and *Ensifer* strains are always assigned to distinct (but closely related) clusters within the phylogenetic tree (see Fig. BXII.α.136), and the node at which the branching between these two clusters occurs is resolved consistently regardless of the method used to analyze the sequences. A number of consistent differences between the *Ensifer* and all available *Sinorhizobium* 16S rDNA sequences were also noted. These were located at *E. coli* positions (Brosius et al., 1978) 658

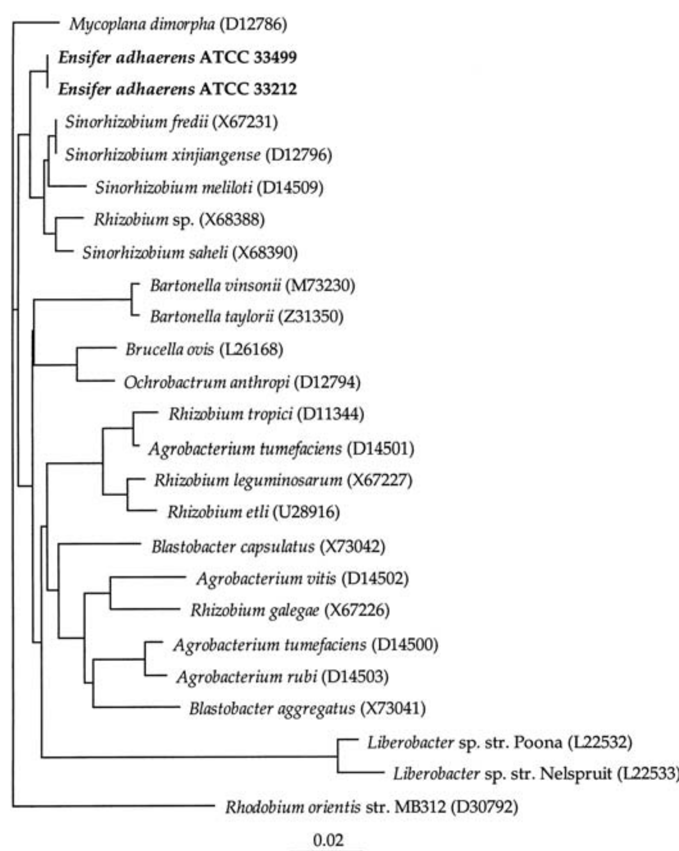

FIGURE BXII.α.136. Phylogenetic tree for two strains of *Ensifer adhaerens* and selected strains of *Bacteria*, based on a distance matrix analysis. Bar = 2 substitutions per 100 bases. *Rhodobium orientis* was used as the outgroup. Parsimony and maximum likelihood analyses yielded virtually identical trees with respect to the positions of *Ensifer* and *Sinorhizobium* and the branching patterns within the cluster containing strains of these two genera. The numbers in parentheses are the GenBank/EMBL accession numbers for the sequences used in the analysis. The GenBank accession numbers for the *Ensifer* sequences are as follows: *E. adhaerens* ATCC 33212^T, AF191739; *E. adhaerens* ATCC 33499, AF191738.

(A in *Ensifer* vs. C in *Sinorhizobium*), 659/746 (T–A pair vs. C–G), 747 (T vs. G), and 1012/1017 (G–C vs. A–T). Additional differences between the *Ensifer* sequences and those for all *Sinorhizobium* species except *Sinorhizobium terangae* were detected at positions 1010/1019 (A–T in *Ensifer* vs. C–G in *Sinorhizobium*) and 1011/1018 (C–G vs. G–C).

The close relatedness of *Ensifer* and *Sinorhizobium* detected by phylogenetic analyses of 16S rDNA sequences, and the high similarities between the 16S rDNA sequences of these organisms, could have implications for the status of *Ensifer* as a separate genus. *Ensifer* is not known to invade root hairs of plants and cause formation of root nodules, but this has not been tested. Similarly, *Sinorhizobium* species are not known to prey on other species of bacteria, but this has not been tested either. In addition, it is not known whether any of the unique traits of *Ensifer* are plasmid-coded and, thus, should not be included in the genus definition. Designation of *Ensifer* as a distinct genus appears to be justified based on current information. However, it is recommended that a detailed direct comparison of *Ensifer* and *Sinorhizobium* strains be carried out to more accurately assess this situation.

Acknowledgments

For the most part, this chapter is a minor revision of the original description of *Ensifer* written for the previous edition of the *Manual* by L.E. Casida, Jr. The principal changes include the addition of information from analysis of 16S rDNA sequences and the addition of data from several more recent publications. The current author thanks L.E. Casida Jr. for providing reprints and other information related to his research on *Ensifer adhaerens*. The two strains of *E. adhaerens* for which 16S rDNA sequences were determined were obtained from the American Type Culture Collection.

List of species of the genus Ensifer

1. **Ensifer adhaerens** Casida 1982, 343[VP]
ad.haer′ ens. L. adj. *adhaerens* adherent.

The characteristics are as described for the genus. Two variants have been isolated from cultures of the type strains. These variants produce less slime, which results in smaller colonies and a drier and slightly whiter appearance of the colonies.

A strain of *E. adhaerens* that differs from the type strain in its rate of attack on *M. luteus* cells but not in most other characteristics, including phage typing, was isolated from the same soil as strain A. However, the soil had been incubated with added *B. subtilis* spores instead of *M. luteus* cells. This strain (designated strain 7A) has been deposited with the American Type Culture Collection under the number ATCC 33499. Strain 7A can be differentiated from strain A by its growth on desoxycholate agar; strain 7A growth remains purple throughout 10 d and then becomes whitish purple.

The habitat is soil.

The mol% G + C of the DNA is: 67 (T_m) and 63 (Bd).

Type strain: A, ATCC 33212.

GenBank accession number (16S rRNA): AF191739.

Genus VII. **Sinorhizobium** *Chen, Yan and Li 1988b, 396[VP] emend. de Lajudie, Willems, Pot, Dewettinck, Maestrojuan, Neyra, Collins, Dreyfus, Kersters and Gillis 1994, 732*

L. David Kuykendall, Fawzy M. Hashem and En Tao Wang

Si.no.rhi.zo′ bi.um. L. n. *sinae* China; Gr. n. *rhiza* a root; Gr. n. *bios* life; M.L. neut. n. *Sinorhizobium* which lives in a root in China; *Rhizobium* isolated in China.

Rods 0.5–1.0 × 1.2–3.0 µm. Commonly pleomorphic under adverse growth conditions. Usually contain granules of polyhydroxybutyrate, which are refractile by phase-contrast microscopy. Nonsporeforming. Gram negative. **Motile** by one polar or subpolar flagellum or one to six peritrichous flagella. Fimbriae have been described on a few strains. **Aerobic, possessing a respiratory type of metabolism with oxygen as the terminal electron acceptor.** Optimal growth temperature, 25–30°C, but can tolerate a wide range of temperatures. Most strains can grow at 35°C; some strains can grow at 10°C, and others (*S. saheli* and *S. terangae*) can grow at temperatures up to 42–44°C (de Lajudie et al., 1994). Tolerate 1.0% NaCl, and some strains grow well on Yeast Mannitol (YM) medium containing 4.5% NaCl. Optimal pH for growth is near neutral (6–8), but some strains can grow at pH 5.0, and others tolerate pH 10.5. Colonies are circular, convex, usually opaque, sometimes translucent, raised, and mucilaginous. **Colonies are usually 2–4 mm in diameter within 3–5 days of growth on yeast mannitol-mineral salts agar** and pronounced turbidity develops after 2–3 days in aerated or agitated broth. Generation times are 3–6 h. Chemoorganotrophic, **utilizing a wide range of carbohydrates and salts of organic acids as carbon sources**, producing acid without gas formation. Cellulose and starch are not utilized. Produce an acidic reaction in mineral-salts medium containing mannitol. Growth on carbohydrate media is often accompanied by **copious extracellular polysaccharide slime production**. Ammonium salts, nitrate, nitrite, and most amino acids can serve as nitrogen sources. **All strains require pantothenate and nicotinic acid.** Peptone is poorly utilized. Casein and agar are not hydrolyzed. **Oxidase positive.** Catalase positive. 3-Ketolactose not produced from lactose. **The organisms are characteristically able to invade the root hairs of temperate-zone and tropical-zone leguminous plants (family Leguminoseae) and incite production of root nodules wherein the bacteria occur as intracellular nitrogen-fixing microsymbionts.** Strains exhibit varying degrees of host specificity, determined by the type of Nod Factors produced. In root nodules the bacteria occur as endophytes exhibiting pleomorphic forms, termed “bacteroids”, which reduce or fix gaseous atmospheric nitrogen into a combined form utilizable by the host plant.

The mol% G + C of the DNA is: 57–66.

Type species: **Sinorhizobium fredii** (Scholla and Elkan 1984) Chen, Yan and Li 1988b, 396 (*Rhizobium fredii* Scholla and Elkan 1984, 484.)

Further descriptive information

Granules of poly-β-hydroxybutyrate are common in older cells, so that upon simple staining the rods appear banded. As in the genus *Rhizobium*, all species are motile by one or more flagella. For most species examined that have multiple flagella, the insertion of the flagella is peritrichous, with random placement. Strains in those species with a single flagellum (*Sinorhizobium fredii*, *S. saheli*, *S. terangae*, and *S. xinjiangense*) are monotrichous with polar or subpolar insertion.

Cell wall composition The cell wall structure of *Sinorhizobium* is generally similar to that of other Gram-negative bacteria. The peptidoglycan consists of glutamic acid, alanine, diaminopimelic acid, and amino sugars. In addition, leucine, phenylalanine, serine, and aspartic acid have been detected in relatively large amounts in the peptidoglycan layer of several pathogenic strains. Lipopolysaccharide cell wall composition varies from strain to strain but consistently contains 2-keto-3-deoxyoctanoic acid (KDO), uronic acid, glucosamine, glucose, and galactose (Carlson, 1982).

Other genetic and physiological features of *Sinorhizobium* are generally the same as for *Rhizobium*. See the chapter on *Rhizobium*. In fact, as everyone in this area of specialization knows, much of what is known about *Rhizobium* was learned from studies on *S. meliloti*.

Enrichment and Isolation Procedures

Like other legume-nodulating bacteria, members of the genus *Sinorhizobium* live in soils where legumes occur and may persist for years without host plants. They can be most suitably isolated from the root nodules formed on suitable host plants. Surface sterilization of root nodules is followed by sterile water rinses until the contents can be released into sterile physiological saline and streaked onto a medium with Congo red. Like *Rhizobium*, *Sinorhizobium* colonies remain white as they do not take up the dye.

Maintenance Procedures

Strains of *Sinorhizobium* are usually maintained on YEM medium, containing 20–50% glycerol at either −20°C or −70°C when available. Freeze-drying is also an accepted practice.

Differentiation of the genus *Sinorhizobium* from other genera

See Tables BXII.α.112 and BXII.α.113 in the chapter on the genus *Rhizobium*. Apart from phenotypic characters that distinguish them as individual species, there are no common distinct characters that differentiate these species as separate from members of the genus *Rhizobium*. The closely related genus *Ensifer* has not been tested for a variety of features unique to legume-nodulating and symbiotic nitrogen-fixing genera including these very traits and its failure to absorb Congo Red. These closely related genera can now be recognized by 16S rDNA sequencing and other molecular methods. *Sinorhizobium* can be differentiated from unrelated genera by cellular fatty acid analysis. Although *Sinorhizobium* and *Rhizobium* generally have qualitatively identical fatty acid composition, there appears to be a quantitative difference in $C_{16:0\ 3OH}$ fatty acid between *Sinorhizobium* and *Rhizobium*, in that the concentration is generally lower in *Sinorhizobium* than in *Rhizobium* (Tighe et al., 2000).

Taxonomic Comments

The original proposal of *Sinorhizobium* Chen et al., 1988b, was questioned on the basis that there was little to discriminate this genus from *Rhizobium* (Graham et al., 1991; Jarvis et al., 1992). Subsequently, de Lajudie et al. (1994) proposed an emended description of the genus based on a comparative analysis of 16S rDNA sequences, which showed that *Rhizobium meliloti* and *Sinorhizobium fredii*, together with two new species *Sinorhizobium terangae* and *Sinorhizobium saheli*, formed a separate phylogenetic branch distinct from *Rhizobium* species (*R. leguminosarum*, *R. tropici*). Rome et al. (1996) named a sixth species, *Sinorhizobium medicae*, for strains isolated from various *Medicago* species, together with strains previously recognized as *Rhizobium meliloti* type B (Eardly et al., 1990). Two new species, *S. arboris* and *S. kostiense*, were described recently from legume trees in Sudan and Kenya (Nick et al., 1999). Wang et al. (1999a) reported three new groups within this genus for isolates from *Leucaena leucocephala* in Mexico.

Inferred phylogenies based on comparative analyses of 16S rDNA sequence data show that *Sinorhizobium* species, and *Ensifer adhaerens* (Casida, 1982), a bacterial predator of bacteria in soil, form a clade(s) distinct from *Rhizobium* and *Agrobacterium* species. Apart from phenotypic characters which distinguish them as individual species, and except for the quantitative difference in $C_{16:0\ 3OH}$ fatty acid content described above, there are no common distinct characters which differentiate these species as separate from members of the genus *Rhizobium*. At the time of this writing, perhaps only about one-half of the investigators in the field accept the taxonomic validity of *Sinorhizobium*. This new genus, together with *Ensifer*, will probably not stand if supporting data that provide evidence of distinct taxa cannot be gathered. The present fragile nature of these genera will be further undermined when strains from different soils and hitherto untested legume/*Rhizobium* combinations are found to be intermediate between the genera.

The taxonomic relationships of *Sinorhizobium* are discussed fully and further descriptive information is given in the chapter on *Rhizobium*. Perhaps the ultimate tool of taxonomy, the complete genome sequence for *S. meliloti*, was recently reported by Galibert et al. (2001).

Differentiation of the species of the genus *Sinorhizobium*

See Tables BXII.α.112 and BXII.α.113 in the chapter on the genus *Rhizobium*. Reports of specific phenotypic differences are needed for some species. The species of *Sinorhizobium* can also be differentiated by comparative sequence analysis of 16S rRNA gene sequence data. Fatty acid analysis can also be useful to discriminate *Sinorhizobium* from other related genera (Jarvis et al., 1996).

List of species of the genus Sinorhizobium

1. **Sinorhizobium fredii** (Scholla and Elkan 1984) Chen, Yan and Li 1988b, 396[VP] (*Rhizobium fredii* Scholla and Elkan 1984, 484.)
fred′i.i. M.L. gen. n. *fredii* of E.B. Fred.

The characteristics are as described for the genus and as listed in Tables BXII.α.112 and BXII.α.113 in the chapter on the genus *Rhizobium*. Motile by one polar flagellum or by 1–3 peritrichous flagella. Relatively fast growing: colonies are 2–4 mm in diameter after 3–5 days growth on yeast extract mannitol agar. Temperature growth optimum is 25–30°C. Most strains grow at 35°C, and some grow at 10°C. Optimal pH for growth, 6–8; range pH 5.0–10.5. Most strains grow on YMA containing 1.0% NaCl, but a few strains tolerate >3.0% NaCl. Require pantothenate and nicotinate as growth factors. Utilize relatively few organic substrates as sole sources of carbon. Two chemovars were proposed—fredii and siensis—that were differentiated by the ability of siensis to reduce litmus and produce a final pH in growth media greater than 6.1, and its resistance to kanamycin (20 ppm). Later revisions have led to a consolidation of these groups. *S. fredii* can be differentiated from the other *Sinorhizobium* species by auxanographic characteristics, protein SDS-PAGE profile, DNA–DNA reassociation, and comparative analysis of 16S rDNA sequence data.

This species effectively nodulates *Cajanus cajan*, *Glycine max* cv. Peking, *Glycine soja*, and *Vigna unguiculata*. Dowdle and Bohlool (1985) reported new strains that are symbiotically competent with North American cultivars of soybean. Some original strains, including the type strain, were also found to nodulate *Medicago sativa* (Hashem et al., 1997) with efficient symbiotic nitrogen fixation (Kuykendall et al., 1999).

The mol% G + C of the DNA is: 60–64 (T_m).

Type strain: PRC 205, ATCC 35423, ICMP 11139, NCIB 12104, USDA 205.

GenBank accession number (16S rRNA): D01272, X67231.

2. **Sinorhizobium arboris** Nick, de Lajudie, Eardly, Suomalainen, Paulin, Zhang, Gillis and Lindström 1999, 1366[VP]
ar′bo.ris. L. fem. n. *arbor* tree; n. *arboris* of the tree.

Short, aerobic, Gram-negative rods that are motile by one or two polar or subpolar flagella. Maximum growth temperature is about 42°C. On YEM medium, most strains produce circular, cream-colored, semi-translucent colonies that become very mucilaginous and often spread over the entire plate within 2–4 d. Utilize a wide range of carbon sources and amino acids for growth. Grow on L-isoleucine and tolerate 3% (w/v) NaCl, heavy metals (but not Al), and antibiotics. Produce melanin and grow at pH 8.5. However this species cannot be identified by physiological features and biochemical traits alone. Nodulates *Acacia sengal* and *Prosopis chilensis*. SDS-PAGE whole protein pattern, MLEE, rep-PCR genomic fingerprinting, RFLP analysis of amplified 16S rRNA, total DNA–DNA hybridization, and 16S rDNA sequence comparison are useful for distinguishing closely related species at the molecular level.

The mol% G + C of the DNA is: 60.6–61.8 (T_m).

Type strain: HAMBI 1552, LMG 14919.

GenBank accession number (16S rRNA): Z78204.

3. **Sinorhizobium kostiense** Nick, de Lajudie, Eardly, Suomalainen, Paulin, Zhang, Gillis and Lindström 1999, 1366[VP]
kos.ti.en′se. L. neut. adj. *kostiense* pertaining to Kosti, the region in Sudan where most of these organisms have been isolated.

Short, aerobic, Gram-negative rods that are motile by one or two polar or subpolar flagella. Maximum growth temperature is about 38–40°C for most strains. On YEM medium, most strains produce circular, cream-colored, semi-translucent colonies that become very mucilaginous and often spread over the entire plate within 2–4 d. Utilize a relatively narrow range of carbon sources and amino acids for growth. Tolerate 1% (w/v) NaCl; sensitive to heavy metals except lead and copper. Sensitive to most antibiotics. Produce melanin but fail to grow at pH 5.5 or 8.5. This species cannot be identified by physiological features and biochemical traits alone. Nodulates *Acacia sengal* and *Prosopis chilensis*. SDS-PAGE whole protein pattern, MLEE, rep-PCR genomic fingerprinting, RFLP analysis of amplified 16S rRNA, total DNA–DNA hybridization, and 16S rDNA sequence comparison are useful for distinguishing closely related species at the molecular level.

The mol% G + C of the DNA is: 57.9–61.6 (T_m).

Type strain: HAMBI 1489, LMG 15613.

GenBank accession number (16S rRNA): Z78203.

4. **Sinorhizobium medicae** Rome, Fernandez, Brunel, Normand and Cleyet-Marel 1996, 979[VP]
me′di.cae. L. fem. n. *medica* from *medica lucerne* (plant belonging to the genus *Medicago*); L. gen. n. *medicae* of *medica*.

The characteristics are as described for the genus and as listed in Table BXII.α.112 in the chapter on the genus *Rhizobium*. Fast growing: semi-translucent, circular, and mucoid colonies spread over the plate in 3–5 days on yeast extract mannitol agar. Temperature growth optimum, 25–30°C. Most strains grow at 35°C but not at 42°C; 40°C is the maximum temperature for growth. Optimal pH for growth, 6–8; range pH 5.0–10. Grows in media containing 2% NaCl but does not grow well in media containing 3% NaCl. Resistant to nalidixic acid. Differentiated from other *Sinorhizobium* and *Rhizobium* spp. based on differences in 16S rDNA sequence data. Sequence similarities indicate a very close relationship to *S. meliloti* (99.7%).

Strains have been isolated from various *Medicago* species in different geographical sites including southern France and the eastern Mediterranean basin, which are in the center of origin of the genus *Medicago*. Isolated from *Medicago orbicularis*, *M. polymorpha*, *M. rugosa*, and *M. truncatula*. *Sinorhizobium medicae* strains fix nitrogen with *M. polymorpha*, whereas *S. meliloti* forms ineffective nodules.

The mol% G + C of the DNA is: 61.0–63.0 (T_m).

Type strain: A 321, USDA 1037.

GenBank accession number (16S rRNA): L39882.

5. **Sinorhizobium meliloti** (Dangeard 1926) de Lajudie, Willems, Pot, Dewettinck, Maestrojuan, Neyra, Collins, Dreyfus, Kersters, and Gillis 1994, 731[VP] (*Rhizobium meliloti* Dangeard 1926, 194.)
me.li.lo′ti. M.L. masc. n. *Melilotus* generic name of sweet clover; M.L. gen. n. *meliloti* of *Melilotus*.

The characteristics are as described for the genus and as listed in Tables BXII.α.112 and BXII.α.113 in the chapter on the genus *Rhizobium*. Motile by 2–6 peritrichous flagella. Variable growth on YMA containing 2% NaCl. Variable growth at 39–40°C. Does not require thiamine or pantothenate for growth; some strains require biotin. pH range for growth, 5.0–9.5. Utilizes a relatively wide range of organic substrates as sole sources of carbon. Distinguished from other *Sinorhizobium* and *Rhizobium* species by DNA–DNA reassociation data, differences in protein profiles obtained by SDS-PAGE, and 16S rDNA sequence comparison. Sequence similarities indicate a close relationship to *S. medicae*. Two subpopulations have been distinguished by DNA hybridization and multilocus enzyme electrophoresis.

Forms nitrogen-fixing nodules on *Melilotus*, *Medicago*, and *Trigonella*. Gao and Yang (1995) reported a Chinese *Sinorhizobium meliloti* strain that nodulated and fixed nitrogen in association with both alfalfa and soybean. Well characterized genetically. Symbiosis-controlling genes are carried on megaplasmids. In addition, strains harbor various numbers (0–4) of large pRme plasmids (90–500 kb) (Boivin et al., 1997).

The mol% G + C of the DNA is: 62–63 (T_m).

Type strain: ATCC 9930, ICMP 12623, LMG 6133, USDA 1002.

GenBank accession number (16S rRNA): X67222.

6. **Sinorhizobium saheli** de Lajudie, Willems, Pot, Dewettinck, Maestrojuan, Neyra, Collins, Dreyfus, Kersters, and Gillis 1994, 732^VP
sa' hel.i. N.L. gen. n. *saheli* of the Sahel, the region in Africa from which they were isolated.

The characteristics are as described for the genus and as listed in Tables BXII.α.112 and BXII.α.113 in the chapter on the genus *Rhizobium*. Motile by one or more polar or subpolar flagella. Colonies can be mucoid and spreading on yeast extract mannitol agar. Old colonies become brown. Can grow at 44°C. Utilizes a range of organic substrates as sole sources of carbon (Table BXII.α.113 in the chapter on the genus *Rhizobium*). Distinguished from other *Sinorhizobium* and *Rhizobium* species by DNA–DNA reassociation data, differences in protein profiles obtained by SDS-PAGE, and 16S rDNA sequence comparison. Haukka et al. (1998) reported two different sequences for a 230-nucleotide segment of the 16S ribosomal RNA gene in the type strain of *S. saheli*.

Nodulates different *Sesbania* species (*S. cannabina*, *S. grandiflora*, *S. rostrata*, *S. pachycarpa*) growing in the Sahel; in addition to these species, strains can nodulate *Acacia seyal*, *Leucaena leucocephala*, and *Neptunia natans*. Can form effective stem nodules on *Sesbania rostrata* when plants are not previously nodulated on their roots (Boivin et al., 1997).

The mol% G + C of the DNA is: 65–66 (T_m).

Type strain: ORS 609, DSM 11273, ICMP 13648, LMG7837.

GenBank accession number (16S rRNA): X68390.

7. **Sinorhizobium terangae** de Lajudie, Willems, Pot, Dewettinck, Maestrojuan, Neyra, Collins, Dreyfus, Kersters, and Gillis 1994, 732^VP (*Sinorhizobium teranga* (sic) de Lajudie, Willems, Pot, Dewettinck, Maestrojuan, Neyra, Collins, Dreyfus, Kersters, and Gillis 1994, 732.)
te' ran.gae. N.L gen. n. *terangae* of *teranga* hospitality, in the language of West African Wolof people; referring to the isolation of this species from different host plants.

The characteristics are as described for the genus and as listed in Tables BXII.α.112 and BXII.α.113 in the chapter on the genus *Rhizobium*. Motile by one or several polar or subpolar flagella. Colonies are mucoid and spreading on yeast extract mannitol agar. Old colonies become brown. Can grow at 44°C. Utilizes a range of organic substrates as sole sources of carbon (Table BXII.α.113 in the chapter on the genus *Rhizobium*). Differentiated from other *Sinorhizobium* and *Rhizobium* species by DNA–DNA reassociation data, differences in protein profiles obtained by SDS-PAGE, and 16S rDNA sequence comparison.

Nodulates *Acacia* species (*A. senegal*, *A. laeta*, *A. tortilis* subsp. *raddiana*, *A. horrida*, *A. mollissima*) and *Sesbania* species (*S. rostrata*, *S. cannabina*, *S. aculeata*, *S. sesban*). Two biovars were distinguished based on the host range of strains (Lortet et al., 1996): *S. terangae* biovar sesbaniae for strains able to nodulate *Sesbania* species (*S. grandiflora*, *S. pubescens*, and *S. rostrata*) but not *Acacia* species (*A. senegal*, *A. tortilis* subsp. *raddiana*, and *A. nilotica*) nor *Leucaena leucocephala*; *S. terangae* biovar acaciae for strains able to nodulate *Acacia* species (*A. senegal*, *A. tortilis* subsp. *raddiana*, and *A. nilotica*) and *Leucaena leucocephala* but not *Sesbania* species (*S. grandiflora*, *S. pubescens*, and *S. rostrata*).

The mol% G + C of the DNA is: 60.8–61.6 (T_m).

Type strain: ORS 1009, DSM 11282, ICMP 13649, LMG 7834.

GenBank accession number (16S rRNA): X68391.

8. **Sinorhizobium xinjiangense** Chen, Yan and Li 1988b, 396^VP (*Sinorhizobium xinjiangensis* Chen, Yan and Li 1988b, 396.)
xin.jian.gen' se. M.L. adj. *xinjiangense* pertaining to the suburbs of Xinjiang, China.

The characteristics are as described for the genus and as listed in Table BXII.α.112 in the chapter on the genus *Rhizobium*. Motile by one polar flagellum or by 1–3 peritrichous flagella. Relatively fast growing: colonies are 2–4 mm in diameter after 3–5 days growth on yeast extract mannitol agar. Temperature growth optimum, 25–30°C. Most strains grow at 35°C and some grow at 10°C. Optimal pH for growth, 6.0–8.0; range, 5.0–10.5. Does not grow on YMA containing 1.5% NaCl, but some strains tolerate 4.5% NaCl.

The species was proposed based on nutritional and biochemical differences from *R. leguminosarum*, *S. fredii*, *S. meliloti*, *Agrobacterium tumefaciens*, and *A. rhizogenes*. 16S rDNA sequence similarities indicate a close relationship to *S. fredii*. The species differs from *S. fredii* in that, unlike *S. fredii*, *S. xinjiangense* cannot grow at low and high pH (<5.5 and >8.5 respectively). All strains of *S. xinjiangense* produce acid in litmus milk, and are sensitive to a number of antibiotics such as vancomycin (25 μg/ml), chloramphenicol (125 μg/ml), penicillin (25 μg/ml), and streptomycin (5 μg/ml). Isolated from *Glycine max*.

The mol% G + C of the DNA is: 60–64 (T_m).

Type strain: ATCC 49357, CCBAU 110, IAM 14142, ICMP 11141.

GenBank accession number (16S rRNA): D12796.

Family II. **Bartonellaceae** Gieszczykiewicz 1939, 25[AL]

DAVID F. WELCH

Bar.to.nel.la' ce.ae. M.L. fem. n. *Bartonella* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Bartonellaceae* the *Bartonella* family.

Small coccobacilli, may be beaded or filamentous and <3 μm in their greatest diameter. Erythrocytic forms stain lightly with many aniline dyes but distinctly with Giemsa's stain after methanol fixation. Gram negative, not acid-fast. Some species have polar flagella. Cultivable, but highly fastidious, *in vitro*, on blood-enriched bacteriological media. Arthropod transmission has been established. Etiological agents demonstrable in diverse clinical material from humans and erythrocyte-associated bacteria of other vertebrates. Cause bartonellosis, cat scratch disease, bacillary angiomatosis, endocarditis, trench fever, and a spectrum of other human inflammatory lesions.

On the basis of 16S rRNA gene sequence analysis, the family *Bartonellaceae* is in the *Alphaproteobacteria*. The genus *Bartonella* was removed from the order *Rickettsiales* and the family *Rickettsiaceae*, resulting in a single genus within the family *Bartonellaceae* (Brenner et al., 1993). The genus *Rochalimaea*, then contained within the family *Rickettsiaceae*, was at the same time combined with *Bartonella*, and subsequently *Grahamella* was merged with *Bartonella* (Birtles et al., 1995).

Type genus: **Bartonella** Strong, Tyzzer and Sellards 1915, 808 emend. Birtles, Harrison, Saunders and Molyneux 1995, 7.

Genus I. **Bartonella** *Strong, Tyzzer and Sellards 1915, 808[VP] emend. Birtles, Harrison, Saunders and Molyneux 1995, 7*

DAVID F. WELCH

Bar.to.nel' la. M.L. dim. ending *-ella*; M.L. fem. dim. n. *Bartonella* named after Alberto L. Barton, who described these organisms in 1909, after studying the agent of Carrion's disease.

Morphology is small (0.5–0.6 × 1.0 μm), **slightly curved bacillus**. Not acid-fast. **Faintly stains Gram negative** (stains poorly or not at all with many aniline dyes) but satisfactorily with Romanowsky's or Giemsa's stain. Warthin-Starry silver staining of fixed tissue sections reveals bacilli in clusters. May be seen in stained blood films appearing as rounded or ellipsoidal forms or as slender, straight, curved, or bent rods, occurring singly or in groups. They characteristically occur in chains of several segmenting organisms, sometimes swollen at one or both ends and frequently beaded. In the tissues, they are situated **within the cytoplasm of endothelial cells** as isolated elements or are grouped in rounded masses. **Intraerythrocytic forms occur** in the blood of felines, small rodents, birds, fish, and other animals. In cultures, the cells may be very **autoadherent**. Some species possess unipolar flagella. **The presence of pili** is associated with the marked adherence and may mediate specific interaction with host endothelial cells and erythrocytes leading to intracellular localization.

Aerobic but **highly fastidious**. May be cultivated on media enriched with blood components in the presence of air or 5% CO_2. **Growth occurs at 20–37°C after prolonged incubation** (7–21 d). No growth on MacConkey or nutrient agars. Cocultivation with an endothelial cell line can also be performed and this method may be more successful in recovering organisms from specimens such as tissue. There are **numerous reservoirs and vectors** for *Bartonella* spp. The organisms are transmitted by arthropod vectors (*Lutzomyia verrucarum*, *Pediculus humanus*, *Ctenocephalides felis* [*Siphonaptera pulicidae*], and possibly ticks); *B. bacilliformis* is found only in the Andes region of South America. Etiological agents of human bartonellosis, cat scratch disease, bacillary angiomatosis, peliosis hepatis, trench fever, endocarditis, and neuroretinitis. **Six species cause *Bartonella*-associated infectious diseases in humans.** The organisms are usually catalase and oxidase negative, aerobic, and they do not produce acid from carbohydrates. *Bartonella* spp. have relatively simple gas–liquid chromatography profiles consisting mainly of $C_{18:1}$, $C_{18:0}$, and $C_{16:0}$ acids. A portion of the 16S–23S rRNA intergenic spacer region can be targeted with primers that can distinguish *Bartonella* from other genera including those closely related within the *Alphaproteobacteria*.

The mol% G + C of the DNA is: 37–41.

Type species: **Bartonella bacilliformis** (Strong, Tyzzer, Brues, Sellards and Gastiaburu 1913) Strong, Tyzzer and Sellards 1915, 808 (*Bartonia bacilliformis* Strong, Tyzzer, Brues, Sellards and Gastiaburu 1913, 1715.)

FURTHER DESCRIPTIVE INFORMATION

Stained blood films have been used to detect intraerythrocytic *B. bacilliformis* in patients with Oroya fever. Bacilli may be demonstrated by use of the Warthin-Starry silver stain during the early stages of lymphadenopathy in cat scratch disease due to *B. henselae*, but typically not during the later granulomatous stage of inflammation. When seen in blood smears, *B. bacilliformis* consists of small, polymorphic forms. The maximum morphological range is seen in the blood of man, where the organisms appear as red–violet rod or coccal forms situated on or in the red cells when stained with Giemsa's stain. Bacilliform bodies are the most typical, measuring 0.25–0.5 × 1.0–3.0 μm. The cells are often curved and may show polar enlargement and granules at one or both ends. Rounded organisms measure ~0.75 μm in diameter and a ring-like variety is sometimes abundant. By light microscopy or by "stripping" in the pseudoreplica technique for electron microscopy (Peters and Wigand, 1955), the organisms appear to be situated on the surface of erythrocytes; however, they have also been reported to occur within erythrocytes in thin sections observed by electron microscopy (Cuadra and Takano, 1969). The Gram stain of a colony from solid media reveals small, Gram-negative, slightly curved rods resembling *Campylobacter*, *Helicobacter*, or *Haemophilus*. Cells, especially of *B. henselae*, are very autoadherent, as can be demonstrated by attempting to scrape colonies off a culture plate with a loop. In semisolid media, a mixture of rods and granules appears. The organisms may occur singly or in large and small, irregular, dense collections measuring up to 25 μm or more in length. Punctiform, spindle-

shaped, and ellipsoidal forms that vary in size from 0.2–0.5 × 0.3–3.0 μm also occur.

The organisms have a trilaminar cell wall, the formation of which can be inhibited by penicillin. The cellular fatty acid composition among *Bartonella* spp. is relatively simple, compared to that of many other Gram-negative bacteria, in that they have gas–liquid chromatography profiles consisting mainly of $C_{18:1}$, $C_{18:0}$, and $C_{16:0}$ acids. *B. elizabethae* and *B. vinsonii* contain a greater amount of $C_{17:0}$ than the other species. *B. bacilliformis* contains a significant amount of $C_{16:1}$. An unusual branched-chain fatty acid (11-methyloctadec-12-enoic acid) is found in *Afipia* spp. but not in *Bartonella* spp., and *Brucella* spp. contain a relatively large amount of $C_{19:0}$ cyclopropane acids. In culture, the cells of two species (*B. bacilliformis* and *B. clarridgeiae*) possess a tuft of 1–10 unipolar flagella (Peters and Wigand, 1955; Lawson and Collins, 1996a). Other species, especially *B. henselae*, *B. alsatica*, and *B. tribocorum*, have pili. Phenotypically similar to type 4 pili, they mediate adherence to and entry into human epithelial cells (Batterman et al., 1995). Flagella have not been demonstrated in tissues, but the pili have been.

Bartonella spp. demonstrate various colonial morphologic types, from clear (*B. bacilliformis*) to smooth white (*B. quintana* and *B. alsatica*) to rough tan (*B. henselae* and *B. tribocorum*). Several species embed in the agar. Colonies of *B. henselae* are typically of two types: (i) irregular, raised, whitish, rough (cauliflower or molar tooth or verrucous), and dry in appearance or (ii) smaller, circular, tan, and moist in appearance, tending to pit and adhere to the agar. Both types are usually present in the same culture (Fig. BXII.α.137). The degree of colonial heterogeneity varies by species and by strain, and is probably related to the degree of piliation. Repeated subcultures of *B. henselae* tend to have increasing proportions of smooth colonies. *B. quintana* may appear as uniformly smooth colonies in primary cultures. Cultures of *B. henselae* on blood agar may produce an odor similar to the caramel odor (diacetyl) produced by *Streptococcus milleri*.

The majority of isolates require more than 7 days of incubation before they can be detected by culture. A source of blood or hemoglobin in the medium is necessary in most cases. *B. bacilliformis* may be cultivated in semisolid agar containing fresh rabbit serum and rabbit hemoglobin or containing the blood of human, horse, or rabbit, with and without the addition of fresh tissue and carbohydrates. It may also be cultivated in other culture media containing blood, serum, or plasma, in Huntoon's hormone agar, in semisolid gelatin media, and in blood–glucose–cysteine agar. It can also be grown in certain tissue cultures and in the chorioallantoic fluid and yolk sac of the chicken embryo. The other species can be recovered on blood or chocolate agar media as well.

Bartonella spp. are typically inert biochemically. In conventional carbohydrate utilization tests no acid or gas production occurs from amygdalin, L-arabinose, dextrin, dulcitol, fructose, D-galactose, D-glucose, inulin, lactose, maltose, D-mannitol, D-mannose, raffinose, L-rhamnose, salicin, sucrose, trehalose, or D-xylose. Gelatin is not liquefied. Esculin is not hydrolyzed. H_2S is not detected with lead acetate.

Bartonella is a monophyletic genus within the *Alphaproteobacteria*. Species of *Bartonella* are animal cell associated but closely related to the plant cell associated genera, *Agrobacterium* and *Rhizobium*. Common pathogenic domains necessary for invasion and survival in association with cells have been preserved in the chromosomes of both the animal- and plant-associated *Alphaproteobacteria*. These have evolved through reductions of the larger genomes, including a second chromosome in some instances, of chemoautotrophic ancestors (Moreno, 1998). There is also a high level (~95%) of similarity between *Bartonella* and *Brucella* according to 16S rRNA gene sequence analysis (Brenner et al., 1993). Phylogenetic analysis of *Bartonella* species can be done based on either 16S rRNA or citrate synthase (*gltA*) gene sequencing. The latter has been compared to 16S rRNA gene sequence analysis and some investigators (Birtles and Raoult, 1996) believe the *gltA*-derived phylogeny is more useful than the phylogeny derived from 16S rDNA sequence data for investigating the evolutionary relationships of *Bartonella* species. The *gltA* method may result in amplification of two products of differing

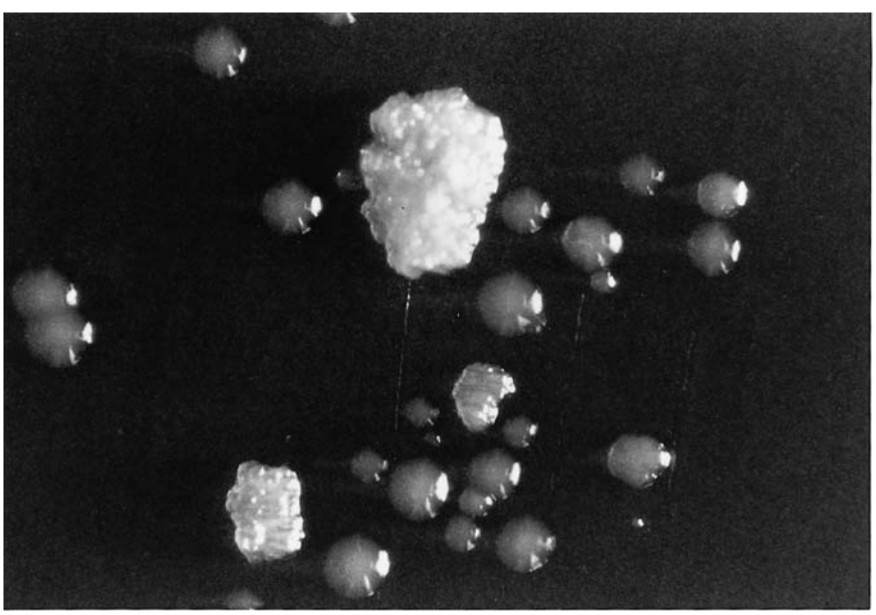

FIGURE BXII.α.137. Colonies of *Bartonella henselae* (40× magnification), showing heterogeneous mixture of smooth and rough types.

sizes from *B. bacilliformis* (Birtles, 1995). Limited work with heat shock protein (groEL) genes of some *Bartonella* species has also been conducted, leading to similar phylogenetic conclusions (Haake et al., 1997).

A portion of the 16S rDNA consisting of 241 nucleotides can be amplified using primers p24E and p12B (Relman et al., 1990a). Signature sequences, e.g., a 3 base pair difference between *B. quintana* and *B. henselae* (Koehler et al., 1992), occur within this fragment.

A genus-specific primer set targeting the internal portions of the 16S–23S intergenic spacer region can distinguish *Bartonella* species from other *Alphaproteobacteria*, including *Brucella abortus*, *Agrobacterium tumefaciens*, and *Rhizobium meliloti* (Minnick and Barbian 1997). These investigators also developed species-specific primers. Distinguishing among isolates of the same species using DNA fingerprinting methods has been applied mainly with *B. henselae*. Pulsed-field gel electrophoresis (PFGE), 16S rRNA type-specific PCR, enterobacterial repetitive intergenic consensus (ERIC)-PCR, repetitive extragenic palindromic (REP) PCR, and arbitrarily primed (AP)-PCR have all been used to clearly distinguish several subtypes (Sander et al., 1998). These methods provide useful epidemiological tools and demonstrate a high degree of genetic heterogeneity.

FtsZ proteins (the highly conserved cell division protein) of *B. bacilliformis*, *B. henselae*, and *B. quintana* are about twice as large as the FtsZ proteins reported in most other organisms. The amino acid sequences of *B. henselae* and *B. quintana ftsZ* are 81–83% identical to the corresponding protein in *B. bacilliformis*, suggesting that localized differences within the sequence of the *Bartonella ftsZ* genes may be used as the basis for species-specific identification (Kelly et al., 1998b). *B. henselae* harbors a bacteriophage that has been cloned and sequenced (Anderson et al., 1997; Bowers et al., 1998). Associated with the bacteriophage is a 31-kDa major protein (Pap31) that is targeted to the cell membrane. *B. vinsonii* subsp. *berkhoffii* contains a 12-base insertion sequence in the 16S rRNA gene that is not present in other *Bartonella* species (Kordick et al., 1996).

The FtsZ protein is antigenic in *B. bacilliformis* and in *B. henselae* due to its partial exposure at the cell surface (Padmalayam et al., 1997). Antigenicity is species and strain specific as indicated by the lack of cross-protection between *B. henselae* and *B. clarridgeiae* and the lack of protection between *B. henselae* types I, II, and a wildlife strain (Yamamoto et al., 1998). On the other hand, serological cross-reactions do occur between species and with the genera *Chlamydia* and *Bartonella*. Maurin et al. (1997) reported eight patients originally diagnosed as having *Chlamydia pneumoniae* endocarditis whose sera reacted with *B. quintana* antigens in a microimmunofluorescence technique. Adsorption of sera with *B. quintana* or *C. pneumoniae* antigens removed anti-*C. pneumoniae* antibodies, whereas adsorption with *C. pneumoniae* antigens did not change antibody titers to *B. quintana*. There is also cross reactivity between *B. henselae* and *Coxiella*. La Scola and Raoult (1996b) demonstrated that >50% of chronic Q fever patients they studied had antibodies that reacted significantly against *B. henselae* antigen.

Agglutination of suspensions of *B. bacilliformis* by sera from convalescent patients has been reported. Immune sera fix complement in the presence of the organisms. When various isolates have been employed, no significant titer differences have been found in quantitative tests. Immune rabbit sera do not agglutinate *Proteus* strains OX19, OX2, or OXK at titers above 1:20. Serodiagnosis of cat scratch disease by indirect immunofluorescence or enzyme immunoassay is a practical technique and carries a sensitivity of approximately 85% and a specificity of approximately 95%. IgM reactivity is directed to an 8-kDa band and IgG to 209-, 208.5-, 208-, 116-, and 80-kDa bands by Western blot analysis of *B. henselae* serum samples (Litwin et al., 1997).

Bartonella spp. generally display high levels of *in vitro* susceptibility to antibacterial agents. Agar dilution testing shows resistance only to fosfomycin, colistin, and vancomycin (Maurin et al., 1995). *B. bacilliformis* is resistant *in vivo* to neosalvarsan and to other arsenical compounds in general. It is sensitive to penicillin, streptomycin, chloramphenicol, and oxytetracycline. Oral chloramphenicol is the standard treatment for *B. bacilliformis* infection. When grown with penicillin, the organism produces L forms (Sharp, 1968). *B. henselae*, *B. quintana*, and *B. elizabethae* are susceptible to the macrolides azithromycin, clarithromycin, dirithromycin, erythromycin, and roxithromycin based on testing in Vero cell cultures (Ives et al., 1997). Agents that should be considered in therapy of cat scratch disease include azithromycin or rifampin. In the initial antimicrobial treatment of hepatosplenic cat-scratch disease in children, rifampin therapy, initiated alone or in combination, results in improvement within 1–5 days (Arisoy et al., 1999). A placebo-controlled clinical study showed that azithromycin caused an 80% decrease in initial lymph node volume in 7 of 14 azithromycin-treated cat scratch disease patients during the first 30 days of observation (Bass et al., 1998). Erythromycin, doxycylcine, or ciprofloxacin is recommended for therapy of bacillary angiomatosis.

B. bacilliformis, *B. quintana*, *B. henselae*, and *B. elizabethae* are the primary pathogenic species in humans. *B. clarridgeiae*, originally isolated from a domestic cat, may cause lymphadenopathy in humans (Kordick et al., 1997). *B. vinsonii* is potentially pathogenic, as documented by a human isolate of *B. vinsonii* subsp. *arupensis* (Welch et al., 1999). *B. henselae* and *B. clarridgeiae* were discovered during the 1990s, largely in the course of testing for opportunistic infections in human immunodeficiency virus (HIV)-infected individuals. In recent years, *B. quintana* bacteremic infection (trench fever) in the absence of HIV has been identified sporadically, mainly in homeless persons in North America and Europe, but it was a major cause of morbidity during WW I. There is archeological evidence for pre-Colombian existence of bartonellosis due to *B. bacilliformis* in South America. The spectrum of diseases caused by *Bartonella* spp. other than *B. bacilliformis* includes trench fever, cat scratch disease, bacillary angiomatosis, bacillary peliosis, relapsing bacteremia, endocarditis, lebers neuroretinitis, and aseptic meningitis (Wong et al., 1995a; Raoult et al., 1996).The mechanism of pathogenesis by which *Bartonella* spp. cause disease is not fully understood. A central feature is an effect that causes proliferation of microvascular endothelial cells and neovascularization (angiogenesis). Surface-exposed determinants such as adhesins and other outer membrane proteins are of substantial importance in the pathogenesis (Burgess and Anderson, 1998). A process of adherence, followed by invasion of feline erythrocytes, is involved in establishing long-term bacteremia in cats (Mehock et al., 1998). Intracellular localization of *B. quintana* has been demonstrated *in vivo* and within endothelial cell cultures (Brouqui and Raoult, 1996). Upon engulfment by human endothelial cells, the organisms appear in vacuoles similar to the morulae seen in ehrlichiae- or chlamydiae-infected cells. *B. vinsonii* subsp. *vinsonii*, *B. grahamii*, *B. taylorii*, and *B. doshiae* were isolated from small wild mammals. *B. vinsonii* subsp. *berkhoffii* was isolated from a dog with endocarditis and *B. vinsonii* subsp. *arupensis* was isolated from

naturally infected mice and a man with a febrile illness. Human bartonellosis is a classically biphasic disease caused by *B. bacilliformis* and manifested as a progressive anemia (Oroya fever) followed by a cutaneous eruption (Verruga Peruana). While typical bartonellosis has remained endemic for the past century in highland provinces near the Peruvian border, there have recently been an increasing number of atypical cases in which monophasic verrucous cutaneous disease is the only clinical manifestation (Amano et al., 1997). These cases consist of mild clinical disease, possibly associated with less virulent bacterial strains.

The transmission of Oroya fever is dependent on the ecology of the sand fly (*Phlebotominae*: *Lutzomyia verrucarum*) vector and is therefore typically confined to an elevation of 2500–8000 feet above sea level in a band less than 100 miles wide and ~1000 miles long on the western slopes of the Andes mountains in Peru, Ecuador, and Colombia. However, the atypical cases tend to now be disseminating or re-emerging in previously disease-free areas.

Experimental Oroya fever has not been successfully produced in animals, except rarely in an atypical form in monkeys. Experimental Verruga Peruana has been produced in man and in a number of species of monkeys. The other species of *Bartonella* are less geographically confined. The vector of *B. quintana* is *Pediculus humanus*, the human body louse. Outbreaks of trench fever (also known as Volhynia fever, Meuse fever, His-Werner disease, shinbone fever, shank fever, and quintan or five-day fever) therefore occur focally, often associated with conditions of poor sanitation and personal hygiene that may predispose to exposure to lice. Nonhuman vertebrate reservoirs have not been identified for *B. bacilliformis*, *B. quintana*, or *B. elizabethae.* No arthropod vector has been identified for *B. elizabethae. B. henselae* or *B. clarridgeiae* can induce chronic infection in specific-pathogen-free cats (Guptill et al., 1998, Kordick et al., 1999). There may be minimal clinical signs but histological changes occur and *Bartonella* DNA can be detected in tissues, supporting an etiologic role for *Bartonella* species in idiopathic diseases of cats. *B. henselae* also causes reproductive failure in female cats, but has not been found to be vertically transmitted. In contrast, evidence does suggest the possibility of vertical transmission of *Bartonella* spp. among natural rodent hosts (Kosoy et al., 1998). Stray cats are a major reservoir of *Bartonella* spp., which can be transmitted to pet cats and, consequently, to humans (Heller et al., 1997). It has been demonstrated that the cat flea readily transmits *B. henselae* to cats (Chomel et al., 1996). Cats are also the reservoir for *B. clarridgeiae* and *B. koehlerae.* Mice, voles, and rats carry subspecies of *B. vinsonii. Bartonella* can be detected in various rodent populations, most of which are also reservoirs of tick-borne pathogens such as *Borrelia burgdorferi*, *Ehrlichia* spp., and *Babesia microti* (Kosoy et al., 1997; Hofmeister et al., 1998). These observations, along with the case reports of bacteremia due to *B. henselae* in men who had sustained tick bites prior to their illnesses (Lucey et al., 1992), suggest that *Bartonella* spp. may also be transmitted by ticks. Schouls et al. (1999) have also found *Bartonella* DNA in a high proportion of an *Ixodid* tick population.

Enrichment and Isolation Procedures

The specimen source of most isolates of *Bartonella* is blood or tissue. The fastidious nature of these organisms requires that precautions be taken to minimize delayed attempts at isolation. If storage of specimens is necessary, they should be kept frozen. Blood collected in tubes containing EDTA can be plated after 26 d at −65°C with no loss of sensitivity (Brenner et al., 1997). Blood-lysis tubes (Isolator; Wampole, Cranbury, NJ) yield good recovery from freshly collected specimens (Welch et al., 1992). *Bartonella* spp. have been isolated using agar, in semisolid media, and in broth. Broth-based systems generally tend to have lower sensitivity. If a broth-based blood culture system that relies on CO_2 detection to indicate growth is used, it should be combined with acridine orange staining at the end of a 7-d incubation and subculture to solid media (Spach et al., 1995). Combining the subculture of blood culture broth into shell vials has been reported to produce sensitivity of 71% for recovery of *B. quintana* or *B. henselae* from patients with endocarditis, bacillary angiomatosis, and lymph nodes of cat scratch disease and no prior antibiotic therapy (La Scola and Raoult, 1999b). The sensitivity of culture was still low when compared with that of PCR-based detection or serological methods of diagnosis. A modified RPMI 1640 medium has also been described by Wong et al. (1995b) for recovery of *B. henselae* from both tissue and blood. Isolator-processed blood should be plated on enriched (chocolate- or blood-containing) medium incubated at 35–37°C (30°C for *B. bacilliformis*) under conditions of 5–10% CO_2 and >40% humidity. For optimal recovery, the medium should be as freshly prepared as possible. Plates should be sealed after the first 24 h of incubation to preserve the moisture content of the medium. Isolates have been obtained from liver, spleen, lymph node, and skin after homogenization either by direct plating or by cocultivation with an endothelial cell line (Koehler et al., 1992). The cocultivation method may be more successful in recovering organisms from tissue specimens. Selective culture techniques have not been developed, so recovery of isolates from contaminated specimens may not be possible. During Oroya fever, the organisms can be isolated from blood and from endothelial cells of lymph nodes, spleen, and liver. In cases of Verruga Peruana, they are found in the blood and in the eruptive lesions. The organisms can also be isolated from the sand fly vector (*Phlebotomus* spp.). Other species have also been isolated from their respective arthropod vectors, and *B. henselae* is readily isolated from the blood of cats. In human cases of cat scratch disease, attempts at isolating the organism are rarely successful.

Maintenance Procedures

Viability of cultures can usually be maintained by passage on blood or chocolate agar at biweekly intervals. During serial transfers, the greatest longevity of *B. bacilliformis* is achieved at a temperature of 28°C. Cultures of this and the other species are best maintained during storage at −70°C in a blood- or hemoglobin-containing medium. Long-term storage is best accomplished by lyophilization. Retrieval of viable cultures that have been lyophilized may be enhanced by suspending dried cells in a blood–broth mixture followed by culture on fresh blood agar media.

Differentiation of the genus *Bartonella* from other genera

The organism originally described as the cat scratch bacillus (*Afipia felis*) is distinct genotypically and phenotypically from *Bartonella* spp. It is ~90% related to *Bartonella* based on 16S rRNA gene sequence similarity. See Table BXII.α.119 for additional characteristics useful in differentiating the *Bartonella* spp. from the genus *Afipia.* Another organism found in the blood of cats and similarly confused in the past with *Bartonella*, *Haemobartonella felis*, can now be clearly identified using a set of *H. felis*-specific primers that selectively amplify a 1316-bp DNA fragment of the 16S rRNA gene of *H. felis* (Messick et al., 1998).

(*continued*)

Taxonomic Comments

Bartonella is the only genus of the family *Bartonellaceae* within the *Alphaproteobacteria*. *B. bacilliformis* was the original and only member of the genus until 1993. The genus *Rochalimaea* was then united with the genus *Bartonella* in the family *Bartonellaceae* based on a proposal by Brenner et al. (1993). 16S rRNA gene sequence data and DNA hybridization data revealed high levels of relatedness between *Bartonella bacilliformis* and the four *Rochalimaea* species, indicating that these species were members of a single genus. The name *Bartonella* was retained as the genus name since it had nomenclatural priority over the name *Rochalimaea*. More recently, the genera of *Grahamella* and *Bartonella* were merged, and at present, 16 species/subspecies belong to the genus. The former *Rochalimaea* and, subsequently, *Grahamella* spp. were uni-

fied as *Bartonella* based on DNA–DNA hybridization data showing that they were not as closely related as previously thought to members of the order *Rickettsiales* (Brenner et al., 1993).

There are a number of unclassified isolates, mostly recovered from rodents, presumed to be *Bartonella* spp. based on 16S rRNA gene sequence data. Further growth in the number of species and subspecies in the genus is thus expected to occur in the future.

ACKNOWLEDGMENTS

This description of the genus *Bartonella* contains information presented by Miodrag Ristic and Julius P. Kreier in the first edition of this *Manual*.

List of species of the genus Bartonella

1. **Bartonella bacilliformis** (Strong, Tyzzer, Brues, Sellards and Gastiaburú 1913) Strong, Tyzzer and Sellards 1915, 808[AL] (*Bartonia bacilliformis* Strong, Tyzzer, Brues, Sellards and Gastiaburú 1913, 1715.)
ba.cil.li.for′ mis. L. dim. n. *bacillus* a small staff, rodlet; L. n. *forma* shape, form; M.L. adj. *bacilliformis* rod-shaped.

Displays characteristics of the genus *Bartonella*. Optimal growth occurs at 25–28°C on enriched media. Cells have 1–10 polar flagella; some may have subpolar or lateral flagella. Etiologic agent of Carrion's disease (Oroya fever, Verruga Peruana). Other characteristics useful in identification are shown in Table BXII.α.119.

Genome size is 4×10^8 Da.

The mol% G + C of the DNA is: 39 (T_m).

Type strain: ATCC 35685.

GenBank accession number (16S rRNA): Z11683.

Additional Remarks: The neoptype strain ATCC 35685 was proposed by Brenner et al. (1991b).

2. **Bartonella alsatica** Heller, Kubina, Mariet, Riegel, Desacour, Dehio, LaMarque, Kasten, Boulouis, Mounteil, Chomel and Piémont 1999, 287[VP]
al.sa′ ti.ca. L. adj. *alsatica* from Alsace, the region in eastern France near the Rhine River where wild rabbits, from which strains of the species were isolated and identified, were trapped.

Displays characteristics of the genus *Bartonella*. Colonies grown on blood agar appeared after 10 d as small, white, smooth, regular colonies (diameter ~1 mm). Additional characteristics useful in Identification are shown in Table BXII.α.119.

The mol% G + C of the DNA is: 37 (capillary electrophoresis).

Type strain: IBS 382, CIP 105477.

GenBank accession number (16S rRNA): AJ002139.

3. **Bartonella birtlesii** Bermond, Heller, Barrat, Delacour, Dehio, Alliot, Monteil, Chomel, Boulouis and Piémont 2000, 1978[VP]
birt.les′ i.i. M.L. gen. n. *birtlesii* of Richard J. Birtles, whose studies have contributed to an improved understanding of the taxonomy of the genus.

The mol% G + C of the DNA is: not determined.

Type strain: IBS 325, CIP 106294, CCUG 44360.

GenBank accession number (16S rRNA): AF204274.

4. **Bartonella clarridgeiae** Lawson and Collins 1996b, 836[VP] (Effective publication: Lawson and Collins 1996a, 71.)
clar.ridge′ i.a.e. M.L. fem. adj. *clarridgeiae* named in honor of Jill E. Clarridge III, the microbiologist who first isolated the organism, in Houston, Texas.

Displays characteristics of the genus *Bartonella*. Possesses polar flagella. Additional characteristics useful in identification are shown in Table BXII.α.119.

The mol% G + C of the DNA is: not determined.

Type strain: Houston-2 cat, ATCC 51734.

GenBank accession number (16S rRNA): X89208.

5. **Bartonella doshiae** Birtles, Harrison, Saunders and Molyneux 1995, 7[VP]
do′ shi.ae. M.L. gen. n. *doshiae* named in honor of Nivedita Doshi, who was technically responsible for work with *Legionella* and *Bartonella* at the Central Public Health Laboratory in London.

Displays characteristics of the genus *Bartonella*. Additional characteristics useful in identification are shown in Table BXII.α.119.

The mol% G + C of the DNA is: 41 (T_m).

Type strain: R18, ATCC 700133, NCTC 12862.

GenBank accession number (16S rRNA): Z31351.

6. **Bartonella elizabethae** (Daly, Worthington, Brenner, Moss, Hollis, Weyant, Steigerwalt, Weaver, Daneshvar and O'Connor 1993) Brenner, O'Connor, Winkler and Steigerwalt 1993, 785[VP] (*Rochalimaea elizabethae* Daly, Worthington, Brenner, Moss, Hollis, Weyant, Steigerwalt, Weaver, Daneshvar and O'Connor 1993, 880.)
e.liz′ a.beth.a.e. M.L. fem. adj. *elizabethae* named after St. Elizabeth's Hospital in Brighton, Massachusetts, where the organism was isolated.

Displays characteristics of the genus *Bartonella*. There is incomplete hemolysis on rabbit blood agar. Additional characteristics useful in identification are shown in Table BXII.α.119. Etiologic agent of endocarditis and neuroretinitis.

The mol% G + C of the DNA is: 41 (T_m).

Type strain: F9251, B91-002005, ATCC 49927.

GenBank accession number (16S rRNA): L01260.

7. **Bartonella grahamii** Birtles, Harrison, Saunders and Molyneux 1995, 7[VP]
gra.ham′ i.i. M.L. gen. n. *grahamii* of Graham, named in honor of G.S. Graham-Smith who observed the organisms subsequently named *Grahamella* in the blood of moles.

Displays characteristics of the genus *Bartonella*. Additional characteristics useful in identification are shown in Table BXII.α.119.

The mol% G + C of the DNA is: 40 (T_m).

Type strain: V2, ATCC 700132, NCTC 12860.

GenBank accession number (16S rRNA): Z31349.

8. **Bartonella henselae** (Regnery, Anderson, Clarridge, Rodriguez-Barradas and Jones 1992) Brenner, O'Connor, Winkler and Steigerwalt 1993, 785[VP] (*Rochalimaea henselae* Regnery, Anderson, Clarridge, Rodriguez-Barradas and Jones 1992, 272.)
hen' sel.a.e. M.L. gen. n. *henselae* named in honor of Diane M. Hensel, who isolated many of the original strains detected in bacteremic patients from Oklahoma.

Displays characteristics of the genus *Bartonella.* Additional characteristics useful in identification are shown in Table BXII.α.119. Etiologic agent of septicemia in immunocompromised hosts, endocarditis, bacillary angiomatosis, peliosis hepatis, cat scratch disease, and HIV-associated neurological syndromes.
The mol% G + C of the DNA is: 41 (T_m).
Type strain: Houston-1, G5436, ATCC 49882.
GenBank accession number (16S rRNA): M73229.

9. **Bartonella koehlerae** Droz, Chi, Horn, Steigerwalt, Whitney and Brenner 2000, 423[VP] (Effective publication: Droz, Chi, Horn, Steigerwalt, Whitney and Brenner 1999, 1122.)
koeh' ler. ae. M.L. fem. adj. *koehlerae* named in honor of Jane E. Koehler, who was the first to isolate *Bartonella* species from bacillary angiomatosis lesions and whose studies of *B. quintana* and *B. henselae* isolates from human immunodeficiency virus-infected patients have contributed to an improved understanding of *Bartonella*-associated disease in humans.

Displays characteristics of the genus *Bartonella.* Growth is optimal on chocolate agar, and primary colonies are observed after 14 d of incubation at 35°C in a CO_2-enriched environment. Additional characteristics useful in identification are shown in Table BXII.α.119.
The mol% G + C of the DNA is: not determined.
Type strain: C-29, ATCC 700693.
GenBank accession number (16S rRNA): AF076237.

10. **Bartonella peromysci** (Ristic and Kreier 1984b) Birtles, Harrison, Saunders and Molyneux 1995, 7[VP] (*Grahamella peromysci* (ex Tyzzer 1942) Ristic and Kreier 1984b, 719.)
pe.ro.mys' ci. M.L. gen. n. *peromysci*, of *Peromyscus* a genus of mice.

Displays characteristics of the genus *Bartonella.* Additional characteristics useful in identification are shown in Table BXII.α.119. Distinguished from *B. talpae* by the host specificity.
The mol% G + C of the DNA is: unknown.
Type strain: No type strain available.

11. **Bartonella quintana** (Schmincke 1917) Brenner, O'Connor, Winkler and Steigerwalt 1993, 784[VP] (*Rochalimaea quintana* (Schmincke 1917) Krieg 1961, 163; *Rickettsia quintana* Schmincke 1917, 961.)
quin.ta' na. M.L. fem. adj. *quintana* fifth, referring to 5-day fever and the clinical disease produced by the species.

Displays characteristics of the genus *Bartonella.* Etiologic agent of trench fever, bacillary angiomatosis, and septicemia. Additional characteristics useful in identification are shown in Table BXII.α.119.
The mol% G + C of the DNA is: 40 (T_m).
Type strain: ATCC VR-358.
GenBank accession number (16S rRNA): M11927, M73228.

12. **Bartonella talpae** (Ristic and Kreier 1984b) Birtles, Harrison, Saunders and Molyneux 1995, 7[VP] (*Grahamella talpae* (ex Brumpt 1911) Ristic and Kreier 1984b, 719.)
tal' pae. M.L. gen. n. *talpae* of *Talpa*; M.L. fem. n. a genus of moles.

Displays characteristics of the genus *Bartonella.* Additional characteristics useful in identification are shown in Table BXII.α.119. Distinguished from *B. peromysci* by the host specificity.
The mol% G + C of the DNA is: unknown.
Type strain: No type strain is available.

13. **Bartonella taylorii** Birtles, Harrison, Saunders and Molyneux 1995, 7[VP]
tay.lor' i.i. M.L. gen. n. *taylorii* of Taylor, named in honor of A.G. Taylor who led various microbiologic studies at the Central Public Health Laboratory in London.

Displays characteristics of the genus *Bartonella.* Additional characteristics useful in identification are shown in Table BXII.α.119.
The mol% G + C of the DNA is: 41 (T_m).
Type strain: M6, NCTC 12861.
GenBank accession number (16S rRNA): Z31350.

14. **Bartonella tribocorum** Heller, Riegel, Hansmann, Delacour, Bermond, Dehio, Lamarque, Monteil, Chomel and Piémont 1998, 1338[VP]
tri.bo.co' rum. L. n. gen. pl. *Triboci* the tribes, mentioned by Caesar (51 BC) in his *Commentarii de Bello Gallico*, which were living in the region near the Rhine River in eastern France. Wild rats, from which two strains of the species were isolated, were trapped there.

Displays characteristics of the genus *Bartonella.* Colonies grown on blood agar appear as small, white, smooth, regular colonies (~1 mm diameter) after 10 d. Electron microscopic examination shows small bacilli without flagella, approximately 1–2 × 0.5 μm. Additional characteristics useful in identification are shown in Table BXII.α.119.
The mol% G + C of the DNA is: 38 (capillary electrophoresis).
Type strain: IBS 506, CIP 105476.
GenBank accession number (16S rRNA): AJ003070.

15. **Bartonella vinsonii** (Weiss and Dasch 1982) Brenner, O'Connor, Winkler and Steigerwalt 1993, 785[VP] emend. Kordick, Swaminathan, Greene, Wilson, Whitney, O'Connor, Hollis, Matar, Steigerwalt, Malcolm, Hayes, Hadfield, Breitschwerdt and Brenner 1996, 708 (*Rochalimaea vinsonii* Weiss and Dasch 1982, 313.)
vin.so' ni.i. N.L. gen. n. *vinsonii* named in honor of J. William Vinson who, with Henry S. Fuller, originally demonstrated that *Bartonella vinsonii* subsp. *vinsonii* (*Rochalimaea vinsonii*) could be grown on blood agar.

The mol% G + C of the DNA is: See subspecies data below.
Type strain: See subspecies below.

a. **Bartonella vinsonii** *subsp.* **vinsonii** (Weiss and Dasch 1982) Brenner, O'Connor, Winkler and Steigerwalt 1993, 785[VP] emend. Kordick, Swaminathan, Greene, Wilson, Whitney, O'Connor, Hollis, Matar, Steigerwalt, Malcolm, Hayes, Hadfield, Breitschwerdt and Brenner 1996, 708 (*Bartonella vinsonii* (Weiss and Dasch 1982) Brenner, O'Connor, Winkler and Steigerwalt 1993, 785; *Rochalimaea vinsonii* Weiss and Dasch 1982, 313.)

Displays characteristics of the genus *Bartonella*. Additional characteristics useful in identification are shown in Table BXII.α.119. Vole is the animal host (also known as the "Canadian vole agent").

The mol% G + C of the DNA is: 41 (T_m) (Daly et al., 1993).

Type strain: ATCC VR-152.

GenBank accession number (16S rRNA): L01259, Z31352.

b. **Bartonella vinsonii** *subsp.* **arupensis** Welch, Carroll, Hofmeister, Persing, Robison, Steigerwalt and Brenner 2000, 3[VP] (Effective publication: Welch, Carroll, Hofmeister, Persing, Robison, Steigerwalt and Brenner 1999, 2601.)
a.rup.en' sis. N.L. fem. adj. *arupensis* coming from ARUP (Associated Regional and University Pathologists, Inc.) in Salt Lake City, Utah, the laboratory where the type strain was initially characterized.

Exhibits characteristics of the species *Bartonella vinsonii*. Grows on heart infusion agar in the presence of X factor. Other characteristics useful in identification are shown in Table BXII.α.119. Isolated from a human and mice (*Peromyscus leucopus*). Presumptively pathogenic for humans.

The mol% G + C of the DNA is: not determined.

Type strain: OK 94-513, ATCC 700727, isolated from a 62-year-old bacteremic man.

GenBank accession number (16S rRNA): U71322.

Additional Remarks: Other reference strain, UMB (Hofmeister et al., 1998, 413).

c. **Bartonella vinsonii** *subsp.* **berkhoffii** Kordick, Swaminathan, Greene, Wilson, Whitney, O'Connor, Hollis, Matar, Steigerwalt, Malcolm, Hayes, Hadfield, Breitschwerdt and Brenner 1996, 908[VP]
berk.hof' fi.i. M.L. gen. n. *berkhoffii* named in honor of Herman A. Berkhoff, a veterinary microbiologist whose research contributed to the understanding of *Bartonella* infections in domestic animals and recognition of this subspecies.

Exhibits characteristics of the species *Bartonella vinsonii*. Can be distinguished from *Bartonella vinsonii* subsp. *vinsonii* by DNA methods. 16S rRNA gene contains an insertion sequence designated I1-I12 in the variable region V2. Other characteristics useful in identification are shown in Table BXII.α.119. Etiologic agent of canine endocarditis.

The mol% G + C of the DNA is: not determined.

Type strain: 93-CO1, ATCC 51672.

GenBank accession number (16S rRNA): L35052.

Species Incertae Sedis

1. **Wolbachia melophagi** (Nöller 1917) Philip 1956, 267[AL] (Nöller 1917, 70.)*
me.lo.pha' gi. M.L. gen. n. *melophagi* of *Melophagus*, named after the genus of its natural host, *Melophagus ovinus*, a wingless fly commonly called sheep ked.

The characteristics are as described for the genus *Wolbachia* with the following additional characteristics. Coccoid cells 0.4–0.6 μm or short rods 0.3–1.0 μm. Grow on blood-glucose-bouillon agar and chicken embryo yolk sacs but not in cultured eucaryotic cells. Natural hosts are a wingless fly, *Melophagus ovinus*, and *Diptera* that infest goats, pigs, and horses. Grows extracellularly in the host insect's gut, where the wolbachiae form rows of short rods associated with the intestinal epithelium. Apparently nonpathogenic for hosts.

The mol% G + C of the DNA is: not determined.

Type strain: no strain isolated.

GenBank accession number (16S rRNA): X89110 (strain MO6).

**Editorial Note:* Dumler et al. (2001) have indicated that 16S rDNA sequence analysis places *Wolbachia melophagi* in the genus *Bartonella*.

Family III. **Brucellaceae** Breed, Murray and Smith 1957, 394[AL]

George M. Garrity, Julia A. Bell and Timothy Lilburn

Bru.cel.la' ce.ae. M.L. fem. n. *Brucella* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Brucellaceae* the *Brucella* family.

The family *Brucellaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA gene sequences; the family contains the genera *Brucella* (type genus), *Mycoplana*, and *Ochrobactrum*.

Chemoorganotrophs with an aerobic, respiratory metabolism. Family includes pathogens and soil organisms.

Type genus: **Brucella** Meyer and Shaw 1920, 173[AL]

Genus I. **Brucella** *Meyer and Shaw 1920, 173[AL]*

Michael J. Corbel and Menachem Banai

Bru. cel'la. L. dim. ending *-ella*; M.L. fem. n. *Brucella* named after Sir David Bruce, who first recognized the organism causing undulant (Malta) fever.

Cocci, coccobacilli, or short rods, 0.5–0.7 × 0.6–1.5 μm. Arranged singly and, less frequently, in pairs, short chains, or small groups. True capsules are not produced. Do not usually show true bipolar staining. Resting stages are not known. Gram negative. **Nonmotile;** do not produce flagella. **Aerobic,** possessing a respiratory type of metabolism and having a **cytochrome-based electron transport system** with oxygen or nitrate as the terminal electron acceptor. Nitrate reductase is produced. **Many strains**

require supplementary CO_2 for growth, especially on primary isolation. Colonies on serum-dextrose agar or other clear media are transparent, raised, convex, with an entire edge and a smooth, shiny surface. They appear a **pale honey color** by transmitted light. Smooth strains produce perosamine synthetase and a distinctive lipopolysaccharide (LPS). Nonsmooth variants of the smooth species occur, but there are also stable nonsmooth nomenspecies with a distinctive host range. Optimal temperature for growth 37°C. Growth occurs between 20 and 40°C. Optimal pH for growth 6.6–7.4. **Catalase positive.** Usually oxidase positive, but negative strains occur. Chemoorganotrophic. Most strains require complex media containing several amino acids, thiamin, nicotinamide, iron, and magnesium ions; some strains may be induced to grow on minimal media containing an ammonium salt as the sole nitrogen source. **Growth is improved by serum or blood, but hemin (X-factor) and nicotinamide adenine dinucleotide (NAD: V-factor) are not essential. Acid production does not occur from carbohydrates in conventional media,** except for *B. neotomae*. Do not produce indole. **Do not liquefy gelatin** or inspissated serum. Do not lyse erythrocytes. Do not produce **acetyl methyl carbinol** (Voges–Proskauer test.) **The methyl red test is negative.** Intracellular parasites, transmissible to a wide range of animal species including man. The genome typically comprises two circular chromosomes, but a single large chromosome is present in *B. suis* biovar 3.

The genus is essentially genetically **monospecific**, nomenspecies and biovars reflecting deletions, insertions, or rearrangements in a largely conserved genome. The 16S rRNA gene sequence data, distinctive lipid composition, shared proteins and sensitivity to trifolitoxin indicate affiliation to the order *Rhizobiales* in the *Alphaproteobacteria*. The closest relationships are to the genus *Ochrobactrum* and to a lesser extent to the genus *Mycoplana*, and the three genera comprise the known membership of the family *Brucellaceae*.

The mol% G + C of the DNA is: 57.9–59.

Type species: **Brucella melitensis** (Hughes 1893) Meyer and Shaw 1920, 179 (*Streptococcus melitensis* Hughes 1893, 235.)

Further descriptive information

Cell morphology When grown in nutritionally adequate liquid or solid media such as serum-dextrose broth (SDB)[1] or serum-dextrose agar (SDA)[2], *Brucella* cells are coccoid, coccobacilli, or short rods with slightly convex sides and rounded ends. Freshly isolated strains tend to be more coccoid than laboratory-adapted cultures; this is also true of organisms growing *in vivo*. In general, the morphology of *Brucella* strains is constant and pleomorphic forms are rare, except in old cultures growing under adverse conditions.

Brucella cells stain readily by conventional methods. Although not truly acid fast, they do tend to resist decolorization by weak acids and thus stain red by Macchiavello's stain or by the modified Ziehl–Neelsen technique used by Stamp et al. (1950). They are usually stained red by the modified Köster method (Christofferson and Ottosen, 1941), but *B. ovis* is an exception. True capsules do not occur although capsule-like structures have been reported.

Fine structure The ultrastructure of the *Brucella* cell is broadly similar to that of other Gram-negative bacteria but shows a number of significant differences from that of cells of the *Enterobacteriaceae*, as typified by *Escherichia coli* (De Petris et al., 1964; Dubray, 1972, 1976; Dubray and Plommet, 1976).

The *Brucella* cell wall is composed of an outer membrane comprising an external layer of lipopolysaccharide (LPS), a range of outer membrane proteins including some with porin activity, lipoproteins, and phospholipids. In negatively stained thin sections, this layer appears about 9 nm thick (Dubray, 1976). It is the location of the major surface antigens in both smooth and nonsmooth cells. It is supported by an electron-dense inner layer 3.5 nm thick corresponding to cross-linked muramic-acid-containing peptidoglycan. Some of the outer membrane proteins extend through this layer to the periplasmic region, which appears as a zone of low electron density 3–6 nm thick in smooth-phase cells but up to 30 nm thick in nonsmooth cells (Dubray and Plommet, 1976). As in other Gram-negative bacteria, it is the site of periplasmic enzymes involved in cell wall biosynthesis and various metabolic functions.

The cytoplasmic inner membrane has a typical three-layered lipoprotein structure (De Petris et al., 1964; Dubray and Plommet, 1976). Granular aggregations adjacent to the cytoplasmic membrane mark the location of polyribosomal complexes (Dubray, 1972, 1976).

The *Brucella* cytoplasm is homogeneous and is interspersed with small vacuoles and polysaccharide-containing granules (Dubray, 1972). The nuclear apparatus comprises an osmiophobic mass intersected by osmiophilic filamentous structures (De Petris et al., 1964; Peschkov and Feodorov, 1978).

Cell wall composition The detailed chemical structure of the *Brucella* cell wall has not been fully determined. Gross analyses have indicated that the cell wall accounts for about 21% of the total bacterial dry weight in smooth cultures and 14% in nonsmooth strains. The walls of smooth *Brucella* cells contain approximately 37% protein, 14% carbohydrate, 18% lipid, 0.4% muramic acid, and 0.1% 2-keto-3-deoxyoctulosonic acid (KDO). For nonsmooth *Brucella* cells walls the corresponding values are approximately 47.5% protein, 13% carbohydrate, 17% lipid, 0.4% muramic acid, and 0.1% KDO (Kreutzer et al., 1977).

The external layer of the outer membrane comprises mainly LPS interspersed with a variety of proteins and lipids. The LPS of smooth *Brucella* cell walls is unusual in that it partitions into the phenol layer on phenol–water extraction (Baker and Wilson, 1965). The LPS of the nonsmooth strains is extremely hydrophobic and cannot be extracted with phenol–water but is soluble in phenol–hexane–chloroform (Moreno et al., 1979).

The LPS of both forms consists of a lipid A containing both 2,3-diamino-2,3-dideoxyglucose and 2-amino-2-deoxyglucose in the glycose backbone, a feature of some other members of the *Proteobacteria* (Weckesser and Mayer, 1988). Both amide- and ester-linked fatty acids are attached to the aminoglycose skeleton.

1. Serum-dextrose broth (SDB): tryptone-soya broth (Oxoid), 30 g; distilled water, 1000 ml; sterile horse serum (inactivated at 56°C for 30 min), 50 or 100 ml; D-glucose (25%, w/v, solution autoclaved at 105°C for 20 min), 40 ml. The medium is prepared by dissolving the tryptone-soya broth powder in the water and autoclaving at 115°C for 15 min. After cooling, the sterile horse serum and glucose are added aseptically. Note: Any good quality peptone medium such as Tryptose broth (Difco), or *Brucella* broth (Gibco) may be used as alternatives to tryptone-soya broth. Serum-dextrose agar (SDA): blood agar base No. 2 (Oxoid) 40 g; distilled water, 1000 ml; sterile horse serum (inactivated at 56°C for 30 min), 50 or 100 ml; D-glucose ((25% w/v) solution autoclaved at 105°C for 20 min), 40 ml. The blood agar base is dissolved in the water with the aid of gentle heating and then autoclaved at 121°C for 15 min. After cooling, the horse serum and glucose are added aseptically and plates or slopes poured immediately. Note: Tryptose agar (Difco) or *Brucella* agar (Gibco) are satisfactory alternative basal media.

The amide-linked acids include 3-O-$C_{(16:0)\ 12:0}$ (25%), 3-O-$C_{(16:0)\ 13:0}$ (4%), 3-O-$C_{(16:0)\ 14:0}$ (64%), and 3-O-$C_{(18:0)\ 14:0}$ (7%) as diesters with $C_{16:0\ 3OH}$ as the unsubstituted fatty acid. The ester-linked acids comprise $C_{16:0}$, $C_{16:0\ 3OH}$, $C_{18:0\ 3OH}$, and $C_{18:0}$ acids, which account for 37%, 12.5%, 3.5%, and 4.5%, respectively, of the total fatty acids. Lactobacillic and unsaturated fatty acids are absent from the lipid A of *Brucella* although represented in many other lipid components (Cherwonogrodzky et al., 1990).

The lipid A is linked through KDO to the core polysaccharide composed of D-glucose, D-mannose, and 6-amino 6-deoxyglucose (quinovosamine) (Bowser et al., 1974). Heptose is absent from *Brucella* LPS. In the case of some rough strains, a short homopolymer of 4,6-dideoxy-4-formamido-D-mannose (*N*-formyl-D-perosamine) may be attached to the core polysaccharides (Perry and Bundle, 1990), but in many strains this is absent and some may also be deficient in quinovosamine (Moreno et al., 1984). D-Glucose and D-mannose, and possibly quinovosamine, are components of the major epitope of nonsmooth *Brucella* strains.

In the case of smooth strains, the LPS carries an O chain linked to the core polysaccharide. The O chain comprises a homopolymer of about 100 residues of *N*-formyl-D-perosamine. In the case of A-dominant *B. abortus* LPS, the O chain consists of a majority of glycose residues linked alpha-1,2, but with a very small proportion linked alpha-1,3 (Caroff et al., 1984a, b; Bundle et al., 1987).

In the case of M-dominant *B. melitensis* LPS, the O chains consist of unbranched linear polymers of pentasaccharide units, comprising four residues linked alpha-1,3. The difference in linkage produces penta- or hexasaccharide units with different preferred conformations. The common presence of nonterminal tetrasaccharide units of alpha-1,2 linked *N*-formyl-D-perosamine explains the crossreactivity observed between the LPS of all smooth *Brucella* strains (C epitope) (Cloeckaert et al., 1998).

The A- and M-specific epitopes are actually present as minority structures in both types of LPS. In the case of strains typified by *B. abortus* biovar 1, the O chains contain predominantly A epitopes with a very small proportion of M epitope, attributable to the few alpha-1,3 linked residues. In strains typified by *B. melitensis* biovar 1, the reverse situation applies. It should be noted that strains of *B. abortus*, *B. melitensis*, or *B. suis* can be A-, M-, or A- and M-antigen positive (see Table BXII.α.120 and Dubray and Limet, 1987). Strains that are both A- and M-antigen positive synthesize LPS with O chains that contain both A and M structural features in relatively high proportion (Perry and Bundle, 1990).

N-Acylated-D-perosamine also occurs in the O chains of the LPS complexes of *E. coli* 0157, *Escherichia hermannii*, *Salmonella* O30 (Bundle et al., 1987), *Stenotrophomonas maltophilia* strain 555, *Vibrio cholerae* (Redmond, 1979; Kenne et al., 1982), and *Yersinia enterocolitica* 09 (Caroff et al., 1984b), all of which crossreact serologically with smooth *Brucella* strains (Corbel, 1985). Crossreactions also occur between *Brucella* and *Francisella tularensis* (Francis and Evans, 1926; Ohara et al., 1974), although the basis of this has yet to be determined.

The outer membrane proteins include the 88–94-kDa high molecular weight group 1, the 43 kDa and 36–38-kDa porin proteins of group 2 (Douglas et al., 1984), and the 25–27-kDa proteins of group 3, as well as minor proteins of 15–31 kDa. A lipoprotein of 8 kDa is also covalently linked to the peptidoglycan skeleton. These components are present in all the nomenspecies but with quantitative differences (Santos et al., 1984; Verstreate and Winter, 1984). In addition to the above, *B. melitensis* contains a 31 kDa outer-membrane protein and another of 30–40-kDa.

In all *Brucella* strains, the group 2 proteins are by far the most abundant. The genes for the 36-kDa porins (*omp2a* and *omp2b*) have been cloned, and the peptide sequences determined (Ficht et al., 1990). The function of the group 3 proteins, formerly assumed to be analogues of Omp A, has yet to be determined. The *omp2* genes and those encoding the Group 3 proteins demonstrate polymorphisms, which permit grouping into clusters corresponding approximately to nomenspecies and biovars (Cloeckaert et al., 1995). The 8 kDa lipoprotein resembles the Braun lipoprotein of *E. coli* in molecular weight, isoelectric point, and amino acid composition but differs from it in being surface exposed (Gomez-Miguel et al., 1987). The Omp 10, Omp 16, and Omp 19 outer membrane proteins are also reported to be lipoproteins (Tibor et al., 1999).

The *Brucella* outer membrane is unusual in being particularly rich in myristic, palmitic, and stearic acids, in containing moderate quantities of *cis*-vaccenic and arachidonic acids, low quantities of C_{17} and C_{19} cyclopropane fatty acids and no hydroxy fatty acids. This unusual fatty acid composition may contribute to hydrophobic interactions in the *Brucella* outer membrane and enhance its stability (Cherwonogrodzky et al., 1990).

TABLE BXII.α.120. Differentiation of the species and biovars of the genus *Brucella*[a]

[b]For more certain differentiation of biovar 3 and 6, thionine at 1:25,000 (w/v) is used; biovar 3 gives a positive growth response, biovar 6 is negative.

[c]Dye concentration, 1:50,000 (w/v).

[d]Growth will occur in the presence of thionine at a concentration of 1:150,000 (w/v).

The peptidoglycan framework of the cell wall comprises a glycan skeleton of D-glucosamine and muramic acid linked by short chains of alanine, glutamic acid, and alpha, epsilon-diaminopimelic acid. However, it also contains covalently linked proteins and lipid and is unusually resistant to lysozyme, even in the presence of detergents and chelating agents.

The lipid composition of *Brucella* cells has a number of distinctive features, which reinforce the taxonomic affiliation of the genus to the group of bacteria known as the alpha 2 subdivision of the *Proteobacteria*.

The bound lipids are mainly associated with the LPS, lipoprotein, and glycolipid fractions of the outer membrane. The free lipid fraction comprises mainly phospholipids and neutral lipids (Wober et al., 1964; Thiele and Kehr, 1969; Thiele and Schwinn, 1969). Phosphatidylcholine is the principal phospholipid, in contrast to most bacterial species (Thiele and Schwinn, 1973). It may also form an antigenic determinant (Casao et al., 1998). Its presence confers distinctive properties on the outer membrane and may account for its reduced susceptibility to phospholipases and lysozyme. Phosphatidylglycerol and diphosphatidylglycerol are also present as major lipids. Phosphatidyl ethanolamine, phosphatidyl serine, and cardiolipin are represented as minor components. The fatty acids associated with the phospholipid fraction are unusual in that lactobacillic ($C_{19:\,cyclo}$) acid, typical of Gram-positive but not Gram-negative species, is usually the major cyclopropane fatty acid, together with its metabolic precursor *cis*-vaccenic ($C_{18:1\,cyclo}$) acid. *B. canis* is an exception, and has *cis*-vaccenic acid as the major fatty acid, with lactobacillic acid in only trace amounts. This largely accounts for the distinct position of *B. canis* vis-à-vis the other nomenspecies when fatty acid composition is used for taxonomic analysis (Tanaka et al., 1977).

The neutral lipids include unusual wax-like esters containing large quantities of myristic ($C_{14:0}$), palmitoleic ($C_{16:1}$), stearic ($C_{18:0}$) and *cis*-vaccenic ($C_{18:1}$) acids. Lactobacillic acid is absent from these compounds.

Other distinctive free lipid components of *Brucella* include ubiquinone Q-10 and ornithine-containing lipids (Thiele and Schwinn, 1973). The latter make up 32% of the total neutral lipid. They contain lactobacillic, *cis*-vaccenic, and palmitoleic acids in ester linkage and palmitic and stearic acids in amide linkage, but no hydroxy fatty acid. The function of the ornithine lipids is unknown but they are structural components of the outer membrane. It has been suggested that they are implicated in the attachment of *Brucella* cells to the surface of macrophages and lymphocytes (Cherwonogrodzky et al., 1990). Minor free lipid components include 1,3 and 1,2 diesters of glycerol and monoesters of ethylene glycol.

Cultural characteristics Most *Brucella* strains behave as slow-growing, fastidious organisms on primary isolation. Although laboratory-adapted strains may be induced to grow in synthetic media containing an ammonium salt as the sole nitrogen source, the majority of fresh isolates have complex nutritional requirements and grow poorly on ordinary nutrient media unless these are supplemented with blood, serum, or tissue extracts. Liver infusion agar was at one time widely employed for the cultivation of brucellae, but better-defined media of more consistent composition are now preferred.

For most purposes, SDA is the medium recommended and will support the growth of all species and most strains (Jones and Morgan, 1958). Tryptose agar (Difco), *Brucella* agar (Gibco),[3] and Tryptone-soya agar (Oxoid) or equivalent media will support the growth of most strains without serum supplementation and the growth of nearly all, if heated equine serum is added to a final concentration of 5–10% (v/v). The function of the serum is not simply nutritional but is also reported to neutralize inhibitors present in the peptone component of ordinary culture media, and may be replaced by other colloids, including Tween 40. Strains of *B. abortus* biovar 2 and some of biovar 4, and *B. ovis* are the most fastidious and grow best on media containing 10% (v/v) serum.

Potato infusion agar[4] supports the growth of many *Brucella* strains and is often employed as the medium of choice for antigen or vaccine production, as it does not favor dissociation (Alton et al., 1988). For the most fastidious strains, it may be necessary to supplement this medium with horse serum to achieve satisfactory growth. Although wide variations occur between strains within nomen species, in general the most rapid growth and largest colony size are achieved by isolates of *B. suis* biovar 1 and 3 and *B. canis*. Growth is least vigorous for *B. ovis*, followed by many strains of *B. melitensis* biovar 1 and *B. suis* biovar 2. Strains of the other species and biovars usually occupy an intermediate position.

On primary isolation, colonies of any *Brucella* strain are rarely visible before 48 h. At this stage, colonies on SDA are usually 0.5–1.0 mm in diameter, raised, convex with a circular outline and an entire edge. In transmitted light, the colonies of smooth strains have a shiny surface and appear a clear pale yellow. In reflected light, the colonies have a smooth glistening surface but are slightly opalescent and bluish gray. The colonies of non-smooth strains are of similar size and shape to smooth colonies but vary considerably in color, consistency, and surface texture. They range from smooth-intermediate (SI) variants, which are morphologically indistinguishable from smooth (S) colonies but may differ in antigenic properties and phage susceptibility, through intermediate (I) forms to rough (R) and mucoid (M) variants.

R colonies are usually much less transparent than S colonies, with a more granular, dull surface, and range in color from matte white, yellowish white, or buff, to brown. Unlike S colonies, which are soft and easily emulsifiable to form stable suspensions in saline solutions, R colonies are often friable or viscous and difficult to detach cleanly from the agar surface. They will not form uniform suspensions in saline solutions but produce granular aggregates, threads, or clumps. M colonies are similar to R colonies in color and opacity but have a sticky glutinous texture.

The colonial variants of *Brucella* are best studied after four days' growth on glycerol-dextrose agar (GDA)[5], under oblique illumination as described by Henry (1933). Differentiation of the various colonial types is greatly facilitated by staining with ammonium oxalate-crystal violet before examination in reflected

3. Albimi *Brucella* agar is no longer available, but an equivalent product is obtainable as *Brucella* agar from Gibco Laboratories, Grand Island, New York, NY 14072, U.S.A. High quality peptone based media from other suppliers are also satisfactory.

4. Potato infusion agar: Bacto potato infusion agar (Difco), 49.0 g; glycerol, 20.0 g; distilled water, 1000 ml. The glycerol is dissolved in the water and the dehydrated medium is suspended in this solution and heated to the boiling point until dissolved. The medium is sterilized at 121°C for 15 min. It should be prepared immediately before use.

5. Glycerol dextrose agar: to blood agar base No. 2 (Oxoid) or Tryptose agar (Difco) that has been autoclaved and cooled to 56°C, sterile solutions of glycerol and D-glucose are added to give final concentrations of 2% (w/v) and 1% (w/v), respectively.

light (White and Wilson, 1951). Under these conditions, S colonies appear pale yellow, R colonies are stained red with a coarse granular appearance, and other dissociated colonies are stained various shades of pink, purple, or blue. Apart from S, R, and M colonies, numerous transitional phases may occur in cultures undergoing dissociation to the nonsmooth state.

Nonsmooth variants may arise as a result of a genetic deletion leading to synthesis of an incomplete LPS structure. This can result in mutation or deletion of genes in the *rfb* operon, of which the perosamine synthetase gene is particularly critical (Godfroid et al., 1998). However, in some nonsmooth strains other changes may accompany the LPS modification and involve deeper structures within the cell wall (Dubray and Plommet, 1976; Kreutzer and Robertson, 1979).

Most *Brucella* strains grow moderately well on sheep blood agar but the colonial appearance is not distinctive. The organisms are nonhemolytic, but a greenish brown discoloration may develop around the colonies. This is most apparent in old cultures and is probably attributable to alkali production.

The more vigorous strains of *B. abortus*, *B. melitensis*, and *B. suis* will grow on MacConkey agar, producing small lactose-negative colonies. In general, the growth of the more fastidious *Brucella* strains is inhibited on media containing bile salts, tellurite, or selenite. Tolerance to synthetic dyes varies considerably between strains and is employed as the basis for differentiation of biovars (see below and Table BXII.α.120).

Nutrition and growth conditions Growth in simple nutrient liquid media is usually poor unless these are supplemented with blood, serum, or tissue extracts. Most strains will grow fairly well on unsupplemented, high-quality, enriched, peptone-based media such as *Brucella* broth (Gibco) or Tryptone broth (Difco).

Good growth is obtained in SDB or other media supplemented with serum. It is essential to maintain adequate aeration if satisfactory growth is to be obtained. After static incubation for 7 days at 37°C in SDB, smooth strains produce a slight to moderate uniform turbidity with a light, powdery deposit. Nonsmooth strains may produce a granular or slimy deposit, variable turbidity, and pellicle formation, sometimes accompanied by a "stalactite" appearance. Growth in static liquid media favors dissociation of S-phase cultures to nonsmooth forms. Vigorous aeration will prevent this if the medium remains adequately buffered near neutral pH.

In semisolid media, CO_2-requiring cultures of *B. abortus* and *B. ovis* produce a disk of growth a few millimeters below the surface of the medium. CO_2-independent *Brucella* species produce a uniform turbidity from the surface down to a depth of a few millimeters. There is no growth under the anaerobic conditions prevailing in static deep cultures.

The optimal growth temperature for all *Brucella* strains is 36–38°C, but growth of most strains will occur in the range 20–40°C. All strains lose viability at 56°C, although temperatures as high as 85°C may be necessary to ensure sterilization of dense suspensions (Swann et al., 1981).

Metabolism and metabolic pathways The organisms are aerobic, although many strains grow best under microaerophilic conditions. The electron transport of *B. abortus* (the only species closely studied in this regard) consists of a branched system involving cytochromes $a + a_3$, *b*, *c*, and *o*, flavoproteins, and ubiquinone. It is unusually resistant to respiratory inhibitors (Rest and Robertson, 1975). Energy-yielding processes are essentially oxidative, and *Brucella* cultures show little ability to acidify carbohydrate media in conventional tests. They have been reported to lack phosphofructokinase (Robertson and McCullough, 1968a, b), although this enzyme was reported in extracts of *B. suis* by Roessler et al. (1952). The inability to acidify carbohydrate media has also been attributed to inhibition by peptone constituents, and acidic reactions have been demonstrated in peptone-free media (Pickett and Nelson, 1955). *B. neotomae* is exceptional in that it is reported to produce acid (but not gas) from D-glucose, D-galactose, L-arabinose, and D-xylose in conventional peptone-water sugar media (Stoenner and Lackman, 1957).

Glucose catabolism occurs via the hexose monophosphate pathway in conjunction with the tricarboxylic acid cycle (Robertson and McCullough, 1968a, b; Rest and Robertson, 1974). *meso*-Erythritol is metabolized by many *Brucella* strains in preference to glucose (Anderson and Smith, 1965), and D-erythritol-1-phosphate and other intermediates in the erythritol pathway will reduce the entire electron transport system (Rest and Robertson, 1975).

Although some laboratory-adapted strains will grow in minimal medium with an ammonium salt as the sole nitrogen source (McCullough and Dick, 1943), the nutritional requirements of *Brucella* cultures in general are complex. Multiple amino acids, thiamin, biotin, nicotinamide, iron, and magnesium ions are essential for growth; iron, manganese, and other trace elements exert a regulatory action. Iron acquisition is dependent on 2,3-dihydroxybenzoic acid siderophore production (Bellaire et al., 1999). Surplus iron is sequestered and stored by a bacterioferritin, which may also facilitate *in vivo* survival by blocking the catalytic role of iron in the formation of reactive oxygen intermediates (Denoel et al., 1995). The growth of many strains is stimulated by calcium pantothenate and *meso*-erythritol. Very few strains will grow with citrate as the sole carbon source.

Sulfur-containing amino acids and proteins are degraded and may be reduced to H_2S, but this varies with species and biovar. Indole is never produced from tryptophan or its proteins, and acetyl methyl carbinol is not produced from glucose (Voges–Proskauer reaction). Hydrolytic activity towards proteins in general is very limited and gelatin, inspissated serum, and litmus milk are not digested. *Brucella* strains either render the latter alkaline or produce no visible change.

The supplementary CO_2 required by strains of *B. abortus* and *B. ovis* for growth is used as a nutritional factor and not simply to lower oxygen tension or pH. It is incorporated directly into pyrimidines, glycine, and alanine (Newton et al., 1954).

The optimal pH for growth is between 6.6 and 7.4. Cultures die rapidly at pH 3.5 or below. Most *Brucella* strains produce alkali on protein or peptone-containing media, and this may act as a growth-limiting factor. Culture media should be adequately buffered near pH 7 for optimal growth. The optimal osmotic pressure is between 2 and 6 atmospheres, equivalent to between 0.05 and 0.15 M NaCl.

A wide range of carbohydrate and amino acid substrates is oxidized (McCullough and Beal, 1951). Manometric measurement of oxidation rates with selected substrates produces metabolic patterns that are characteristic of each species and some biovars (Meyer, 1961; Meyer and Cameron, 1961a, b). The oxidative metabolic patterns show a close correlation with the phage-sensitivity pattern and the preferred natural hosts of the species (Meyer and Morgan, 1962). As indicated in Table BXII.α.121, they are of primary importance in defining the species of *Brucella* and are of additional value in classifying the biovars of *B. suis*

(Stableforth and Jones, 1963; Jones, 1967; Jones and Wundt, 1971).

Procedures for the determination of oxidative metabolic patterns by manometric methods are described by Morgan and Gower (1966), Corbel et al. (1979), and Alton et al., (1988). A nonquantitative technique, using thin layer chromatography to detect substrate utilization, has also been employed (Balke et al., 1977; Corbel et al., 1978). More recently, a simplified colorimetric method that uses chromogenic tetrazolium substrates, and has the advantages of speed and reduced hazard, has been developed (Broughton and Jahans, 1997). Irrespective of technique, the range of substrates used includes L-arabinose, D-glucose, D-ribose, D-xylose, *meso*-erythritol, L-alanine, L-asparagine, L-glutamic acid, L-arginine, L-lysine, DL-citrulline, and DL-ornithine. For some purposes, other substrates including adonitol, L-histidine, L-serine, D-amino acids, and urocanic acid may also be used.

All strains are catalase positive and superoxide dismutases are produced (Bricker et al., 1990). The species *B. abortus*, *B. melitensis*, *B. suis*, and *B. canis* are usually oxidase positive in tests with tetramethyl-*p*-phenylenediamine, but some strains are oxidase negative and this can be a useful epidemiological marker. Most *Brucella* strains produce nitrate reductase and reduce nitrates to nitrites. Nitrites may be further reduced (Zobell and Meyer, 1932). *B. canis*, *B. neotomae*, and *B. suis* strains normally show very strong urease activity. Most strains of *B. abortus* and *B. melitensis* also produce urease, but a few do not. This may be useful as an epidemiological marker. *B. ovis* does not usually hydrolyze urea, but some strains may do so on prolonged incubation.

Genetics

Genome composition The members of the genus form a close-knit group. The DNA base composition is in the range 57.9–59 mol% G + C. DNA–DNA hybridization studies have indicated that all nomenspecies show >90% similarity to the type strain (Hoyer and McCullough, 1968a, b; Verger et al., 1985; De Ley et al., 1987). This is consistent with the concept of a single species, and Verger et al. (1985) have proposed a system of classification in which all of the current nomenspecies would be classified as biovars of *B. melitensis*. However, recent advances in knowledge of the molecular genetics of *Brucella* have provided a clearer insight into the phylogenetic position of the genus and the evolution of the distinct types within it. Unexpectedly, the molecular genetic data have provided evidence in support of the classical differentiation into nomenspecies and biovars, which were defined on the basis of patterns of phenotypic characteristics that aligned with the preferred host specificity (Michaux-Charachon et al., 1997).

Restriction endonuclease analysis using low-cleavage-frequency enzymes such as *Xba*I or *Not*I, combined with pulsed field gel electrophoresis, produced patterns which were characteristic of each nomenspecies but showed little difference between biovars within these taxa (Allardet-Servent et al., 1988). This study also suggested a genome size of about 2.6×10^6 bp for *B. melitensis* 16M and *B. suis* 1330^T. However, development of a partial physical map of the *B. melitensis* biovar 1 strain 16M genome suggested an apparent size of about 3.3×10^6 bp (Allardet-Servent et al., 1991). An extension of this study led to the conclusion that the genome consisted of two chromosomes of 2.1

and 1.5×10^6 bp, respectively (Michaux et al., 1993). This was confirmed by insertion into each replicon of the I-*Sce*-I unique restriction site, which is a nonsymmetrical double-stranded sequence extending over 18 bp, followed by restriction fragment analysis with *Pac*I and *Spe*I (Jumas-Bilak et al., 1995). Two rRNA operons and the gene for the DnaK heat shock protein are located on the large chromosome, and a third rRNA operon and the gene encoding the equivalent of the GroEL chaperonin are located on the small chromosome. As both replicons encode functions essential for survival and replication, they are clearly chromosomes rather than plasmids (Michaux et al., 1993).

Application of these methods to the full range of nomenspecies and biovars has produced a rather more complex picture, which has confirmed genomic differences between phenotypically distinguishable types (Michaux-Charachon et al., 1997; Jumas-Bilak et al., 1998). *B. melitensis* biovars 2 and 3 have a similar genomic structure to biovar 1. *B. abortus* strains have a large chromosome of about 2.1×10^6 bp and a small replicon of about 1.15×10^6 bp. However, in biovars 1–4 the small chromosome contains a 640×10^3 bp inversion, whereas in biovars 5–9 it resembles that of *B. melitensis*. The *B. suis* biovar 1 genome is grossly similar in size and structure to that of *B. melitensis* biovar 1, except that its small chromosome is about 50×10^3 bp longer. In contrast, *B. suis* biovars 2 and 4 each have a large chromosome of 1.85×10^6 bp and a small chromosome of 1.35×10^6 bp. *B. suis* biovar 3 appears to be unique in that it contains a single chromosome of 3.2×10^6 bp. This molecule incorporates the sequences present in the large and small chromosomes of the other types. The genome structure of *B. canis* is indistinguishable from that of *B. suis* biovar 1, reinforcing the view that it is a stable R mutant of that organism. On the other hand, the large chromosome of *B. neotomae* resembles that of *B. melitensis* biovar 1, whereas its small chromosome resembles that of *B. suis* biovar 1. The *B. ovis* genome is broadly similar to that of *B. melitensis* biovar 1 but contains 30 copies of the insertion sequence IS*6501*, compared with the 5–10 copies found in the other nomenspecies. The complete genome of *B. melitensis* 16M has been published (DelVecchio et al., 2002). Analysis of this genome has indicated the absence of Type I, II, and III secretion systems but the presence of Type IV and V secretion systems and genes encoding flagellin, hemolysin, and fusion proteins.

Within the genomes of all strains studied, numerous small insertions and deletions, ranging from $1–32 \times 10^3$ bp, and three *rrn* sites have been found. These may contribute to observed differences between nomenspecies and biovars (Mercier et al., 1996; Michaux-Charachon et al., 1997). Insertion and repeated sequences have been widely documented in *Brucella* strains (Halling and Zehr, 1990). These may influence the expression of specific genes. For example, the BCSP31 protein is not expressed by *B. ovis*, possibly because of the presence of multiple copies of a repeated sequence downstream of the gene. The insertion sequence IS*6501* is universally present and has proved to be useful for identification of the genus (Ouahrani et al., 1993).

RNA composition Analysis of ribosomal RNA gene sequences has disclosed the unexpected phylogenetic position of the genus *Brucella* (De Ley et al., 1987; Dorsch et al., 1989). 5S rRNA gene sequence analysis indicates that *Brucella* is highly homogeneous, with about 95% relatedness to the *Agrobacterium* group but with a more distant relationship to *Bartonella*. The 16S rRNA gene sequence is typical of the *Alphaproteobacteria*. 16S rRNA/DNA binding has confirmed the close relationship to *Ochrobactrum* and a rather more distant one to *Agrobacterium*, *Mycoplana*, and *Phyllobacterium*.

Extrachromosomal genetic elements Hitherto, there have been conflicting reports on the natural presence of plasmids or other forms of extrachromosomal DNA, such as transposons, in *Brucella*. Indirect evidence for the occurrence of plasmids, such as infectious antibiotic resistance, is also lacking. However, a small cryptic plasmid has been reported to be present in many strains. The existence of bacteriocins specific for the genus *Brucella* has not been confirmed, although bacteriocin-like effects have been occasionally reported (Pickett and Nelson, 1950; Todorov and Koleva-Todorova, 1971). Many bacteriophages active upon members of the genus *Brucella* have been described. These phages have not been shown to lyse bacteria of other genera and thus are of taxonomic value for identification at both genus and species level.

Phages and phage typing The phage-susceptibility pattern is of major importance in definition of the species of *Brucella*. For culture identification, it is convenient to use phage preparations standardized at the routine test dilution (RTD). This is defined as the minimum concentration that produces complete lysis of the propagating strain for that phage. It is essential that phage strains be maintained on the approved propagating strain, as the host range may be modified by adaptation to new strains.

Based on their host range, the phages may be classified into seven distinct groups. These are summarized in Table BXII.α.122.

The phages in group 1, typified by the Tbilisi (Tb) strain (Popkhadze and Abashidze, 1957), are capable of efficient replication only in cells of *B. abortus* in the S, SI, or I phases. Limited replication also occurs in S, SI, or I cultures of *B. neotomae*, but the efficiency of plating is low. At high concentrations, these phages produce lysis of S, SI, or I cultures of *B. suis* by a bacteriocin-like effect. Cultures of *B. melitensis*, *B. canis*, and *B. ovis* are not lysed, nor are cultures of *B. abortus*, *B. neotomae*, or *B. suis* in the M or R phases.

Group 2 comprises those phages typified by the Firenze (Fi) strain 75/13 (Corbel and Thomas, 1976). These replicate in, and form plaques on, S, SI, and I cultures of *B. abortus*, *B. neotomae*, and *B. suis* but not on those of other *Brucella* species. They are also inactive on M and R strains of *Brucella*. The efficiency of plating is somewhat higher on *B. abortus* strains than on those of *B. neotomae* or *B. suis* biovar 4, and very much higher on these than on *B. suis* biovars 1, 2, and 3.

Group 3 includes those phages typified by the Weybridge (Wb) strain (Morris and Corbel, 1973). All of these replicate and form plaques on S, SI, and I cultures of *B. abortus*, *B. neotomae*, and *B. suis*. The efficiency of plating on the three species varies between the phages of this group, within a range of about 2 $\log_{10}$ units. Some of these phages have been reported to form plaques on cultures of *B. melitensis*, but the efficiency of plating is very low (Moreira-Jacob, 1968; Douglas and Elberg, 1976). None of the phages of group 3 will lyse M or R strains of any *Brucella* species, including *B. canis* and *B. ovis*.

Group 4 comprises the Berkeley phages Bk_0, Bk_1, and Bk_2 (Douglas and Elberg, 1976, 1978). The most useful of these, Bk_2, replicates and causes lysis in S-phase cultures of *B. abortus*, *B. melitensis*, *B. neotomae*, and *B. suis*. It shows no lytic activity towards *B. canis*, *B. ovis*, or other nonsmooth *Brucella* strains, even at high concentrations. Its lytic activity towards the smooth strains is drastically reduced as these undergo dissociation to nonsmooth forms. This is particularly the case with *B. melitensis* cultures, and

TABLE BXII.α.122. Lytic activity of phages for smooth (S) and rough (R) *Brucella* species[a]

[a]L, confluent lysis; PL, partial lysis, single plaques, or growth inhibition; NL, no lysis; V, variable, some strains lysed; RTD, routine test dilution.

[b]Biogroups 1 and 4.

[c]Biogroups 2, 3, and 5.

the efficiency of plating of Bk_2 phage on this species may vary considerably between strains.

Group 5 includes those phages lytic for nonsmooth *Brucella* strains. All are derived from phage R, which was developed as a mutant selected from a mixture of phages active on smooth *Brucella* strains (Corbel, 1977b, 1979). Phage R is lytic for nonsmooth cultures of *B. abortus* but not for other species. The strain is genetically unstable, however, and produces smooth-specific phage mutants at high frequency during replication. Phage R/O is lytic for *B. ovis* and some S-phase *B. abortus* and *B. suis* strains, but not for *B. melitensis* or nonsmooth cultures of *B. abortus*, *B. melitensis*, *B. suis*, *B. neotomae*, or *B. canis*. It is genetically unstable and its host range is subject to variation between successive batches. Phage R/M is lytic for some R-phase cultures of *B. melitensis* and, like phages R and R/O, is genetically unstable. Phage R/C was developed by passage of phage R/O on cultures of *B. canis* RM 6/66. Unlike the other phages in this group, it is relatively stable in host range and is therefore the most useful for taxonomic purposes. It is lytic for *B. canis*, *B. ovis*, and nonsmooth strains of *B. abortus*. Some nonsmooth strains of *B. suis* and *B. melitensis* are inhibited by it at high concentrations. It is not lytic for completely smooth strains of *B. abortus*, *B. melitensis*, *B. suis*, or *B. neotomae*, although it will produce plaques on strains of *B. abortus* in the SI, I, M, or R phases.

Group 6 is typified by the Izatnagar (Iz_1) phage. This is lytic for smooth cultures of all *Brucella* nomenspecies and produces patchy incomplete lysis on rough cultures of *B. melitensis*, *B. neotomae*, and *B. suis* (Corbel et al., 1988). The lytic activity towards nonsmooth cultures is rapidly lost if the phage is propagated on smooth cultures.

Group 7 is represented by the Nepean (Np) phages. These have a lytic spectrum similar to the Group 1 phages but produce complete lysis of *B. neotomae* at RTD (routine test dilution) and do not lyse *B. suis* at 10^4 RTD (Rigby, 1990).

The brucellaphages are morphologically similar, with a hexagonal head 55–80 nm in width and a tubular, apparently noncontractile tail 14–33 nm long. Most of the phage strains have a mean head diameter of about 60 nm and a tail length of about 25 nm. Attachment of the phages is mediated via short fibrous structures linked to the distal end of the tail, which interact with protein or glycoprotein components forming part of the outer membrane of the bacteria (Corbel, 1977a). All of the brucellaphages are relatively stable to organic solvents and nonionic and anionic detergents. They are inactivated by heat, cationic detergents, and oxidizing agents, show a variable stability to proteolytic enzymes and reducing agents, and do not require divalent cations for their interaction with *Brucella* cells. All contain DNA as their genetic material and, for the phages of group 1, this has a mol% G + C of 45.3–46.7(T_m). In spite of their isolation from different sources and geographical areas over a wide range of time, their general properties and the results of restriction nuclease analysis indicate that the brucellaphages hitherto described probably comprise host range variants of a single phage (Rigby, 1990).

Although phage typing is used primarily for identification at the nomenspecies level and usually gives a clear-cut result, some *Brucella* strains may show deviation from the standard pattern of lysis. This is particularly true for *B. melitensis* strains, which can be divided into subtypes according to pattern of susceptibility to Bk_2, Iz_1, and Wb phages (Corbel, 1987, 1989b).

Genetic exchange Chromosomal DNA exchange by conjugation has not been demonstrated between *Brucella* strains. This has impeded the application of classical methods of genetic analysis to the genus. However, transfer of plasmids by conjugation has been demonstrated between *Brucella* strains and *E. coli* under laboratory conditions. Tn5-associated kanamycin resistance has been transferred using a triparental cross protocol (Smith and Heffron, 1987). The IncP broad-host-range plasmid R751 encoding trimethoprim resistance has also been transferred from *E. coli* to reference strains of the six *Brucella* nomenspecies (Verger et al., 1993). Similar results were obtained with the broad-host-range plasmids pTH10 (IncP, Tc^R, Km^R), pSa (IncW, Tc^R, Km^R), and pR751 (IncP, Tp^R). The three plasmids were transferred successfully by conjugation from an *E. coli* donor to *B. abortus* S19, and were maintained in the transconjugant strain with no effects on biotyping properties. Moreover, plasmid transfer was also demonstrated from *B. abortus* to a recipient *E. coli* strain. In contrast, electroporation of narrow-range ColE1-derived plasmids failed to manifest a replicating plasmid, but rather facilitated transposon integration into the chromosome (Rigby and Fraser, 1989). Most recent molecular transformations of *B. abortus* have used the plasmid pBR1MCS (Kovach et al., 1994).

Variation Spontaneous variation in some of the properties of *Brucella* cultures is not uncommon. This usually results from mutations involving the modification of individual characteristics. Probably the most frequent mutation is the production of

nonsmooth variants from S-phase organisms. Inactivation of the perosamine synthetase gene results in production of stable rough mutants (Godfroid et al., 1998). Other characteristics are also subject to variation. CO_2-independent variants are rapidly selected from CO_2-dependent cultures of *B. abortus* and, much less frequently, from *B. ovis*. Loss of H_2S production and urease production occurs occasionally. Changes in resistance to various dyes, including basic fuchsin, thionine, thionine blue, safranin O, and to *meso*-erythritol, and various antibiotics, occur with varying frequency. Modification of such characteristics may result in alteration of biovars. For example, *B. abortus* biovar 2 can convert to biovar 1 by acquiring resistance to basic fuchsin; the mutation rate for resistance to this dye is 6.0×10^{-10}/cell division (Shibata et al., 1962). Variations in surface antigens or phage sensitivity in S-phase cultures occur infrequently; nevertheless, smooth phage-resistant variants of *B. abortus* have been isolated under both laboratory and field conditions (Corbel and Morris, 1974, 1975; Harrington et al., 1977).

In general, *Brucella* strains maintain their nomenspecies identity, which is closely related to their preferred host specificity.

Cell wall-defective variants of *Brucella* may be induced by penicillin or glycine (Hines et al., 1964; Roux and Sassine, 1971; Hatten, 1973), hormones (Meyer, 1976), or cell cultures of immune macrophages (McGhee and Freeman, 1970a). They may also be recovered from the blood or tissues of animals or humans infected with *Brucella* strains (Nelson and Pickett, 1951; Ross and Corbel, 1980). Artificially induced spheroplasts are osmotically unstable and require hypertonic media for survival and growth. Naturally occurring *Brucella* L-forms are less osmotically sensitive but have more exacting growth requirements than the parent *Brucella* strains. Thus, they may require specially enriched media containing reducing agents (Nelson and Pickett, 1951) or high concentrations of horse serum (Corbel et al., 1980).

Cell wall-defective *Brucella* variants are highly pleomorphic and, if induced to grow on solid media, they produce bizarre colonies. These may vary from tenacious, granular, fried egg colonies of the *Mycoplasma* type, which may or may not be surrounded by a lipid film, to colonies resembling those of normal smooth or intermediate *Brucella* cultures, but very much smaller (Nelson and Picket, 1951; Corbel et al., 1980). *Brucella* L-forms and spheroplasts normally show partial or complete loss of surface antigens but may also express surface antigens characteristic of nonsmooth cultures. They usually show a reduced sensitivity to brucellaphages but may be susceptible to growth inhibition or lysis. Their pathogenicity towards experimental animals is slight or absent, unless they revert to the parent form.

Antigenic structure Smooth species of *Brucella* show complete crossreaction in agglutination tests with unabsorbed antisera to smooth *Brucella* organisms. This crossreaction does not extend to nonsmooth variants in the M or R phases. Crossreactions between nonsmooth strains can be demonstrated by agglutination tests with unabsorbed antiserum to a rough *Brucella* strain or to the R antigen of *B. ovis*. By using crossabsorbed antisera, different quantitative distribution of two major surface epitopes, A and M, can be demonstrated in smooth strains (Wilson and Miles, 1932) and is of value in differentiating biovars of the major species (see Table BXII.α.120). It should be emphasized that this procedure should only be performed with high-quality monoclonal or polyclonal reagents of validated specificity. These antigenic determinants, together with the common C epitope, are present on the O chain of the LPS, the immunodominant surface antigen of smooth *Brucella* species. The structure of this, and the related R LPS, is discussed under "Cellular composition".

An antigenic relationship, attributable to the presence of *N*-acylated-D-perosamine, has been confirmed between the LPS antigens of smooth *Brucella* species and *Yersinia enterocolitica* 0:9, *Francisella tularensis*, *Salmonella* 0:30 serotypes, *Vibrio cholerae*, and the 0:157 antigen of *E. coli* and *E. hermannii* (Corbel, 1985). The 8-kDa Braun lipoprotein also crossreacts with the homologous protein of *E. coli* (Gomez-Miguel et al., 1987).

Serological crossreactions between nonsmooth *Brucella* strains and organisms of other genera have received relatively little attention. Evidence for crossreactions between *B. canis* and *Actinobacillus equuli*, mucoid strains of *Pseudomonas aeruginosa*, and some serotypes of *Pasteurella multocida* has been presented (Weber, 1976; Carmichael et al., 1980). The outer membrane lipoproteins share antigenic determinants with *Agrobacterium* and other members of the former *Rhizobiaceae* (Cloeckaert et al., 1999).

Minor surface or subsurface antigens common to smooth and certain nonsmooth *Brucella* strains have been described. These include the "native hapten", also referred to as component 1 or second polysaccharide, present in phenol-water, ether-water, or trichloroacetic acid extracts of smooth strains and the rough strain *B. melitensis* B115 (Diaz et al., 1968; Moreno et al., 1981), which corresponds to free O chain (Cloeckaert et al., 1992). This is present in crude preparations of the polysaccharide B, which was formerly thought to be an antigen but is now known to be a nonantigenic cyclic beta-glucan (Perry and Bundle, 1990).

Many of the minor surface or subsurface antigens previously reported in smooth and some nonsmooth *Brucella* strains and designated as χ, β, and γ antigens, and the f antigen (Freeman et al., 1970; McGhee and Freeman, 1970b) have subsequently been identified with outer membrane proteins, bacterioferritin, or enzymes. Some of these proteins, including those with molecular masses of 10-, 16.5-, 19-, 25–27-, 36–38-, and 89-kDa, stimulate significant immune responses in infected individuals. Specific functions have been attached to some, such as the lumazine synthetase (Goldbaum et al., 1999), bacterioferritin (Denoel et al., 1995), and stress proteins (Robertson and Roop, 1999).

The soluble internal antigens released on disruption of *Brucella* cells can be demonstrated by immunodiffusion, immunoelectrophoresis, or immunoblotting. They are, in many cases, common to both smooth and nonsmooth strains. Some appear to be unique to the *Brucella* genus, but several at least are shared with other genera in the *Rhizobiales*, particularly *Ochrobactrum* (Velasco et al., 1998). Of particular importance is the L7/L12 ribosomal protein. This plays a key role in the induction of cell-mediated immunity and is a major protective antigen of *Brucella* (Bachrach et al., 1994a, b; Oliveira and Splitter, 1996).

Antibiotic sensitivity *Brucella* strains show sensitivity to a wide range of antimicrobial agents, but there is limited correlation between activity *in vitro* and therapeutic efficacy, mainly because the latter is influenced by pharmacodynamics, and sustained high intracellular levels are essential for eradication of the infection. Variations in susceptibility between nomenspecies, and even between biovars and strains within species, occur. Antibiogram resistance patterns have been used for characterization at the strain level and have suggested a clonal structure, at least in *B. abortus* biovar 1 (Corbel, 1989a).

Sensitivity to beta-lactams is variable; some strains are sensitive to benzylpenicillin, ampicillin, and amoxicillin but most are resistant to methicillin, nafcillin, piperacillin, and ticarcillin. Similarly, sensitivity to cephalosporins tends to be limited except that for some third generation agents such as cefotaxime, ceftizoxime, and ceftriaxone, MICs are in the range 0.25–2 mg/l. Sensitivity to most macrolides is low but clarithromycin and azithromycin are active in the range 2–8 mg/l. The MIC for chloramphenicol is 2–3 mg/l for most strains. For rifampicin and rifapentine, MICs are in the range 0.1–2 mg/l. Similarly, sensitivity to tetracyclines is generally about 0.1 mg/l.

Nearly all strains are resistant to nalidixic acid, but MICs for fluoroquinolones are in the range 0.5–1 mg/l. Sensitivity to cotrimoxazole is borderline. Most *Brucella* strains are resistant to polymyxins, amphotericin B, bacitracin, cycloheximide, clindamycin, lincomycin, nystatin, and vancomycin at concentrations that inhibit many other organisms, and this fact has allowed the formulation of selective culture media (Farrell, 1974). *Brucella* strains are sensitive to the rhizobial peptide trifolitoxin, and on this basis have been classified in the bacteria known as Group 1 of the alpha-2 *Proteobacteria* (Triplett et al., 1994).

Pathogenicity *Brucella* species are pathogenic for a wide variety of animals, frequently producing generalized infections with a bacteremic phase followed by localization in the reproductive organs and the reticuloendothelial system. Infection in the pregnant animal often results in placental and fetal infection and this frequently causes abortion. The organisms may localize in mammary tissue and can be excreted in the milk. Because all the main species of meat- and milk-producing domesticated animals are susceptible to brucellosis and act as sources of human infection, the economic impact of the disease is enormous.

Typically, growth *in vivo* is intracellular and the organisms can survive within both granulocytes and monocytes. Infections in the natural host are rarely lethal and often mild, with clinical manifestations occurring mainly in the pregnant animal. Nevertheless, localization can occur in a wide range of organs with production of a variety of lesions.

All the *Brucella* species may produce infection in laboratory animals including guinea pigs, mice, and rabbits, but the severity of the infection varies considerably with the virulence of the infecting strain. For the guinea pig, the order of pathogenicity is *B. melitensis* > *B. suis* > *B. abortus* > *B. neotomae* > *B. canis* > *B. ovis* (Braude, 1951; Isayama et al., 1977).

The more pathogenic strains usually produce a local abscess at the site of inoculation, followed by bacteremia of varying duration. The regional lymph nodes may become enlarged and granulomatous changes develop. Similar changes occur in the liver and spleen and frequently in other organs, particularly the testes and epididymides. *B. melitensis* and *B. suis* biovars sometimes produce fatal infections (Braude, 1951). The other species rarely produce severe disease, and infection is usually self-limiting within a period varying from a few weeks to more than 6 months. The mouse is more susceptible to persistent infection with *B. neotomae*, *B. canis*, and *B. ovis* than the guinea pig (Isayama et al., 1977). Pathogenic effects of these nomenspecies are limited to slight-to-moderate splenic enlargement.

Infection in humans arises from direct or indirect contact with infected animals or by consumption of milk or meat products derived from them. Person-to-person transmission is extremely rare and plays no part in the natural history of the disease. Entry of the organisms may be via the respiratory or gastrointestinal mucosa, or the percutaneous route. The subsequent pathogenesis is believed to follow a similar pattern to that observed in experimental animals, with proliferation in lymphoid tissue succeeded by a bacteremic phase of variable duration with, in some cases, localization in specific organs. The infection may be completely subclinical, or it can produce a subacute or acute febrile illness. In the absence of adequate antibiotic therapy, this can persist for many months and may be accompanied by the development of severe complications such as endocarditis, meningoencephalitis, arthritis, spondylitis, and orchitis. A postinfectious, chronic, debilitating syndrome may also result. *B. melitensis* accounts for the majority of severe infections, followed by *B. suis*. *B. abortus* and *B. canis* are usually associated with milder disease. Infection elicits both antibodies and cell-mediated immunity. The LPS is the dominant antigen in the serological response but antibodies and delayed hypersensitivity to a variety of proteins can develop. Further details are given by Young and Corbel (1989) and Madkour (2000).

Ecology Although easily cultivated *in vitro*, under natural conditions *Brucella* species behave as obligate parasites and do not pursue an existence independent of their animal hosts. However, under suitable conditions of temperature and humidity they can persist in the environment, for example in soil or surface water, for long periods. Their distribution is worldwide, apart from the few countries from which they have been successfully eradicated. Considerable local variations in the prevalence of particular nomenspecies and biovars occur. This is of epidemiological importance (Corbel, 1989a).

Enrichment and Isolation Procedures

The isolation of *Brucella* may be attempted from any tissue or secretion. Those most likely to yield positive cultures include abortion material (placental cotyledon, amniotic fluid, vaginal discharge, fetal gastric contents, fetal lung, and fetal liver), lymph nodes, bone marrow, mammary gland, uterus, seminal vesicles and accessory glands, testes, and epididymides, or other organs with local lesions, milk, colostrum, semen, and blood.

Uncontaminated materials may be inoculated directly on to SDA plates. Where contaminating organisms are likely to be present, a selective medium should be used. SDA supplemented with the antibiotic formulation of Farrell (1974)[6] is satisfactory for the isolation of most smooth strains of *Brucella*, but may be too inhibitory for *B. canis* and *B. ovis*. For the isolation of these species from contaminated material, modified Thayer–Martin medium (Brown et al., 1971), or SDA containing 10% (v/v) heated horse serum and VCN-F inhibitor (BBL),[7] may be used. These media are less selective than Farrell's SDA, and it is advisable to dilute heavily contaminated material, such as semen, in 5–10 volumes

6. Farrell's selective medium: prepared from SDA. After addition of horse serum and glucose to the molten medium cooled to 56°C, antibiotics are added to give the following final concentrations: bacitracin, 25 U/ml; polymyxin B, 5 U/ml; cyclohexamide, 100 µg/ml; vancomycin, 20 µg/ml; nalidixic acid, 5 µg/ml; and nystatin, 100 U/ml.

7. Modified SDA antibiotic medium: SDA is prepared as previously described, but with horse serum added to a final concentration of 10% (v/v) and No. 1 agar (Oxoid) added to give a final concentration of 3% (w/v). To each liter of molten medium cooled to 56°C, one vial of VCN inhibitor (Difco; reconstituted in 10 ml of sterile distilled water) is added. This is followed by addition of 1 ml furadantin solution (10 mg/ml of 0.1 N NaOH), and the plates are poured immediately. The medium contains vancomycin (3 µg/ml), sodium colistimethate (7.5 µg/ml), nystatin (12.5 U/ml), and furadantin (10 µg/ml) (final concentrations).

of sterile isotonic solution and filter it through a membrane filter (0.8 μm pore size) before plating it out. All cultures should be incubated at 37°C under air supplemented with 5–10% (v/v) CO_2—unless isolation of a CO_2-independent species of *Brucella* is being attempted.

Direct inoculation of selective media is usually satisfactory for isolation of *Brucella* from heavily infected materials, even in the presence of contaminating organisms. However, when the *Brucella* concentration is likely to be low, as in blood, milk, or semen samples, enrichment procedures should be used. Incubation of milk samples at 4°C concentrates *Brucella* cells in the cream layer, which should then be cultured.

Enrichment may be achieved either by intramuscular inoculation of the samples into guinea pigs, followed by culture of the spleen tissue four weeks later, or by growth in a liquid enrichment medium. Guinea pig inoculation is only likely to succeed with virulent strains of *B. melitensis*, *B. abortus*, and *B. suis*.

Enrichment cultures may be performed by the two-phase system of Castañeda (1947). As liquid phase, SDB supplemented with 25% (w/v) trisodium citrate is used. The solid phase is SDA containing 2.5% (w/v) agar. The medium is made selective by adding the antibiotic formulation of Farrell (1974) to the liquid phase.

For cultures of *B. ovis* and *B. canis* the antibiotic formulation may be replaced by VCN-F inhibitor. The sample is mixed with the liquid phase and the bottles incubated at 37°C under air (with supplementary CO_2 if required). At intervals of 2–3 days, the liquid phase is tipped over the solid phase and the bottles re-incubated. Incubation is continued for up to 6 weeks or until colonies appear on the solid phase, whichever is sooner.

Blood or tissue samples may be enriched for *B. canis* by inoculation of the yolk sacs of 6–8-day-old chick embryos. Yolk from eggs with dead embryos is plated onto SDA or other suitable medium. Culture of cell-wall-defective forms of *Brucella* may be attempted by culturing samples of blood, synovial fluid, and solid tissue on Farrell's selective medium enriched with 20% (v/v) horse serum. Incubation should be continued for at least 14 days before discarding the plates. The plates should be examined for microcolonies under a stereomicroscope.

Maintenance Procedures

Cultures may be maintained for short periods by streaking onto SDA slopes, incubating for 72 h under air (+ 10% CO_2, v/v, if required) and then sealing the slope and storing at 4°C. This procedure needs to be repeated every 6–8 weeks. It is unsatisfactory for long-term maintenance of strains, as these are liable to change their characteristics on repeated subculturing.

Brucella cultures may be preserved satisfactorily by vacuum drying. The strains are grown on SDA slopes incubated at 37°C under air (+ 10% CO_2, if required) for 72 h. The growth is washed off the slopes and suspended in sterile rabbit serum to give a suspension of about 10^{10} organisms/ml. This is distributed in 0.1-ml volumes into sterile tubes sealed with cotton-wool plugs. The tubes are stored over phosphorus pentoxide in a desiccator kept at 4°C. The desiccator is evacuated daily until a pressure of 0.05-mm Hg can be obtained. The tubes are then sealed under vacuum in glass ampoules containing a small quantity of silica gel. Under these conditions, *Brucella* cultures may remain viable for many years.

Brucella strains may also be preserved satisfactorily by freeze-drying. General directions for this have been given by Lapage et al. (1970) and details of the technique by Boyce and Edgar (1966).

Storage in liquid nitrogen will maintain *Brucella* cultures with a smaller decrease in viability than is produced by either vacuum drying or freeze-drying (Davies et al., 1973). Cultures are grown for 72 h on SDA slopes at 37°C in air (+ 10% CO_2, if required) and the growth suspended in single-strength Bacto-glutamate medium[8] to form a dense suspension. This is left undisturbed at 4°C for 7 days, after which volumes of up to 1 ml are placed in sterile glass screw-capped vials. The vials are allowed to equilibrate in the vapor phase or immersed in the liquid.

Procedures for Testing Special Characters

Safety precautions All *Brucella* isolates should be regarded as potentially pathogenic for man. Adequate precautions against accidental infection should be taken at all stages of work involving live cultures. It is strongly recommended that all such procedures be performed by suitably trained staff using efficient exhaust protective cabinets. Particularly hazardous techniques, such as the determination of oxidative metabolism rates by respirometric methods, are best left to reference laboratories experienced in their use. Where possible, hazardous procedures should be replaced by methods that do not require viable bacteria or else are easily contained. Specific indications of safety precautions to be adopted during work with *Brucella* cultures have been given by Corbel et al. (1979) and Alton et al., (1988).

Oxidative metabolism rates For respirometric methods, cells are grown in Roux flasks containing SDA for 48 h. They are harvested in Sorensen's phosphate buffer (pH 7.0), washed 3 times by centrifugation (10,000 × g for 15 min), and standardized turbidimetrically to a cell concentration equivalent to 0.9 mg N/ml, as determined by micro-Kjeldahl analysis. Measurements of oxygen uptake are performed using either a Warburg constant volume respirometer or a Gilson differential respirometer (see *Manometric Techniques* by Umbreit et al., 1972). Oxygen uptake with various substrates is expressed as μl/mg of cell nitrogen per hour ($Q_{O_2}N$). The following substrates are normally used for *Brucella* studies: group 1: L-alanine, L-asparagine, and L-glutamic acid; group 2: L-arginine, DL-citrulline, DL-ornithine, and L-lysine; group 3: L-arabinose, D-galactose, D-glucose, D-ribose, D-xylose, and *meso*-erythritol. Other substrates are sometimes used. The substrates are prepared as 10% (w/v) solutions in Sorensen's phosphate buffer (pH 7.0), sterilized by filtration, and stored at −20°C until needed. The DL-citrulline solution should be sterilized by autoclaving at 121°C for 15 min.

The $Q_{O_2}N$ values obtained by either the Gilson or the Warburg method are corrected for endogenous O_2 uptake (by subtracting the $Q_{O_2}N$ value for controls lacking substrate) and are compared with expected values for each species (Meyer and Cameron, 1961a, b; Meyer, 1969; Verger and Grayon, 1977). The results may be conveniently expressed in the form of a three-level metabolic profile (Verger and Grayon, 1977) or as a pattern of + and − signs (see Table BXII.α.121).

Thin-layer chromatography The oxidative metabolic pattern may be determined semi-quantitatively by thin-layer chromatog-

8. Bacto-glutamate medium: Bacto-casitone (Difco) or equivalent, 25 g, is dissolved in 100 ml of distilled water and autoclaved at 115°C for 20 min. To this solution, 50 g of sucrose and 10 g of monosodium glutamate are added and dissolved by steaming for 10 min. The medium is filtered under positive pressure through Seitz EKS filters into sterile containers and finally autoclaved at 106°C for 15 min.

raphy. The results do not always coincide precisely with those obtained by respirometry, possibly because nonoxidative degradation of substrates may occur; however, the overall pattern is generally satisfactory for culture identification. The method used is a modification of that described by Balke et al. (1977). The amino acid and carbohydrate substrates are incubated with the *Brucella* suspension, and the supernatant fluids are then tested for the presence of the substrate. It is essential to include *Brucella* reference strains as standards during such testing. Details of the technique are given by Corbel and Brinley-Morgan (1984).

Substrate-specific tetrazolium reduction The method of Broughton and Jahans (1997) can be performed under containment conditions and is much more convenient and safer than respirometry. The strains are cultured on Trypticase soy agar (or equivalent) layers for 48–72h at 37°C in 10% CO_2. The bacteria are then harvested in phosphate-buffered saline, pH 7.2 and adjusted turbidimetrically to a concentration equivalent to 10^{10} organisms/ml. The substrates L-alanine, L-asparagine, L-glutamic acid, L-arginine, DL-ornithine, L-lysine, D-galactose, D-ribose, D-xylose, *meso*-erythritol, and urocanic acid are prepared as separate solutions in PBS at 20 g/l, adjusted to pH 7.2 if required, and sterilized by membrane filtration. These stock solutions are stored at 4°C and diluted to 1.25g/l in sterile PBS immediately before use. Each column in a flat-bottomed microtiter plate is loaded with 100 µl of substrate. Volumes of 50 µl of each cell suspension are added to four rows of wells, and the plates incubated at 37°C in 10% CO_2 for 18 h. After incubation, 50 µl of a sterile solution of 1 g/l of 3-[4,5-dimethylthiazol-2yl] 2,5 tetrazolium bromide (MTT) in PBS is added to each well. After 1 h at room temperature (18–22°C), 50 µl of 40% formaldehyde is added to each well and after a further 2–4 h, the optical density of each well is determined using a microplate reader at 630 nm. The values for the four replicates of each substrate are calculated. Comparisons are performed with reference strains included in each run. The pattern of utilization of substrates is similar to that obtained with respirometry, but the oxidation of urocanate distinguishes *B. suis* from *B. canis*.

Determination of phage sensitivity The colonial phase of the test culture must first be determined by streaking GDA plates and incubating under a suitable gas atmosphere at 37°C for up to 5 days. The colonial morphology is then examined in obliquely transmitted light according to Henry (1933) or after ammonium oxalate-crystal violet staining according to White and Wilson (1951). If the culture has colonies of only a single phase, representatives of these are selected for phage typing. If a mixture of smooth and nonsmooth colonial forms is present, then smooth colonies are selected for subculturing and phage typing.

For routine phage typing, a suspension of cells is prepared as described for the slide agglutination test (see below). Plates of SDA or TSA are inoculated with this suspension so as to produce confluent growth. Typing may be performed using the Tb phage standardized at the routine test dilution (RTD) and at 10,000 × RTD, or by using phages representing groups 1–5 of Corbel and Thomas (1980) standardized at RTD. For typing smooth cultures, Tb phage alone, when used at both concentrations, is usually adequate, but for nonsmooth or atypical cultures, the additional phages are useful. Discrete drops of phage preparation (~25 µl) are applied to the surface of the inoculated plate and allowed to soak in the agar. The plates are then inverted and incubated for 37°C under the appropriate gas atmosphere. They are inspected for growth and phage lysis after 24 h incubation, and at further 24 h intervals if required. The results of the phage sensitivity test can only be interpreted accurately if the colonial phase of the culture is known. In addition to the initial examination of the colonial morphology of the culture, a further check should be done by testing a sample of growth from each phage plate for agglutinability in 0.1% aqueous acriflavine (clumping indicates nonsmooth cells).

CO_2 requirement The culture is streaked onto duplicate SDA slopes. One of these is incubated at 37°C under an air atmosphere, the other under air supplemented with 5–10% CO_2. Growth on both slopes indicates an absence of CO_2-dependence, whereas growth only with CO_2 supplementation indicates a CO_2 requirement. The test should be performed on freshly isolated cultures as CO_2-dependence can be rapidly lost by *Brucella* strains.

H_2S production The culture is inoculated onto an SDA or TSA slope, and a strip of lead acetate-impregnated paper is placed in the mouth of the tube. This must not come into contact with the medium or with condensation on the wall of the tube. The culture is incubated under the appropriate atmosphere for 4–5 days. The paper strip is examined and changed daily. Blackening of the paper indicates H_2S production. Slight blackening of the tip of the paper for the first day only is not considered positive.

Agglutination with monospecific antisera The growth from an SDA slope incubated for 48 h is suspended in ~0.5 ml of sterile saline to give an opacity equivalent to ~10^{10} cells/ml. One drop of this suspension is mixed with an equal volume of 0.1% aqueous acriflavine on a glass slide and examined for agglutination. The absence of agglutination indicates a smooth culture. In this case, one drop of the suspension is added to each of a series of drops of A and M monospecific antisera, and to negative control serum, on a glass slide. After agitation for 1 min, each drop is examined for agglutination. Smooth *Brucella* cultures will produce agglutination with either A and /or M sera, but not with the negative control serum.

If the culture is nonsmooth (agglutination occurs with acriflavine), one drop of culture suspension is added to a drop of R antiserum and to a drop of negative control serum, with subsequent agitation for 1 min. The absence of agglutination in either serum will exclude a nonsmooth *Brucella* strain. Agglutination with only the R antiserum is strongly suggestive of a nonsmooth *Brucella*. Agglutination with both sera may also indicate nonsmooth *Brucella*, although rough organisms of other genera occasionally react in this way.

Urease activity Christensen's agar slopes are each inoculated with a single loopful of culture suspension prepared as described for the slide agglutination tests. The slopes are examined immediately and after 15 min, 1 h, 2 h, and 24 h incubation at 37°C. Cultures of *B. suis*, *B. canis*, and *B. neotomae* almost invariably produce an immediate positive reaction, turning the medium magenta within 15 min. Most strains of *B. abortus* and *B. melitensis* will give positive reactions after 1–2 h and nearly all after 18–24 h. The reference strain *B. abortus* 544 is an exception and is urease-negative even at 24 h. *B. ovis* cultures are also urease-negative under these conditions, although some strains will give positive reactions if incubated for up to 7 days.

Growth in the presence of dyes Cell suspensions prepared as for the slide agglutination tests are used to inoculate plates of SDA or other basal media containing the dyes basic fuchsin

or thionine[9]. The plates are divided into four quadrants and one loopful of suspension is applied to each quadrant and streaked five times in succession without recharging the loop. The plates are incubated at 37°C under the appropriate gas atmosphere for up to four days. Growth on three or more streaks is considered to indicate resistance to the dye. Growth on only one or two streaks is not considered significant. Other dyes, such as safranin, methyl violet, pyronine Y, thionine blue, or malachite green, are occasionally used in addition to basic fuchsin and thionine. In each case, it is essential that plates inoculated with the biovar 1 reference strains for each *Brucella* species are incubated and examined in parallel with the test cultures.

Nucleic acid amplification procedures Procedures using the polymerase chain reaction (PCR) are being used increasingly for diagnostic purposes. Because of their speed, sensitivity, and safety they are likely to replace culturing methods in many instances. This means that in the future, fewer strains are likely to be available for conventional typing. A useful degree of typing is achievable by molecular methods if attention is paid to the selection of suitable primers. Use of the rRNA gene spacer region (*rrs-rrl*) and IS*6501* allows identification at genus level. Selection of primers for the *omp2a*, *2b*, and *25* genes will permit putative identification to nomenspecies and, in many cases, biovar level. The procedures used are those described in the original reports (Halling and Zehr, 1990; Cloeckaert et al., 1995; Ficht et al., 1996; Fox et al., 1998c).

Differentiation of the genus *Brucella* from other genera

Most of the bacterial species known to cross-react serologically with *Brucella* are unlikely to be misidentified as members of this genus, as they are easily distinguishable by their morphological, cultural, and biochemical characteristics. A possible exception is *F. tularensis*; however, this organism is unlikely to grow on ordinary brucella culture media, is not susceptible to any known brucella phages, and is usually very much smaller than *Brucella* cells. It also shows fermentative activity towards glucose and a variety of other carbohydrates, is catalase negative, has a low cytochrome *c* content, produces rapidly lethal infections in mice, and does not share internal antigens with *Brucella* strains (although unabsorbed antisera will cross-react in agglutination and immunofluorescence tests). Moreover, its DNA base composition (33–36 mol% G + C) is quite distinct from that of *Brucella*, and there is no relatedness of polynucleotide sequences via DNA–DNA hybridization (Hoyer and McCullough, 1968b).

Confusion is most likely to occur with other small, Gram-negative, nonfermentative bacteria. These include *Bordetella* species, particularly *Bordetella bronchiseptica*, which is often isolated from animal sources, and species of *Achromobacter*, *Acinetobacter*, *Branhamella*, *Kingella*, *Moraxella*, and *Neisseria*. Some of the less frequently identified *Pseudomonas* species have also been confused with *Brucella*, as have occasional strains of *Haemophilus* and *Pasteurella*.

Differentiation of these taxa is achieved in the first instance by careful examination of Gram-stained smears. The morphology of many of these organisms is usually sufficiently distinctive to differentiate them from *Brucella*. Examination of growth and colonial morphology on brucella culture media incubated at 20°C and 37°C, and motility tests at both these temperatures, will enable many other isolates to be eliminated.

At this stage the colonial phase of a suspected *Brucella* strain should be determined. Slide agglutination tests with unabsorbed antiserum to smooth and nonsmooth *Brucella* strains will then permit recognition of true members of the genus in nearly every case. Occasionally, nonsmooth organisms other than *Brucella* are agglutinated by antisera to nonsmooth *Brucella* strains. Subsequent tests with phage R/C will permit *B. canis*, *B. ovis*, and nonsmooth *B. abortus* strains to be definitely identified as members of the genus. The identification of nonsmooth strains of the other species can occasionally present difficulties, particularly if they give atypical results in one or more of the routine typing procedures. In such cases it is necessary to resort to further tests for genus identification. These may include pulsed-field gel electrophoresis of DNA extracts (Allardet-Servent et al., 1988), PCR using genus-specific primers (Halling and Zehr, 1990; Cloeckaert et al., 1995; Fox et al. 1998c), gas-liquid chromatography of the fatty acid methyl esters (Tanaka et al., 1977), and serological demonstration of genus-specific antigens by immunodiffusion or immunoblotting (Velasco et al., 1998).

Taxonomic Comments

Molecular genetic studies, particularly those involving sequencing and hybridization of the ribosomal RNA fractions, have clearly demonstrated that the genus *Brucella* forms a discrete homogeneous group, which, of known taxa, is most closely related to the genus *Ochrobactrum*. It quite clearly belongs in the *Alphaproteobacteria*. Sequencing of 5S and 16S rRNA and competitive binding studies of these molecules with DNA (De Ley et al., 1987; Dorsch et al., 1989; Relman et al., 1992), lipid composition (Weckesser and Mayer, 1988), antigenic relatedness (Velasco et al., 1998; Cloeckaert et al., 1999), and multi-locus enzyme electrophoresis have confirmed a close genetic relationship to *Ochrobactrum* and, to a lesser extent, *Agrobacterium*, *Mycoplana*, and *Phyllobacterium*, and a somewhat more distant relationship to *Bartonella*. *Brucella* also shares gene sequences essential for pathogenicity with *Agrobacterium* (Sola-Landa et al., 1998; O'Callaghan et al., 1999). The cyclic glucan synthetase gene is also shared with other species within the *Rhizobiales* (De Iannino et al., 1998). The phylogenetic relationships summarized by Yanagi and Yamasato (1993) suggested an affiliation to the *Rhizobiaceae*. However, a more recent analysis of this family indicates that *Brucella* and *Ochrobactrum* form a discrete group outside it (Fig. BXII.α.138). This suggests that until evidence to the contrary is presented, these two genera and *Mycoplana* should represent the only known members of the *Brucellaceae*.

The issue of subdivision within the genus is less clear-cut. DNA–DNA binding studies within the genus have shown all nomenspecies to share similar polynucleotide sequences; competitive binding assays have indicated a relatedness of >90% (Hoyer and McCullough, 1968a, b; Verger et al., 1985). This degree of DNA relatedness is indicative of a very close genetic similarity between all members of the genus and is consistent with the concept of a single species. This conclusion has been supported
